Preface

The study reported herein was conducted by the U.S. Army Engineer Waterways Experiment Station (WES) during fiscal years 1991-1992 as part of the Environmental Characterization for Target Acquisition Program. This program was jointly funded by the U.S. Army Aviation Applied Technology Directorate (AATD), Fort Eustis, VA, and by Headquarters, U.S. Army Corps of Engineers, Washington, DC. Mr. Nyle Wilcocks was the AATD Technical Monitor.

These efforts were under the general supervision of Dr. John Harrison, Director, Environmental Laboratory (EL), Dr. Victor Barber, Acting Chief, Environmental Systems Division (ESD), EL, and Mr. H. Wade West, Chief, Environmental Analysis Group (EAG), ESD. Mr. Bruce Sabol, EAG, was the Principal Investigator for this project. Dr. John O. Curtis and Mr. Sabol, EAG, prepared this report. The labor-intensive task of assembling Appendix C was capably performed by Mr. Sean Brewer (EAG contract student).

At the time of publication of this report, Director of WES was Dr. Robert W. Whalin. Commander was COL Leonard G. Hassell, EN.

1 Introduction

Background

One possible scenario for modern military helicopter operations involves the use of both natural and man-made ground features to provide cover for the aircraft until the pilot decides to pop up and attempts to locate and fire on a suspected target. Target acquisition and weapon delivery procedures will ultimately be automated, making use of a number of different sensors whose data may be fused to provide the greatest opportunity for success. The design of such sensors and sensor fusion algorithms can be optimized by a thorough understanding of terrain and target interactions with each other and with each sensor under various environmental conditions.

To this end, the U.S. Army Aviation Applied Technology Directorate (AATD), located at Fort Eustis, VA, managed a field demonstration of multiple sensors called the Multi-Sensor Fusion Demonstration (MSFD) whose purpose was to collect target acquisition performance data on targets on the ground using data from individual sensors as well as combinations of sensors. The MSFD took place in February and March 1988 at Fort Hunter Liggett, CA. Sensors were provided and tested by two organizations, Martin Marietta Orlando Aerospace and a combined team from Hughes Aircraft Company and Texas Instruments. The U.S. Army Engineer Waterways Experiment Station (WES) was initially tasked by AATD to provide ground truth information for these tests and to conduct studies on the impact of environmental conditions on sensor performance, particularly within the visual and thermal infrared portions of the spectrum.

Objectives of This Study

After completion of the MSFD, WES was additionally tasked with providing input to AATD on how test sites might be characterized with respect to sensors that operate in the millimeter wave portion of the spectrum. The WES staff felt that the first step that should be taken to respond to this last tasking was to closely reexamine existing data collected by millimeter wave sensors with the goal of assessing the impact of terrain conditions on the sensors' ability to locate and identify targets of interest and not simply measuring their ability to find those targets. In other words, the objectives of this study are to determine whether or not the terrain presents target-like features to the sensor and to determine if that behavior can be quantified and modeled so that one might be able to predict future test and/or battlefield performance for a given millimeter wave sensor.

WES has developed an image metrics approach to characterizing test sites within the visible and thermal infrared portions of the spectrum.¹ Because radar data like that collected during the MSFD can be displayed in an "image" form (slant range versus azimuth position), the most logical approach to quantifying target-like features within these images was to apply the appropriate target feature metrics (filters) to the radar data collected at Fort Hunter Liggett. Therefore, one path taken in this study was to acquire as much MSFD radar data as possible, to convert those data to "images," and to apply the simplest radar target feature metrics to those images to quantify target-like features within the environment.

The second path taken to characterize test site terrain with respect to radar sensors was to use a very simple reflectance model to predict the backscatter response of radar energy that is due only to terrain surface geometry at the test site. A point light source was placed at the two locations for the MSFD sensor test-beds and a simple Lambertian scattering model was used to calculate backscattered power from a three-dimensional finite element representation of the test site terrain surface. These predictions were compared qualitatively with real data to determine the relative impact of terrain geometry on radar returns. Furthermore, where available, overlays of the locations of trees and significant shrubbery were prepared to supplement the qualitative assessment of the impact of environmental conditions on radar data.

