**A COMPUTER PROGRAM TO CALCULATE GROWTH RATES FOR
CRACKS AT NOTCHES IN REGIONS OF RESIDUAL STRESS**

by

R. Cook

S. Dorey

D. P. Rooke

SUMMARY

This Memorandum describes a computer program which can be used to predict the growth rates of fatigue cracks emanating from notches and growing through residual stress fields. The residual stress distributions, alternating loading conditions and specimen geometry must be specified by the user. The program uses a Green's function technique to calculate the stress intensity factor due to the applied and residual stresses for any crack length. The calculated stress intensity factor can be corrected to account for the exact crack shape, if it is known. The crack growth rate is obtained from a database of experimentally determined crack growth data as a function of stress intensity factor, for a number of different materials.

DTIC QUALITY INSPECTED 1

1 INTRODUCTION

The most common sites of fatigue damage in aircraft structures are fastener holes. The use of life enhancement techniques such as cold expansion and interference fit fasteners are now commonplace in order to combat this problem. Cold expansion increases the fatigue endurance of components by reducing the rate at which fatigue cracks grow. This is achieved by inducing a compressive residual stress field around holes in the region through which the fatigue cracks must grow. The extent of the compressive residual stress zone is typically only a few millimetres and outside this resides a balancing tensile residual stress zone. Most of the fatigue life of a component however is consumed in the growth of small cracks and therefore reducing the growth rate of such cracks can result in significant increases in overall fatigue endurance.

The design of new aircraft structures or repair schemes is now frequently performed using a damage tolerant approach. Initial defects of specific sizes are assumed to exist at all stress concentrations such as fastener holes. Fracture mechanics analyses are used to calculate the fatigue life consumed in growing a crack of the assumed initial defect size to a size which can be reliably detected by inspection. Damage tolerant design applied to cold expanded holes therefore requires that the growth rates of cracks subjected to both residual and applied stresses can be calculated.

This Memorandum describes a method of calculating the growth rates of cracks subjected to cyclic loading and growing from open holes through arbitrary residual stress fields. It also describes a computer program which can be used to perform these calculations from information input by the operator. A Green's function technique is used to calculate stress intensity factors at crack lengths specified by the user. Residual and applied stresses and specimen geometry also need to be input by the user. The total stress field is calculated by summing the residual and applied stresses and stress intensity factors are calculated by integrating the product of the stress distribution and the Green's function over the crack length. The Green's function, which is described in Ref 1, is appropriate to a through-the-thickness crack in an infinite sheet; corrections need to be made for the more commonly occurring corner crack. Various corrections for crack and specimen geometry are available in the program and are described in this Memorandum. Crack growth rates are calculated from a materials database for BS L65 and BS L71 aluminium alloys which is included in the program and can be added to by simple modifications. The method of operation of the computer program is described and the results of a test case presented.

2 THEORETICAL BACKGROUND

2.1 The prediction method

This section outlines the method used to obtain crack growth rates from a knowledge of the residual and applied stresses. Residual stress distributions induced prior to fatigue loading need to be determined and stored in the computer. Section 2.2 describes the main features of residual stress distributions, how they are specified and how the program interpolates values at any location. The applied stress distribution is calculated by the program as described in section 2.3. The total stress distribution (residual plus applied) can thus be derived and stress intensity factors calculated with the use of an appropriate Green's function. In section 2.4 a specific Green's function is described which is appropriate to a through crack growing from a central notch in an infinite component. This Green's function is used in conjunction with the residual and applied stresses to give the required stress intensity factor (K) solution. The numerical integration technique used to give the K solution is described in section 2.5. Since the Green's function is appropriate to a through crack in an infinite sheet, the K solution will in general need correcting to account for crack and component geometries. The corrections available in the program are described in section 2.6. Having obtained the required K solution it only remains to calculate the appropriate crack growth rates at specified crack lengths. The method of calculation is described in section 2.7 along with a description of the database used.

2.2 Residual stress fields and their interpolation

The residual stress fields considered in this Memorandum are appropriate to typical stress fields induced around open holes by prestressing or cold expansion. The fields considered were obtained from a number of sources such as finite element analyses, mathematical models describing the stress fields, or simple linear approximations. Whichever source was used, the distributions have certain features in common as illustrated in Fig 1a. These are:

- (a) a compressive residual stress at the hole edge,
- (b) the residual stress decreases in magnitude with distance away from the hole becoming tensile and reaching a maximum a short distance from the hole edge,
- (c) the tensile residual stress then decreases with distance from the hole,
- (d) the magnitude of the maximum compressive stress is significantly greater than the magnitude of the maximum tensile stress.

