Abstract

Porous sintered nickel oxide electrodes were prepared by cathodic electroprecipitation from metal nitrate solutions and characterized by slow (0.1 mV/s) voltammetry in 6 mol/l KOH. Presence of iron or zinc ions resulted in decrease of electrode charging ability and similar changes in voltammograms were observed for both ions. Removal of iron or zinc ions and introduction of lithium ions partially restored the electrode and corresponding voltammogram to original conditions. Presence of cobalt in the electrode material diminished substantially the influence of zinc ions on the electrode properties.

Introduction

Nickel oxide electrode (NOE) was investigated as a cathode suitable for electrochemical power sources since the times of Jungner and Edison [1-3]. Nickel-zinc and nickel-iron accumulators are attractive for traction purposes even today due to the cost and life-time of Ni-Fe accumulator and due to the good peak power and high specific capacity of Ni-Zn accumulator.

Nickel-based electrodes have a wide application. The nickel-metal hydride battery was developed as an environmentally safe replacement for nickel-cadmium batteries. Its high energy density, power and cycle life characteristics prompted subsequent development as a power source for electric vehicles [4,5]. The nickel-hydrogen battery, originally introduced in space applications, has now also terrestrial use. It has a long cycle life, high specific energy, high reliability and good resilience to abuse, in particular to over-charge and polarity reversal. NOE is also used in fuel cells [6], electrolyzers [7], in organic electrosynthesis [8] and in electrolytic hydrogen production as an anode for oxygen evolution [9].

Various metallic additives have been examined in various battery systems [1, 3, 10-13] to modify the electrochemical properties of NOE to meet the need of specific applications [9]. Electrochemical measurements on nickel hydroxide thin films with chemically coprecipitated Co, Fe and Mn [12, 14, 15] were performed several years ago. Electrochemistry of thin film binary composite hydroxides of Ni and 13 other metals using cyclic voltammetry in 1 mol/l KOH is described in [10].

Cobalt and lithium additives improve the charge storage reaction and cycle life time of nickel oxide electrode [1-3]. On the other hand, iron and

zinc decrease its charge storage ability, which in the case of iron is known as the iron poisoning effect (IPE) [1, 10, 16]. Better understanding of the effects of the main metallic additives and impurities on the electrochemistry of the nickel oxide electrode are important contribution to the battery industry.

Our study shows that some of the negative chemical effects of iron and zinc on Ni electrode performance can be alleviated by presence of cobalt and lithium. Influence of iron and zinc on NOE performance under different conditions was studied in 6 mol/l KOH. Unlike experiments in which thin nickel hydroxide films were deposited on smooth electrode surfaces [10,17], our studies were performed on a porous material encountered in actual power source applications. Because the diffusion of ions in the bulk of the porous electrode is slow, voltammetry at the usual scan rates (≥ 5 mV/s) yields distorted voltammograms with no developed peaks. Slow voltammetry (0.1 mV/s) in our work produced well developed peaks enabling descriptive study of ion effects using the features of the voltammograms.

Experimental

The anodes were prepared by cathodic deposition of nickel hydroxide on commercially available calibrated SAFT (Poitiers, France) nickel sinter support (thickness 0.7 mm, area 1 cm^2) from aqueous 1 mol/l nickel nitrate solution or from a mixture of 1 mol/l nickel nitrate and 1 mol/l cobalt nitrate in a 100:1 ratio. Spot welded nickel wire was used as a current collector, nickel foil was used as a counter electrode. The nickel sinter was allowed to soak in the electrolyte for 30 minutes, before current of 1 – 10 mA

was applied at room temperature for duration of several hours so that the total loading capacity was 50 mAh. The electrodes were then dried in air at 55°C for 3 hours and total amount of deposited active mass, 0.02 – 0.04 g per electrode, was determined. Dry electrodes were immersed before formation for 30 minutes in 6 mol/l KOH. The formation took place in a simple cell with a nickel counter electrode, with typical formation charging and discharging current 2 mA. The electrode was charged to 150 % of its capacity and discharged to 0.0 V vs. Hg/HgO. Discharging capacity was determined after the third formation cycle. The solutions were prepared from Fisher Certified A.C.S. chemicals and double distilled water. Fisher Reagent potassium hydroxide contained 0.0003 % of iron and 0.0003 % heavy metals (as Ag). All experiments were performed at 24 ± 1 °C.