Scope of Report

Chapter 2 contains a description of the radar data from the MSFD that were acquired by WES for this study as well as some details about how those data had to be processed to produce "images." A description of the target feature metrics used in this study are found in Chapter 3 along with the results of applying those filters to one of the MSFD tests. Chapter 4 discusses the light model and vegetation overlay studies, and Chapter 5 summarizes the results and makes recommendations for future studies and data collection methodology.

Three appendices are included. Appendix A contains a summary of statistics associated with applying the target feature metrics to all of the available radar scenes. Appendix B summarizes target feature metric statistics as they relate to the man-made targets within each scene. Appendix C is a graphical output summary that contains scene filter results, terrain contour maps, backscatter prediction results, and vegetation overlays for all of the scenes.

2 MSFD Radar "Images"

Data Supplied to WES

Through the efforts of the AATD, radar data for 31 separate MSFD tests were supplied to WES by Martin Marietta. Of these 31 files, which represented all of the MSFD data possessed by Martin Marietta, only 24 could be read on WES data processing systems without errors. Data were not available from the Hughes/Texas Instrument team. Details on the format of the Martin data and the procedures required to generate radar "images" from these data are presented in a later section.

When reduced to image format, the Martin radar can be thought of as illuminating a patch of terrain roughly 420 m in range depth and encompassing an azimuth sweep of about 24 deg.¹ Table 1 contains a listing of all of the useful Martin data by MSFD test numbers. Also contained in that table is an average range and an azimuth angle (clockwise from north) that can be used to approximately locate the center of the illuminated area. The "High" and "Low" site designations on this table signify the location of the radar system for each test. Depression angles from the radar locations to the center of the test sites never exceeded 6 deg.

Figures 1 and 2 contain ground plane representations of the approximate area covered by each of the MSFD tests for the radar located at the high site and low site, respectively. The elevation contour lines superimposed on these figures are at 200-ft intervals.

Creation of Radar "Images"

The 31 MSFD test files sent to WES by Martin Marietta consisted of range-corrected (but not calibrated) inphase and quadrature frequency domain data for the K_a-band circularly polarized radar system used at the MSFD. Data files ranged in size from 23 MBytes to 73 MBytes and contained multiple azimuth sweeps of each test area and usually two sets of different range gate data. The term "range gate" as used in this report refers to a set of data that is collected by the receiver and recorder within a very specific range of time delays following the transmission of the wave form. Each range gate contained 20 coarse range cells that were defined by the pulse width of the radar wave form. Furthermore, the data were collected by stepping frequencies in both an up and down direction, the total bandwidth of the sweep determining a theoretical limit on range resolution. Data were also collected with the center of the beam at two different elevation settings.

¹ A table of factors for converting non-SI units of measurement to SI (metric) units is presented on page vi.

Figure 1. MSFD radar test high site data coverage

Figure 2. MSFD radar low site data coverage

The point of listing all of these variables that were a part of the data collection process is to emphasize that each data file contained an enormous amount of useful information. For the purposes of this study, much of those data were redundant. This is not to say that sophisticated data processing algorithms could not make good use of multiple terrain sweeps, overlapping elevations, and overlapping range gates, but the study reported herein was not intended to be a target detection optimization effort. Before any of the target feature metrics that form the heart of this site characterization procedure could be applied to a given test, some kind of data compression had to be performed. Acquiring a clear understanding of how the data were arranged and developing a procedure for producing a smaller useful data set was a nontrivial matter.

Martin Marietta provided WES with FORTRAN codes that could be used immediately to read record headers for these data files but that lacked the proprietary subroutine that performed the inverse Fourier Transforms for converting to the time (or range) domain. In addition, it was not discovered until much later that the way in which the data are stored in the frequency domain resulted in a wrap-around of data in range; i.e., one had to know the algorithm for locating the center of each coarse range cell. This algorithm was finally obtained from a classified Martin Marietta report.