Some of the distributions (see Fig 1b) also display a region referred to as a compressive yield zone near the hole edge where the compressive stress initially increases in

magnitude with distance from the hole. This occurs if the compressive stress at the hole exceeds the compressive yield point of the material.

Residual stress fields are usually described as a set of values at fixed coordinate points. It is necessary to employ an interpolation routine to calculate values between those specified and a Lagrangian technique suitable for use on a computer was selected. Unfortunately the interpolation was not sufficiently accurate at "certain" points in the distribution, for example at sharp changes of gradient or points of inflection, so that the residual stress distribution had to be split into regions. The typical residual stress distribution, shown in Fig 1a, is split into three regions which enables accurate interpolation. The residual stress distribution in which compressive yielding has occurred, shown in Fig 1b, must be split into at least four regions.

2.3 Stress intensity factors

A stress intensity factor is a single parameter which describes the magnitude of the stress field in the vicinity of a crack tip. The assumption is usually made that the behaviour of a crack is controlled by the stresses around its tip, hence stress intensity factors are very useful in characterising crack behaviour in an elastic body and are widely used for predicting the rate of growth of fatigue cracks. The stressing mode appropriate to a stress intensity factor is usually denoted by K_N , where $N = I, II$ or III specifies the direction of relative movement of the crack faces as opening, sliding or tearing respectively. The cracks with which this report is concerned are opening mode cracks ($N = I$) growing along a line perpendicular to the remotely applied stress.

The stress intensity factor for the situation of a through crack of length L measured from the edge of a circular hole of radius R in an infinite sheet (see Fig 2) is given by:

$$K_I = 1/\sqrt{\pi L} \int_0^L \sigma(x) G(L/R, x/L) . dx , \quad (1)$$

where $\sigma(x)$ is the stress distribution along the crack site in the uncracked configuration,

$G(L/R, x/L)$ is the appropriate Green's function for this configuration.

The stress distribution along a line from a hole in an infinite sheet perpendicular to a remotely applied stress is given by:

$$\frac{\sigma_A}{S} = \frac{1}{2} \left(2 + \left[\frac{1}{1+x/R} \right]^2 + 3 \left[\frac{1}{1+x/R} \right]^4 \right) , \quad (2)$$

where R = radius of the hole

x = distance along the crack

S = remotely applied stress

The stress intensity factor distribution for this stress field is known. Values of stress intensity factor were calculated with no residual stress field present and compared with the known solution to test the accuracy of the computer program. If a residual stress field is present in the component then the stress distribution is given by the sum of the applied and residual stress distributions.

2.4 The Green's function

The Green's function used was developed by Shivakumar and Forman¹ and is for a through crack at the edge of a circular hole in an infinite sheet.

The Green's function $G(L/R, x/L)$ can be expressed as $G(\lambda, \beta)$, that is,

$$G(\lambda, \beta) = \left(\frac{2\beta}{1-\beta} \right)^{1/2} + C(\alpha, \beta) \left[2 \frac{(1+F_\beta)}{(1-\beta^2)^{1/2}} - \left(\frac{2\beta}{1-\beta} \right)^{1/2} \right], \quad (3)$$

where $\lambda = L/R$, $\beta = x/L$ and $\alpha = 1/(1+\lambda)$, and

$$F_\beta = (1-\beta^2)(.2945 - .3912\beta^2 + .7635\beta^4 - .9942\beta^6 + .5094\beta^8) \quad (4)$$

and

$$C(\alpha, \beta) = \sum_{m=1}^5 \left(\sum_{n=0}^3 C_{m,n} \alpha^{m/2} \beta^{n/2} \right), \quad (5)$$

where $C_{m,n}$ are constants whose values are given in Table 1.

Table 1

5	0.7952	-8.4570	26.8666	-16.7296

2.5 Numerical integration

It can be seen that the Green's function is algebraically complex and for this reason, as well as the fact that the residual stress distribution is unlikely to be represented by a

simple polynomial, the integration has to be carried out by numerical means. The method selected is a Gaussian quadrature numerical integration method, chosen because not only is it very accurate but also because, using suitable weighting functions, it is able to take account of the singularity which occurs, due to the $\sqrt{1-\beta}$ and $\sqrt{1-\beta^2}$ denominators, in the Green's function as $\beta \rightarrow 1$.