The EG&G (Princeton Applied Research) 273 potentiostat/galvanostat was used to apply current and control the potential during the experiments. The electrochemical cell was custom made. It was closed with a teflon head through which all electrodes, nitrogen supply and other accessories were introduced. Nickel foils on either side of the nickel oxide working electrode were used as counter electrodes. A Hg/HgO reference electrode in 6 mol/l KOH had a contact with the working solution through a capillary 1 mm apart from the working electrode. It was separated from the working electrolyte by two frits to avoid contamination by added ions. Nitrogen was introduced in the cell during the experiment.

The electrodes were conditioned before each voltammetric experiment. After the last formation cycle a conditioning potential either 500 or 550 mV, depending on the resulting current, was applied for one hour to stabilize the state of charge according to the type of the electrode and/or its history. The

initial potential for voltammetry was either 550 or 600 mV, according to oxygen evolution current. The sweep began negatively at 0.1 mV/s to 0.0 V vs. Hg/HgO, where the scan was reversed and continued to the starting potential.

Important feature on the voltammograms is the the potential of oxygen evolution. For the purpose of this work it was determined as a potential at which the oxygen anodic current drops during negative sweep below 40 mA. The negative sweep was chosen because there was no interference from oxidation peak of NOE.

Results and discussion

Electrode prepared from nickel nitrate

Two electrodes, No. 1 and No. 2., were studied in this work. Electrode No. 1 was prepared by cathodic deposition from 1 mol/l $\text{Ni}(\text{NO}_3)_2$ solution, Electrode No. 2 contained in addition cobalt. Voltammograms obtained from eight experiments with electrode No. 1 are in Fig. 1 and 2 and important values describing the features of these voltammograms are in Table 1.

The table lists the potentials of reduction and oxidation peaks of nickel hydroxide, which are affected by the presence of metal ions. The average peak potential, as a measure of the reversible potential, and the peak potential separation, as a measure of reversibility [10], were calculated. The separation of oxygen evolution (SOE) is a potential difference between the potential of oxygen evolution and the potential of the anodic peak. It is desirable that this value is high for power sources. It is a measure of

electrode material ability to catalyze oxygen evolution:

Curve 1 is a voltammogram recorded during third voltammetric sweep with the electrode conditioned only by formation cycles and charged. Addition of iron ions (0.41 mmol/l $\text{Fe}(\text{NO}_3)_3$) resulted immediately in change of the curve, particularly in its oxidation region (curve 2). Nickel hydroxide oxidation peak shifted positively about 10 mV and the potential of oxygen evolution shifted negatively by about 20 mV. The separation of oxygen evolution (SOE) decreased to 47 mV in comparison with 84 mV for the electrode without iron (curve 1). Average peak potential shifted 10 mV positively and the peak potential separation remained the same. The subsequent voltammetric sweep (curve 3) reflects even more pronounced effect of iron presence. Although the position of the oxidation peak remained the same, oxygen evolution potential shifted further negatively. The separation of oxygen evolution decreased to mere 40 mV, which is nearly half the value for NOE without iron, which is an example of the iron poisoning effect [16]. The average peak potential for curve 3 was only 15 mV more positive than in curve 1 and the peak potential separation decreased as previously reported [10].

After this voltammetric sweep the electrode was washed in running distilled water to neutral reaction and the cell was rinsed and refilled with KOH electrolyte containing 20 g/l LiOH. The peaks shifted negatively and the potential of oxygen evolution separation increased to 77 mV (curve 4). The average peak potential shifted negatively by 34 mV and the peak potential separation increased by 28 mV. These values were larger than those for the fresh electrode which was probably due to the combined effect of iron

removal and the beneficial effect of lithium. The separation of oxygen evolution did not, however, return to its previous value but its increase was significant. Traces of iron were obviously still incorporated in the nickel hydroxide lattice and catalyzed the oxygen evolution. This influence of iron agreed with previous observations in [10,16].