Without going into any great detail, the basic procedure for compressing the Martin files into something more useful for these studies was to create a fine-range resolution, two-dimensional map for each radar elevation setting and for each test. The fine-range map was established by first identifying a pair of azimuth sweeps, one in each of two successive range gates, with azimuth marks on the record

headers that were most compatible. This was done by reading all of the headers and computing the minimum sum of squares of differences between successive range gate sweep azimuth marks; in other words, find the pair of azimuth sweeps in successive range gates that best line up. An inverse Fast Fourier Transform routine was written to produce fine-range resolution data from each coarse range cell, overlapping data were eliminated, and a continuous string of fine-range results was produced for each azimuth setting. The end result for each radar elevation or depression angle setting (the elevation designated "bar0" is a depression angle greater than the elevation designated as "bar1") was a multi-dimensional array of data measurements that are proportional to power returned to the radar from the terrain and/or targets. There were 1,400 fine-range cells within each of 33 different azimuth settings, with a separate "image" for each of the two radar polarization combinations (right circular received and left circular received for right circular transmitted signals). In this way, data files that consisted of tens of MBytes of data were compressed to two files (two elevations) of about 370 kBytes each that could readily be turned into two-dimensional "images" in range-azimuth space.

The intent of these studies is not to find a way to improve signal-to-noise ratios to better detect targets within natural backgrounds, but to answer the following question: Given a single sweep of the terrain, how many target-like features are out there? Therefore, an attempt was not made to optimize the data set beyond selecting the best azimuth alignment of successive range gates. Although not tested during this exercise, a simple averaging of the multiple sweeps (subject to some kind of azimuth alignment reasoning) is highly likely to greatly improve the quality of data for stationary targets. Some kind of comparison of data from the two radar elevation settings probably could also be used to *minimize terrain background response and to enhance man-made target response.*

Numbers alone do not have the impact of graphics in transmitting information to the user. Therefore, several FORTRAN routines were written not only to apply metrics to these compressed data sets but also to display data and results of analyses in both two- and three-dimensional formats. All calculations for these studies were performed on a MicroVAX II 630QE computer system, while color graphics were generated on a Raster Technologies Model One/360 graphics display system.

Naturally, in range-azimuth space, each fine-range cell will be represented by a circular arc, and the entire test data set will be represented by circular segments like those shown on Figure 1. However, because of the somewhat limited capabilities of the graphics display system used for these studies and the very fine arcs required to represent each fine-range resolution cell, a conscious decision was made to display range-azimuth data in a rectangular format to prevent any loss of visual information. The drawback to this, as will be seen in a following chapter, is that one distorts the planar geometry and makes comparisons with the results of light model calculations more difficult than if both could be displayed in range-azimuth space. Although the shape of the data display in the rectangular format is not going to be correct, an effort was made to make the width/depth ratio for the displayed data the same as the azimuth/range depth ratio in the real data.

Another concern about how to best visualize the data and calculation results for each test is how to make certain that one test can be immediately compared with another. In other words, nothing done during the compression of data or the application of metrics to those data should change the relative magnitudes of the results. One should be able to look at a color display of power returns for test MS5502 and one for test MS6701 and be confident that what appears as a given color on one test is comparable with the same color on another test. To this end, some effort was made to determine the bounds of data and metric applications to all of the data before selecting a color bar. The absolute magnitudes of test data are meaningless because the data are uncalibrated.

An example of the data is shown on Figure 3, which contains three different representations of the measure of power returned to the radar from the terrain and targets at the site for test MS6603. On a linear scale, only a few features appear as bright colors representing strong returns. As will be seen later, however, these are not all man-made targets. This type of display is a kind of data thresholding, and is very much a function of the strongest signal within the scene. It would be a simple matter to defeat a sensor system based simply on the magnitude of power returned to a radar through the use of radar corner reflectors that are optimized for the wavelength in question. The accompanying three-dimensional representation of the linear data shows just how complex the terrain returns can be for this test site. It is not at all apparent that there are four man-made targets within this patch of natural terrain, three of which are totally in the open and one is camouflaged with brush. More will be said about this observation later. Terrain elevation data contained in Appendix C reveal that the low returns at the longest slant ranges are due to shadowing.

The preferred representation of data in the range-azimuth plane is logarithmic such as that shown in part (c) of Figure 3. Here it is apparent that there are several areas of strong returns and others that are either in shadow or that absorb most of the millimeter wave energy. The black ovals represent the approximate locations of target vehicles within this scene. Although many target detection algorithms probably operate in the linear domain, there appears to be much more informational content in a logarithmic display, particularly when one is trying to relate terrain features to measured data and the results of calculations. Note in the two-dimensional displays that a histogram of data values has been included. These will be significant in determining the quantitative relationships among various tests and will be further discussed in the next chapter.