Gaussian integration is carried out as follows:- Given a weighting function $W(Y)$ and a function $F(Y)$, there exists a Gaussian formula of the form

$$\int_a^b W(Y) F(Y) dY \approx \sum_{i=1}^n h_i F(Y_i) , \quad (6)$$

where Y_i are the zeros of the appropriate n th degree orthogonal polynomial, and h_i are the corresponding quadrature coefficients. Both Y_i and h_i are tabulated for various weighting functions².

For the purposes of this work, the function $F(Y)$ is the product of the reduced Green's function $g(\lambda, \beta)$ and the total stress distribution, that is $\sigma(x)g(\lambda, \beta)$, and the weighting function is $1/\sqrt{1-\beta}$, where $g(\lambda, \beta)$ is defined as

$$g(\lambda, \beta) = \sqrt{1-\beta} G(\lambda, \beta) \quad (7)$$

An eighth order integration ($n = 8$) was chosen, as it gave an acceptable compromise between running time and accuracy. Obviously, the greater the number of summations that are carried out, the longer will be the processing time but also the greater the accuracy of the process. However, it was found that no significant increase in accuracy was attained by carrying out a higher order integration than eight, so the increase in processing time required to carry out such a process was thought to be unnecessary.

Because of the shape of some of the residual stress fields under consideration, it was necessary to carry out the integration in regions, as described in section 2.1. This is due to the fact that the interpolation method was unable to take sufficient account of sharp changes in gradient of the stress distribution; the distribution was therefore interpolated in sections.

To this end the following scheme was worked out:-

The integral expression for K_I in equation (1) can be written

$$K_I = \sqrt{\frac{L}{\pi}} \int_0^1 \frac{\sigma(L, \beta) g(\lambda, \beta) d\beta}{\sqrt{1-\beta}} . \quad (8)$$

The distribution is split into n regions and the boundaries between regions are denoted by $L_1, L_2, \dots, L_n$ with $\beta_j = L_j/L$ for $j = 1, 2, \dots, (n-1)$; $\beta_0 = 0$ and $\beta_n = 1$. The width of a region is given by $\Delta_j = \beta_j - \beta_{(j-1)}$. Thus, in general,

$$K_I = \sqrt{\frac{L}{\pi}} \sum_{j=1}^n I_j, \quad (9)$$

where

$$I_j = \int_{\beta_{j-1}}^{\beta_j} \frac{\sigma(L, \beta) g(\lambda, \beta)}{\sqrt{1 - \beta}} d\beta. \quad (10)$$

Substitution of $y = (\beta - \beta_{j-1})/\Delta_j$ leads to

$$I_j = \sqrt{\Delta_j} \int_0^1 \frac{\sigma(L, y\Delta_j + \beta_{j-1}) g(\lambda, y\Delta_j + \beta_{j-1})}{\sqrt{\frac{1 - y\Delta_j - \beta_{j-1}}{\Delta_j}}} dy, \quad j = 1, 2, \dots, (n-1)$$

and

$$I_n = \sqrt{\Delta_n} \int_0^1 \frac{\sigma[L(y\Delta_n + \beta_{n-1})] g(y\Delta_n + \beta_{n-1})}{\sqrt{1 - y}} dy. \quad (11)$$

The numerical integrations for I_j ($j = 1, \dots, n-1$) were done using Gaussian quadrature with unit weighting function as the integrand is not singular. Integration of I_n was done using Gaussian quadrature with a weighting function of $(1 - y)^{-1/2}$ to allow for the singularity at $y = 1$.

2.6 Corner crack corrections

As has already been observed, the stress intensity factors obtained by the Green's function approach, are for through cracks in an infinite sheet. In order to obtain stress intensity factors for the more commonly occurring corner cracks in a sheet of finite dimensions, correction factors need to be applied. The correction factors relate to the shape of the crack and the width and thickness of the sample in which the crack is growing. Both correction factors (crack shape and finite width) are based on the work of Newman and Raju³ who developed empirical equations for stress intensity factors based on finite element analyses. The equations developed are relevant to quarter-elliptical corner cracks in finite

width components. They account for both component width and thickness, and the shape of the crack, in terms of its aspect ratio (bore length/surface length). Since the Newman and Raju work is for the case of no residual stress, then the correction factors required cannot be directly determined. Two methods are used to determine the corner crack shape corrections and one method to determine the finite width correction.

