| 13. ABSTRACT (Maximum 200 words)<br><br>X-ray spectroscopy was used to quantify the plasma generated by a focused, Alexandrite laser as a potential alternative source in proximity lithography. An x-ray emission efficiency of 2 - 11% was determined by analysis of spectral data (10 - 14A) from transition-metal targets.                                                                                                                                                                                                                                                                                                                                                                                             |  |                                                                 |                                    |                                                                        |

DTIC QUALITY INSPECTED 3

## EXPERIMENTAL

A compact (table-top), focused Alexandrite (750 nm) pulsed-laser system generated soft x-ray emission from planar-metal targets. Quantitative x-ray spectroscopy (active and passive detection) and pinhole imagery were used to characterize the 10 - 14 Å region that is important for resist exposure in proximity x-ray lithography. X-ray data was collected from transition metal targets. The spectra, acquired on film, were densitometered and computer processed to obtain line intensities from the L-shell transitions in highly-ionized copper and iron plasma. Spectral data was also acquired from K-shell transitions in aluminum in order to compare the effects of less than 8 Å spectral wavelengths (>1.5 keV energy) as the more energetic x-rays have greater penetration in the lithographic process.

The 10 Hz Alexandrite laser system at Allied Signal employs a Ti: sapphire oscillator, a pulse-stretcher (grating-pair), and a three-stage Alexandrite regenerative amplifier stage. The laser can generate chirped pulses (0.75 ns) up to 1 joule. These pulses can be recompressed to shorter pulse widths with an additional grating pair. Spectral data was acquired with both single laser pulses and a train of widely-spaced (8-ns) laser pulses.

## SUMMARY

The diagnostic instrumentation included filtered-PIN diodes, a diffraction-crystal spectrograph, and a film-recording x-ray pinhole camera. The x-ray spectrograph utilized a curved-KAP crystal.

An x-ray spectrum was recorded from a copper target. The most distinct and intense lines originate from transitions to the L-shell in neon-like copper. Spectral lines occur in the 8 - 14 Å region; however, the strongest lines are 2 - 3 level transitions in the 10 - 14 Å range from fluorine-like Cu XXI and Neon-like Cu XX. For the iron data, the same spectral transitions as in copper are generated but are shifted 3 - 4 Å to longer wavelength.

The x-ray output energy was determined assuming uniform emission over  $2\pi$  for the plasma generated at the surface of the planar targets. The soft x-ray conversion efficiency of the focused-laser beam was found to range from 1.9% at  $\frac{1}{4}$  J to 3.2% at  $\frac{1}{2}$  J integrated over the 10 - 14 Å spectral region with an average efficiency of 2.5% for both copper and iron plasma. The total x-ray emission read in the 7 - 18 Å region is stronger for the iron targets by a factor of 3 because of the intense emission between 14 and 18 Å in neon-like Fe XVII. A soft x-ray conversion efficiency of greater than 10% was recorded for a  $\frac{1}{2}$  J iron target shot.

## **CONCLUSIONS**

- **SOURCE STRENGTH**

Alexandrite laser yields highest efficiency from iron target (L-spectrum) and lowest from aluminum (K-spectrum); however, copper has good L-shell spectral output in the 10 - 14 Å region.

- **LITHOGRAPHIC CONSIDERATIONS**

Soft X-ray spectral transmission and absorption calculations revealed that the energy deposition into high-Z loaded PMMA resists can achieve greater than 45% soft x-ray deposition for copper and iron L-spectrum but only 20% for the energetic aluminum spectral distribution