3 Metrics Approach To Quantifying Target-Like Features

Philosophy

Aided Target Recognizer (ATR) algorithms for modern sensor systems often begin the process of locating and identifying targets in cluttered backgrounds by eliminating substantial portions of the data that are not likely to contain real targets. This process, referred to as segmentation, usually involves the application of a gross (in a spatial sense) signal-to-clutter filter to coarse range profiles and assumes that man-made metallic targets produce strong returns compared with the natural backgrounds. Only after areas having high probabilities of containing a target(s) have been identified do the algorithms then process data at its finest spatial resolution to complete the search and identification procedure. To answer questions about the ability of natural target backgrounds to produce target-like features, one must not throw away any data. Thus the approach taken in these studies is to generate and retain the finest spatial resolution information that is available from these data.

It would be an enormous task (as well as an infringement on the proprietary nature of many sensor system algorithms) to apply all of the target feature algorithms to these data that are currently being used or being considered by ATR developers. Therefore, a decision was made to apply only the most commonly used and simplest features as a first step in tabulating statistics on the occurrence of target-like signatures in the MSFD test site backgrounds.

The basic approach, then, to quantifying the occurrence of target-like features in natural backgrounds is to first select several simple, widely accepted target filters, or metrics, for further study. These metrics are then applied to the finest resolution range profiles for a representative set of test site data, and the results are tabulated and stored in data files for further processing. Color graphics displays of the results are generated in range-azimuth space for qualitative interpretation. The metric, or filtered, data files are then analyzed using statistical routines, to determine moments of the histograms and other relevant information such as the relative positions of target data within the filtered data histograms. This latter step requires placing range windows over the known target locations and eliminating the target-related data from the background data to develop background-only histograms or to simply quantify the target signature with respect to the background.

Target Feature Metrics

Following numerous discussions with sensor developers, four simple target feature metrics were selected for application to the MSF⁷ fine-range resolution test site data files. These are listed in Table 2 along with some comments about their general applicability. Even though the amplitude metric does not require any additional data filtering, it proves to be a strong indicator of target presence; as long as all of the test site data sets are properly range corrected, amplitude measurements from different sites and backgrounds can be compared.

Table 2 Simple Target Feature Metrics		
Metric	Definition	Comments
Amplitude	Measure of power for each fine-range resolution cell.	Appropriate for range corrected data. Most useful for quick-look, hot spot identification.
Signal-to-Clutter (S/C)	Ratio of average measure of power in a number of fine-range cells forming a target window to the average in a number of similar-size clutter windows. One buffer window is skipped on either side (in range) of the target window.	Data need not be range corrected if clutter window is not too large. Typical applications are region-of-interest identification and target-size S/C for detection.
Variance	Variance of signal (not measure of power) within a window of fine-range resolution cells. $\frac{n \sum x_i^2 - (\sum x_i)^2}{n(n-1)}$ where x_i is the signal (voltage) amplitude returned from the i^{th} fine-range cell.	An indicator of the presence of one or more strong scatterers. Data need not be range-corrected.
Polarization Ratio	Ratio of total measure of power in the left receive, right transmit channel to the power in the right receive, right transmit channel.	Man-made objects should exhibit strong, double (even) bounce behavior. Relatively smooth terrain should have strong, single (odd) bounce characteristics. Foliage should be neither. Large tree trunks and rock outcroppings are expected to cause problems.

There was some concern regarding how many range-resolution cells should be included in each metric. For example, the signal-to-clutter metric consists of a target window, a buffer window on either side of the target window, and a number of clutter windows outside of the buffers. After much experimenting with the size of these windows, a somewhat meaningful filter size was chosen that includes a 2-m target window, one 2-m window on either side, and four 2-m clutter windows outside of each buffer. Although this may not be the optimum arrangement from a sensor developer's perspective, it formed a reasonable tradeoff between spatial resolution and metric amplitudes. Larger size windows appeared to do nothing more than smear the results. Other filter sizes included a 10-m window for variance calculations and a 2-m window for calculating the ratio of even to odd polarization returns.

The procedure for applying each target feature metric (except for amplitude) was to set the filter at the shortest range for each azimuth, calculate the value of the metric, and insert that value into the fine-resolution cell at the middle of the filter. The filter was then moved out in range by one fine-resolution cell and the calculation performed again. This was repeated for each azimuth until the filter "bumped" into the farthest range cell. In this way, some data is lost at the near- and far-range edges of the range-azimuth data set.