Firstly examining the factors in equations (50-63) of Ref 3, it is apparent that the g_2 factor in Ref 3 accounts for the presence of the hole in calculating the stress intensity factor. It is very similar in magnitude to the factor derived using the Shivakumar and Forman method assuming no residual stress. The first correction factor offered in the present program is the solution calculated by Newman and Raju with the g_2 term set to 1. This correction factor is multiplied by the Shivakumar and Forman solution for a through crack in a residual stress field. This gives the solution for an elliptical crack in an arbitrary residual stress field in an infinite width component. This will subsequently be referred to as the G2 correction. The remaining terms in the equations refer to the geometries of the test piece and crack. The crack aspect ratio and the specimen thickness have to be input by the user. This method assumes that the g_2 term entirely accounts for the presence of the hole and that there is no 'fine tuning' included in the other terms in order to achieve a good fit to the finite element solutions.

The second corner crack correction factor is obtained using the complete Newman and Raju solution, *ie* including the g_2 term. The solution again requires the input of both crack aspect ratio and component thickness, by the user. The complete Newman and Raju solution is divided by the Shivakumar and Forman solution assuming no residual stress field is present. This results in a correction factor which when multiplied by the Shivakumar and Forman solution with a residual stress field present, gives a solution for an elliptical crack in a residual stress field in a component of infinite width.

There is also an option in the program to correct for the finite width of the component. The correction factor available is that due to Newman and Raju and is given by equation (47) of Ref 3.

2.7 Crack rate predictions

Crack rates are calculated by comparing the derived stress intensity factors with known crack rate data. The program calculates the maximum and minimum stress intensity factor values and hence the values of ΔK and stress intensity factor ratio R . A subroutine interpolates or extrapolates as appropriate from a database of crack rates versus stress intensity factors at a range of R values for a specific material to calculate crack growth rate. The routine used in the program is that developed by Edwards⁴. The database used is also the one described in Ref 4 and is based on data obtained using BS L71 and BS L65 aluminium alloys. The data is contained in Lines 10150 to 10290 in the program. Other

data may be substituted in the correct form (see Ref 4), or the program modified to access an alternative database of crack growth rates.

3 THE PROGRAM

3.1 Program outline

The program was written in Hewlett Packard BASIC (BASIC 2.0) and is listed in the Appendix. An outline of the scope of the program is described in this section. Details of how to run the program are given in section 3.2 which can be used as a users guide. The file format required for the residual stress data is described in section 3.3. This format must be used if the user creates data files which can be accessed by the program.

The program will calculate stress intensity factors at crack lengths specified by the operator, taking into account a residual stress field if required. When running the program, the operator will need to input the following information:

- (a) Residual stress field: the residual stress field can be defined either by inputting coordinates via the keyboard or by loading data from a pre-stored file, the format of these files is given in section 3.3. It is also possible to run the program with no residual stress field.
- (b) Crack lengths: stress intensity factors can be calculated either over a range of crack lengths at regular increments or for a number of crack lengths specified by the operator.
- (c) Dimensions of the component and crack aspect ratio: stress intensity factors can be corrected for the component dimensions (thickness and width) and the crack aspect ratio.
- (d) Fracture toughness K_{Ic} : the fracture toughness is required to determine when failure of the test piece will occur.

Stress intensity factor values will be calculated at the specified crack lengths and printed out. The program will then calculate the crack growth rates corresponding to these stress intensity factors.

The operator is given several final options such as re-running the program with the same residual stress field, storing the residual stress field, stress intensity factors and rate values for future reference, plotting current data and plotting previously stored distributions against one another for comparison.

3.2 Running the program

A description is given below of how to run the program, including all of the options. The prompts given by the program are written in block capitals and responses in

parentheses. The running procedure is split into six sections (a)-(f). These sections are shown in the flow diagram in Fig 3.

(a) Inputing residual stress fields (RSF)

(RUN)

MULTI-PLOT (Y/N) – the operator can elect to run the routine to plot previously stored distributions. The Y response is described at the end of this section. The N response gives the following prompt.

INITIAL OPTIONS (Opt1)

0. NO RESIDUAL STRESS FIELD

1. INTERPOLATED RESIDUAL STRESS FIELD

2. RESIDUAL STRESS FIELD LOADED FROM FILE (0,1 or 2)

0. to run program without any residual stress field, ie with applied stress only.