An effect similar to iron poisoning had the immersion of the electrode in a solution containing 6 mol/l KOH + 0.1 mol/l ZnO (curve 5). The potential of the oxidation peak in the first cycle after immersion in zinc containing solution increased and the potential of oxygen evolution remained the same, which decreased the separation of oxygen evolution to 62 mV, which was 15 mV less than the values in absence of zinc (curve 4). The anodic peak began to deform in a similar way as in the presence of iron (curve 2). The average peak potential was 409 mV which agreed with [10] and the peak potential separation decreased to 158 mV compared to 200 mV in the presence of lithium. This lower value was likely caused by traces of iron in the lattice of nickel hydroxide. During the sixth voltammetric cycle in the same electrolyte the oxidation peak increased to 500 mV and the potential of oxygen evolution decreased to 535 mV, which resulted in separation of oxygen evolution by only 35 mV (curve 6). It appears that prolonged exposure to zinc ions had the same effect on electrode No. 1 as iron ions. Comparison of the oxidation peaks on curves 5 and 6 with the peaks on curves 2 and 3 reveals the similarity.

In the following experiment the electrode was immersed into a solution of 6 mol/l KOH with no zinc present. The oxidation peak potential shifted 7 mV negatively and the potential of oxygen evolution remained nearly the same. The values of the average peak potential, the peak potential

separation and SOE slowly shifted in the direction of the values obtained with fresh electrode (curve 7, recorded during the second cycle after zinc removal).

Because restoration of the original values of potentials did not occur within the three cycles after zinc removal, the electrolyte was replaced by 6 mol/l KOH with LiOH, which is known to have a beneficial effect on NOE. After the next three cycles the potential of the oxidation peak reached 478 mV and potential of the oxygen evolution 550 mV with separation of oxygen evolution 72 mV (curve 8). Average peak potential reached 382 mV, which was lower value than that for the original electrode, but 10 mV higher than for the cycle after which iron ions were removed. The peak potential separation changed similarly. Separation of oxygen evolution was 12 mV lower than the original electrode value. Traces of iron were probably still able to decrease partially the potential of oxygen evolution.

Iron and zinc ions also have influence on the position of the reduction peak. Both ions cause an increase of the reduction peak potential and their removal returns the potential nearly to its previous value. All these results are summarized in the Table I.

Galvanostatic (E vs. t) charging curves also were modified in the presence of iron [16] or zinc ions. Figure 3 presents galvanostatic curves for several stages in the experiment. Curve A corresponds to the pure nickel oxide electrode (No. 1) charged in 6 mol/l KOH. It shows a step on the curve that separates the potential of nickel hydroxide oxidation from the potential of oxygen evolution. In the presence of iron ions this step disappeared due to lower oxygen overvoltage which resulted in low charging efficiency of the electrode, a lower end charging potential and decreased discharging capacity,

a behavior also reported previously [16]. Removing the electrode from the environment with iron ions restored the shape of the charging curve, increased the end potential and partially increased the discharging capacity. This was more pronounced in the presence of lithium as was also reported previously [16]. The capacities and charging potentials of electrode No. 1 are in Table 2.

Changes of the galvanostatic charging curve and loss of the discharging capacity similar to those caused by iron ions were also observed in the presence of zinc ions (curve *B* and Tab. 2.) The end potential of charging was 475 mV, 39 mV lower than for a fresh electrode and very similar to 480 mV in the presence of iron. Discharging capacity was 5.4 mAh in comparison with 6.5 mAh for electrode with iron and 9.5 mAh for the fresh electrode. It should be noted that these low values for zinc can be caused by traces of iron incorporated in the lattice of the nickel hydroxide during the previous experiment.

Placing the electrode into a new electrolyte (6 mol/l KOH) without zinc ions, increased the discharging capacity and the potential at the end of charging (Fig. 3, curve *C*). Addition of 20 g/l LiOH caused additional increase of the discharging capacity, but the shape of the charging curve and the end potential of the charging remained the same. Traces of iron or zinc incorporated inside the nickel hydroxide lattice could obviously catalyze oxygen evolution as a reaction parasitic to the charging process.