Representative Results

Range-azimuth displays

Figures 4-7 contain graphics display results of the application of each target feature metric to the same test discussed previously, MS6603. Each figure contains the slant range-azimuth representation in both linear and logarithmic scales along with a crude histogram. Open circles added to the logarithmic displays approximately coincide with the locations of man-made targets at the test site.

Several observations are in order at this time.

- a. Of the four different representations of target feature metrics, only the polarization metric displays a log-normal distribution of terrain signatures. Power returns from natural terrain are often assumed to be distributed log-normally, but the power returned from this test site is most assuredly not log-normal. This observation, which is generally true for the other test sites, is probably due to a combination of low-grazing angles, relatively sparse vegetation, and the presence of small hills and depressions that result in numerous "shadows" within each test area.
- b. Returned signal strength and the amplitudes of filtered data alone are not enough to ensure the detection of man-made targets. An examination of all of the MSFD data reveals that if one knows where these targets are located, the data will often show a strong signature at about that point in space; but other numerous strong features appear to be caused by either the terrain or by man-made clutter within each test site. As for man-made clutter, a consensus exists among MSFD participants that all clutter was not adequately logged, and this study was initiated too long after the demonstration to gather any reliable information by revisiting the site.
- c. The polarization ratio concept is of no value whatsoever as a means of separating man-made objects from natural backgrounds. After some reflection on this question, it appears that even if one had an ideal target-size double-bounce object within the radar's instantaneous field of view, its effect on the returned signal would still be minimized because of the fact that the volume in space occupied by a fine-range cell and the half power beam width of the radar is large enough to result in a volume averaged response that is essentially depolarized. For this test case example, the half power beam width covers an arc with nominal length of over 30 m. The same argument could be made to account for why so-called target amplitudes are not greatly above those of the natural background in many test cases.

Figure 4. Range-azimuth displays of the "measure of power" metric, MS6603

Figure 5. Range-azimuth displays of the "signal-to-clutter" metric, MS6603

Figure 6. Range-azimuth displays of the "variance" metric, MS6603

Figure 7. Range-azimuth displays of the "polarization" metric, MS6603

- d. While all of the target feature metric examples shown are for MSFD data that are derived from sums of squares of measured voltages for the two different polarization combinations, the statistics will show that neither of the polarization combinations by themselves consistently performed better than the other when looked at from the target feature metrics perspective. This is a reflection of observation c.

Range profiles

Consider now another visualization of these target feature metrics, this time as a trace of the metrics along a given azimuth mark. Several of these range profiles are shown in Figures 8-10. It is obvious from the logarithmic representation of power for test MS6603 shown in Figure 4 that a man-made target should be quite apparent along azimuth mark 18 (the 18th vertical strip counting from the left); those profiles are shown on Figure 8. The apparent target position is indicated by the dashed line. Another target should exist along azimuth mark 21, but it appears to be obscured by strong foreground returns. Azimuth mark 21 profiles are shown on Figure 9. Finally, there are numerous significant returns from azimuth mark 24 where there should be no targets of interest. Its profiles are shown on Figure 10.

As with the two-dimensional maps, several observations are in order relevant to these one-dimensional traces.

- a. With respect to the target in azimuth mark 18, its measure of power does exceed all other returns along that profile. The other significant return at about range cell 530 is simply a spill-over from the target located in azimuth mark 17. At this point it is impossible to speculate as to the significance of the shape of this profile because not enough ground truth data exist to indicate whether the reduced returns on either side of the target are due to the shadowing effects from adjacent targets or dips and rises in the local elevation, or whether this is just a strong target signature superimposed on a flat terrain return. A closer examination of the target profile would have to deal with higher order target detection algorithms, anyway, and that was not the objective of these studies.
- b. Regardless of what influences the power profile data, application of the signal-to-clutter metric to a strong isolated return has to produce the characteristic profile shown on part (b) of the figure. For this target, under these test conditions, nothing in the background dominates the signal-to-clutter space quite like the real target. There is one minor anomaly at about range cell 900 that requires more ground truth than that available to explain.
- c. By its very definition, a calculation of the variance of a signal within some window is a measure of how extreme the variations in the signal are. One is therefore not surprised to see the strong signature in variance space because of this rather isolated and dominant target. Large shadows will cause the severe depression of the variance metric seen between range cells 900 and 1100.
- d. Even for the well-defined target in azimuth mark 18, the polarization metric did not reveal any anomalies, as expected.