1. to input a residual stress field from the keyboard.

2. to input a residual stress field from a previously stored file.

Whichever option is taken, the program next asks for the applied stress range:

MAX REMOTE STRESS (MPa)

MIN REMOTE STRESS (MPa)

If Opt1 was 0, then the prompt;

RADIUS OF THE HOLE (mm) is given and the operator should input the radius of the hole. As no RSF is to be input, the program goes on to the next section (*).

If Opt1 was 1, then the prompts to input the residual stress field (RSF) are as follows:

RADIUS? (mm) – operator inputs the radius of the hole,

ORIGIN OF DISPLACEMENT COORDS. (0 OR 1)

0 – FOR CENTRE OF HOLE.

1 – FOR EDGE

– operator inputs the origin used when describing the distances in the residual stress distribution.

VALUE OF X? (mm)

VALUE OF STRESS? (MPa)

– operator inputs a pair of coordinates of the RSF; the position and magnitude of the residual stress.

– the program will continue to give these prompts after each pair of coordinates have been input until a single carriage return is input for X.

The coordinates are printed on the screen as they are input and each pair given a number. When the input loop is terminated, the prompt;

CHANGE ANY? (Y/N) is given. The operator has the chance to change any pair of coordinates which may have been erroneously entered. If there are entries to be changed (Y), the prompt;

ENTRY TO BE CHANGED? is given. The operator should enter the number of the coordinate pair which are to be altered. The operator will then be asked to repeat the entry number and should enter the revised coordinates. The operator will again be asked if there are any inputs to change and this will be repeated until a negative response (N) is given.

STORE DISTRIBUTION? (Y/N). The operator can choose to store the RSF in a file for future use. If so;

CREATE NEW FILE? (Y/N). The RSF can be stored either in a new file or in a file that already exists.

FILE NAME? The operator should input the name of the file to be used/created.

If Opt1 had been 2 then the operator would be asked;

NAME OF FILE? The operator inputs the name of the file containing the RSF to be used.

At this point, the Opt1 = 1 and Opt1 = 2 sequences become coincident.

(b) Plotting and checking of residual stress fields

The coordinates of the distribution are printed on the screen. Whenever a plot is to be made, from any part of the program, the operator will be given the range of coordinates on both axes and asked to define the size of the intervals within these ranges at which to print the grid dimensions.

X-AXIS LABEL SPACING? – Operator inputs the interval at which grid dimensions on X and Y axes are to be printed.

Y-AXIS LABEL SPACING? – The distribution is plotted, after which the operator is given the chance to obtain a hard copy.

NO. OF REGIONS – The operator must decide on the number of regions into which the distribution is to be split.

INPUT NUMBERS OF POSITIONS OF BOUNDARIES.

POSITION OF END OF REGION N (where N = No. of regions; $N \geq 1$)

The coordinates of the RSF values are printed out and numbered so that the operator can use the numbers to indicate where the boundaries between the regions are to be inserted.

The distribution is now re-plotted this time using data interpolated by the program. The operator is thus able to see if the interpolated data accurately represents the original input data. The operator is asked;

OK? (Y/N) and should indicate whether or not the data are satisfactory.

If not, the program allows the operator to re-position the boundaries in order to produce a better result. The program therefore returns to the NO. OF REGIONS prompt.

(c) Input of crack lengths

(*) Now that the RSF has been input (or the no RSF option taken) the program goes on to request the crack lengths at which stress intensity factors are to be calculated.

1 SIFs CALCULATED OVER A RANGE OF CRACK LENGTHS

2 SIF CALCULATED FOR SPECIFIC CRACK LENGTHS

If option 1 (OPT2=1) is taken, the operator will be asked to input the range over which the SIFs are to be calculated, thus;

START OF RANGE. (mm)

END OF RANGE. (mm)

INCREMENTAL LENGTH. (mm)

If option 2. is taken then the prompt;

CRACK LENGTH? is given and the operator can input one or a list of crack lengths. The operator must input a crack length followed by a carriage return. When all crack lengths have been input, the response to the CRACK LENGTH prompt should be carriage return.

(d) Correction factors

The operator is now asked to decide on the type of correction routine to be used. The options are;

0. NO CORRECTION

1. NEWMAN & RAJU WITHOUT G2

2. N&R/SHRIV AS CORR

For an explanation of the two corrections, see section 2.6.