Electrode prepared from nickel nitrate with cobalt

To study the influence of cobalt, electrode No. 2 was prepared in similar way as electrode No. 1 by cathodic deposition from aqueous solution

of 1 mol/l $\text{Ni}(\text{NO}_3)_2$ and 0.01 mol/l $\text{Co}(\text{NO}_3)_2$. The resulting voltammograms are in Fig. 4 and their significant features are listed in Table 3. Perusal of the curves reveals that cobalt has significant influence. Curve 9 is a voltammogram of a freshly prepared electrode after three formation and three voltammetric cycles in 6 mol/l KOH. Potentials of the oxidation and reduction peaks were lower than those for an electrode without cobalt and the potential of oxygen evolution was higher. Negative shift of the reduction peak was about 14 mV which is less than previously reported 100 mV [18]. It is probably due to the same reason as reported in [10], namely lower concentration of Co and also because nickel hydroxide in our case was the α , rather than the β phase. Curve 10 depicts the voltammetric response immediately after addition of the zinc ions. During the first voltammetric cycle all the voltammetric features were nearly the same as for an electrode without zinc, only the peaks were somewhat broader.

The situation changed after seven voltammetric cycles (curve 11). Oxidation and reduction peaks shifted positively by 20 and 61 mV respectively, which resulted in decrease of the peak potential separation. The separation of oxygen evolution was about 10 mV lower than in curve 10. The average peak potential shifted positively 41 mV which corresponded well with [10]. Replacement of the electrolyte by 6 mol/l KOH without zinc ions (curve 12) shifted the potentials somewhat toward the original electrode values.

Curve 13 in Fig. 4 is a fourth voltammetric cycle after adding LiOH to the electrolyte. The oxidation and reduction peaks continued to shift toward the values for the original electrode, but did not reach them. The average peak potential was still about 20 mV greater than the value for

curve 9. There was a significant change in potential of the oxygen evolution, which was 15 mV higher than the original value, thus SOE reached 137 mV.

The values of SOE for the electrode with cobalt are significantly higher in all experiments than the corresponding values for an electrode without cobalt. Known beneficial effect of the cobalt on separation of the oxygen evolution from the nickel hydroxide oxidation seems to remain even in the presence of some amount of zinc. A puzzling feature is the shape of the reduction peak on curve 13. The reduction peaks in the presence of zinc (curves 10, 11) or after removing zinc ions (curves 7, 12) have the tendency to broaden or split, which was not observed in [10]. Broadening of reduction peaks is known in the case of ternary metal hydroxide electrodes [17].

Galvanostatic charging curves were recorded for electrode No. 2 after formation in electrolyte without zinc (Fig. 3, curve *D*) and after 10 voltammetric cycles in the presence of zinc ions (curve *E*). Associated calculated values for these curves are in Table 4. There were two steps on the charging curve *D* for electrode No. 2 in 6 mol/l KOH which are common for electrodes with cobalt added. The lower initial capacity of this electrode in comparison with value for electrode No. 1 without cobalt is due to the lower amount of active mass. Curve *E* illustrates the situation after several voltammetric cycles in the presence of the zinc ions. One of the steps disappeared and the end potential of charging increased due to the influence of zinc ions in the presence of cobalt. Addition of zinc lowered the discharging capacity, but only by about 10 %, in comparison with the 35 % observed for the electrode without cobalt. This shows that in the presence of cobalt zinc does not have the same detrimental effect on the charging ability.

Conclusions

While most authors [10,15,17,18] studied the effect of doping NOE by other cations on thin hydroxide films deposited on platinum, this work was done on a porous thick substrate. Insertion of iron and zinc ions from a solution into the porous structure on nickel provided results not available in other ways.