Unless option 0. is taken, the dimensions of the test piece will be required;

THICKNESS? (mm) – Operator inputs specimen thickness

A/C? – Operator inputs aspect ratio of the crack, where A = length down the bore,
C = length along the surface.

DO YOU WANT A WIDTH CORRECTION? (Y/N) – operator is given the option of leaving out the width correction.

WIDTH? (mm) – if required.

(e) Stress intensity factor and crack growth rate calculations

The program now calculates and prints out the maximum and minimum stress intensity factors and also $\Delta K (= K_{\max} - K_{\min})$ and $R (= K_{\min} / K_{\max})$. After each printout, the option is given of obtaining a hard copy. The operator has the option of plotting $K_{\max}$ vs. L and/or ΔK and R vs. L via the prompts.

PLOT KMAX? (Y/N) and

PLOT KMAX – KMIN AND R? (Y/N)

The operator is then asked whether rate values are to be calculated;

CALCULATE RATE VALUES? (Y/N). If the operator responds in the affirmative, he is given the prompt;

KC VALUE? ($\text{MNm}^{-3/2}$) and should input the K_{Ic} value for the material under consideration. The program then calculates and prints out the predicted rate values corresponding to the calculated stress intensity factors. The option is given for a hard copy of the rate values and for a plot of rate vs. crack length.

The operator is now asked whether or not the distributions (RSF, SIF's and rates) are to be stored for future reference and/or comparison with other distributions. If the response is yes, then the operator can either store them in an existing file or create a new one, giving the name of the file to be used/created.

STORE DISTRIBUTIONS? (Y/N)

CREATE NEW FILE? (Y/N)

FILE NAME?

(f) End options

ANOTHER RUN SAME DIST? (Y/N). This allows the program to be re-run with the same residual stress distribution, for example if different crack lengths are to be used. If the response is yes (Y), the program returns to (*).

If not (N), the operator is now given the prompt;

PLOT GROUPS OF DIST'S? (Y/N). This enables the operator to plot one or more distributions of residual stress fields, stress intensity factors or crack growth rates from previously stored files.

NAME OF FILE? The operator should enter the name of one of the files to be used.

ANOTHER FILE? (Y/N). If another file is to be read the operator enters Y and the program asks for a file name again. This process is repeated until no more files are to be read and the operator answers N.

These options are then given;

0 - EXIT

1 - RESIDUAL STRESS FIELD

2 - STRESS INTENSITY FACTOR DIST.

3 - CRACK GROWTH RATE DIST.

The operator can choose which of the three distributions to plot and they will then be plotted on the same axes for all the files selected,

Option 0. ends the program.

3.3 File format

Residual stress fields may be input via the keyboard, as described in section 3.2, or may be accessed by the program from a data file. It is important when creating a data file to ensure that it has the correct format. Details of the file format required are given below.

The general form of the data file is:-

Lz (1,0)

Lz (2,0)

Lz (3,0)

Lz (0,1), Lz (0,2)

Lz (1,1), Lz (1,2)

Lz (2,1), Lz (2,2)

Lz (n,1), Lz (n,2)

Where Lz (1,0) describes the coordinate system and is equal to

0 if the X coordinates are measured from the centre of the hole

1 if the X coordinates are measured from the edge of the hole

Lz (2,0) = No of entries in the file array

Lz (3,0) = radius of the hole

Lz (0,1) to Lz (n,1) are the distances from the defined origin

Lz (0,2) to Lz (n,2) are the residual stresses at the corresponding positions

The maximum dimension of the array is (50,2), if more than 50 coordinates are used, then the dimension statement (line 7920) must be altered.

4 EXAMPLE - A PRESTRESSED HOLE

An example of the use of this program is presented in this section to illustrate its capabilities. The example chosen is that of a BS 2L65 aluminium alloy test specimen containing a central hole (see Fig 4). Residual stresses may be induced in the component by applying an axial load large enough to cause local yielding around the central hole. A number of specimens were subjected to such prestress treatments and then to cyclic fatigue loading of 110 ± 96.5 MPa, when crack growth measurements were made⁵. The crack growth data measured in the experimental investigation will be compared with the crack growth data predicted using this computer program. The specimen geometry and loading conditions which need to be input to the program are therefore defined as those used in the experimental investigation. The residual stress fields resulting from various prestress levels were determined using a finite element analysis. Other inputs required by the program will be described later in this section.