The effect of zinc and iron on the electrode prepared with pure nickel hydroxide were very similar, including the partial restoration of electrode properties once these ions were removed from the solution. Presence of cobalt in the electrode material diminished the effect of zinc observed in electrodes without cobalt. Cobalt also increased reversibility of the electrochemical reaction. It was observed that zinc in the cobalt-doped electrode even somewhat increased SOE. This could be used for inhibition of the parasitic oxygen evolution reaction to improve the charging efficiency of the nickel oxide electrodes in power sources. No oxidation peak of Co was observed at 1 % concentration although at higher concentrations it can appear [14]. The absence of oxidation peak was previously confirmed in [10,15].

The value of the negative shift of the reduction peak for 1 % Co is lower than otherwise reported 100 mV [18]. This is correct because the electrode in our case was prepared from α -Ni(OH)₂, whereas in work [18] it was β -Ni(OH)₂ and cobalt concentration was 10 %.

It is known that both the amount and the method of introduction of foreign cations in the nickel oxide electrode is important [16] as well as is the mutual ratio of the metal additives, their ratio to nickel hydroxide and their location in the structure of nickel hydroxide [17]. This can be the reason why

zinc with traces of iron had detrimental effect on NOE without presence of cobalt while the electrode made with addition of cobalt was hardly affected. Although zinc appeared to have even beneficial effect on the cobalt containing electrode, no clear advantage was shown.

The peculiar splitting of the reduction peak or appearance of other redox reaction accompanying removal of the electrode from the medium with foreign cations is not quite understood and is possibly caused by formation of a different phase of nickel hydroxide. More work is needed to evaluate the co-effect of different additives on NOE. In particular, trace analysis of the imbedded electrode components at individual stages of the experiment would be desired. Also, other phases of Ni(OH)_2 , mainly β , which were not investigated in this work, should be studied in the presence of co-additives.

Acknowledgment

We thank Prof. Giovanni Davolio (University of Modena, Italy) for samples of the nickel sinter support and for helpful comments. The postdoctoral leave of I.K. was supported by the Office of Naval Research.

- Fig. 3 Galvanostatic charging curves for electrode No. 1 – without cobalt (A,B,C) and electrode No. 2 – with cobalt (D,E). A – 6 mol/l KOH, current 2 mA; B – 6 mol/l KOH + 0.1 mol/l ZnO, current 2 mA; C – 6 mol/l KOH, current 2 mA; D – 6 mol/l KOH, current 2 mA; E – 6 mol/l KOH + 0.1 mol/l ZnO, current 3 mA.
- Fig. 4 Voltammograms for nickel oxide electrode No. 2, with cobalt, with different electrolyte compositions. Scan rate 0.1 mV/s. 9 – 6 mol/l KOH; 10 – 6 mol/l KOH + 0.1 mol/l ZnO; 11 – 6 mol/l KOH + 0.1 mol/l ZnO – 8th cycle after curve 10; 12 – 6 mol/l KOH; 13 – 6 mol/l KOH + LiOH (20 g/l).

TECHNICAL REPORT DISTRIBUTION LIST - GENERAL

Office of Naval Research
Chemistry Division, Code 1113
800 North Quincy Street
Arlington, Virginia 22217-5000

Dr. James S. Murday
Chemistry Division, Code 6100
Naval Research Laboratory
Washington, DC 20375-5000

Dr. Robert Green, Director
Chemistry Division, Code 385
Naval Air Weapons Center
Weapons Division
China Lake, CA 93555-6001

Dr. Elek Lindner
Naval Command, Control and
Ocean Surveillance Center
RDT&E Division
San Diego, CA 92152-5000

Dr. Bernard E. Douda
Crane Division
Naval Surface Warfare Center
Crane, Indiana 47522-5000

Dr. Richard W. Drisko
Naval Civil Engineering
Laboratory
Code L52
Port Hueneme, CA 93043

Dr. Harold H. Singerman
Naval Surface Warfare Center
Carderock Division
Detachment
Annapolis, MD 21402-1193

Dr. Eugene C. Fischer
Code 2840
Naval Surface Warfare Center
Carderock Division
Detachment
Annapolis, MD 21402-1198

Defense Technical
Information Center
Building 5, Cameron Station
Alexandria, VA 22314