Three values of prestress were used in the experimental investigation resulting in three different residual stress distributions across the minimum section of the components. The values of prestress used were $a = 60\%$ of the yield stress on the net section, $b = 70\%$ and $c = 80\%$, resulting in local yielding in all cases at the edge of the hole. Residual stresses determined using a finite element program are plotted in Figs 5, 6 and 7 for the three prestresses ((a), (b) and (c)) used in the experimental investigation. Each distribution was split into three or more regions and the polynomial expressions derived by the program are also shown in these figures as solid curves.

Stress intensity factors were evaluated at crack lengths covering two ranges; 0.1 to 0.5 mm in steps of 0.1 mm and 1 to 6 mm in steps of 0.5 mm. The ranges covered crack lengths at which experimental crack growth data had been measured. Corrections to the stress intensity factor were made using both of the corner crack routines in conjunction with the finite width correction (described in section 2.6). The aspect ratio selected was $A/C = 1.4$ which was thought to most accurately represent what occurred in practice. Crack growth rates were then calculated for each of the prestress levels, crack length ranges and correction factor routines described above. The predicted rates are shown for the three prestress levels in Figs 8, 9 and 10. The experimental data are also shown as solid bars representing the range of measured crack growth rates. The dots on each of the solid bars represent the log mean value of the experimental data.

5 DISCUSSION

The residual stress distributions input to the program consisted of eleven coordinate values and are shown in Figs 5 to 7. The polynomials fitted in segments by the computer program were a reasonable interpretation of the input data. However due to the small

number of coordinates specified, abrupt changes in slope of the fitted curves occur near to the region boundaries where the data is sparse. It is expected that in most applications a larger number of residual stress coordinates will be input to the program enabling better data fits. Predicted crack growth rates using the two different correction routines (Figs 8 to 10) are in reasonable agreement with each other and with the experimentally measured data. This gives some confidence in the methods used but does not give an indication of which correction method should be recommended.

There are two main criticisms of the approach used in this paper. Firstly it is assumed that the residual stress field present in an uncracked body remains unaltered by the presence and growth of fatigue cracks. This is clearly not possible and the residual stress field must redistribute as cracking occurs. This aspect is currently being investigated. Some modification to the models used in the program may be possible, dependent on the complexity of the redistribution process. The second main criticism is that closure of the crack flanks is not taken into account. Calculation of stress intensity factors is based on the range of the total local stresses and takes no account of the fact that the crack may be closed due to compressive residual stresses acting behind the crack tip. The stress intensity factor range experienced by the crack tip will be different from that predicted using the methods described.

Two further criticisms of the method are also being considered. The first is that the majority of the fatigue life of a component containing beneficial compressive residual stresses in the area of crack initiation, will be dominated by short crack growth. It has been shown⁶ that short cracks propagate faster than long cracks when subjected to the same stress intensity factor range calculated by conventional linear elastic fracture mechanics, the effect being most marked at negative stress ratios. The crack rate database contained in the program was derived from long crack data but is used to predict the growth rates of short cracks. From the foregoing it is clear that predicted growth rates at short crack lengths may be underestimated particularly since the presence of compressive residual stresses leads to highly negative stress ratios. Short crack growth rate databases are being generated for future use in the program. The second criticism is that the Green's function solution used in the program is not applicable to most engineering situations as cracks are not generally through the thickness and the components are obviously not infinitely wide. The corrections needed to modify the calculated stress intensity factors could lead to considerable errors in the predictions if they are not entirely appropriate. Other Green's function solutions are currently being sought and determined.

6 CONCLUSIONS

- (1) A method has been devised, and a computer program has been developed, for predicting the growth rates of fatigue cracks emanating from open holes and propagating through arbitrary residual stress fields.
- (2) The program has been used to predict the growth rates of cracks from holes subjected to prestressing. Reasonable agreement was found between predicted and experimental results.
- (3) Shortcomings of the prediction method have been identified and suitable modifications proposed.

17. Abstract This Memorandum describes a computer program which can be used to predict the growth rates of fatigue cracks emanating from notches and growing through residual stress fields. The residual stress distributions, alternating loading conditions and specimen geometry must be specified by the user. The program uses a Green's function technique to calculate the stress intensity factor due to the applied and residual stresses for any crack length. The calculated stress intensity factor can be corrected to account for the exact crack shape, if it is known. The crack growth rate is obtained from a database of experimentally determined crack growth data as a function of stress intensity factor, for a number of different materials.