- e. Whereas the strong target signature on azimuth mark 18 was very isolated, the target location on azimuth mark 21 does not stand out in any of the target feature metric profiles. The test summary indicates that this target should have been in the open but was turned at an angle to the radar. In other words, target signatures are not always the strongest signatures on any given profile. In fact, almost everything in the foreground of this target gave stronger returns. It will be shown later that the strong foreground signals can be attributed to terrain geometry and vegetation.
- f. Finally, consider the target feature metric profiles shown on Figure 10 for azimuth mark 24. Without further ground truth information, it appears that there are no man-made targets along this profile, but, at least in the signal-to-clutter domain, there are strong indications of target-like features between range cells 500 and 900. The very elevated power measurements within the first 400 range cells are uniformly high and produce no target-like features. It appears that anything within the natural terrain that could cause a short range jump in power return could produce a target-like signal-to-clutter response. Within the terrain at Fort Hunter Liggett, such behavior could be the result of the isolated trees at each test site.

Statistics

During early discussions with the AATD staff, it was suggested that by taking a hard look at a good set of existing data and applying the metrics analysis approach, a quantitative way might be developed to characterize a given test site within a given portion of the spectrum. After a great deal of effort was expended on this task, the conclusion to date is that a simple, clean way of quantifying a test site through the "eyes" of a given radar system has not been found. There are, however, hints that such an approach might still work. Ideally, what would be required is well-documented data from other geographical locations that were collected using the same sensor system. Such data do not exist. Nevertheless, the following observations derived from statistical analyses may prove useful for future measurement and analysis programs.

Global target prominence. Literature on imaging ATR systems¹ has defined a metric concept which quantifies the conspicuity of a target portion of an image relative to the entire image. This is referred to as a "global target prominence" (GTP) and is measured by determining the percentile location of a target feature value relative to the histogram of this feature for the entire image or for the portion of the image devoid of targets. This is illustrated in Figure 11. GTP is interpreted as the portion of the image less conspicuous than the target for a specific feature. Values range between 0.0 and 1.0. A value of 1.0 indicates that the target has a higher feature value than anything in the image; conversely, a value of 0.0 indicates that the target has a lower value than anything in the image. This concept is directly adaptable to the radar features used in this study.

Table 3 contains average GTP values for each of the radar target feature metrics. The "all data" column represents the average of target prominences when the target data is considered as part of the histogram for each test. The "backgrounds only" column uses histograms for which the target signatures have been masked. What these numbers say is that the targets, in general, are among the dominant features within all of the test sites. However, given the number of fine-range cells

Figure 11. Graphical representation of global target prominence (GTP)

Table 3 Average Global Target Prominence (GTP) of Radar Features		
(Based on 88 Targets in 24 Scenes; Total Measure of Power Data)		
Measure of Target-Like Features	All Data	Backgrounds Only
Power	0.994	0.994
Signal-to-Clutter	0.990	0.990
Variance	0.973	0.975
Polarization Ratio	0.925	0.925

contained within each test site data set, there are still a large number of other features whose signatures are equally as strong.

Cumulative histogram inferences. One of the most promising approaches to quantitatively characterizing test sites with respect to a given radar sensor was to look for predictable patterns in the histograms of measured and filtered data. The following figures and paragraphs contain some observations regarding the cumulative histograms of measure-of-power data for all of the test sites contained within this study.

Figure 12 contains all of the MSFD test site cumulative histograms presented on a logarithmic scale. There is no obvious clustering of these curves that could be attributed to something unique about the terrain at different sites within Fort Hunter Liggett. In fact, disregarding the two anomalous responses from tests MS6701 and MS5803, all of the remaining test results for power measurements are quite closely clustered. There are, however, a couple of observations worth noting.

CUMULATIVE HISTOGRAMS

HIST_TYP=w/otargets

	MS63012	MS6403	MS6603	MS6701

Figure 12. Cumulative histograms of power data (all tests)

Figure 13 is another plot of cumulative histograms for test sites whose average range is different from all of the others. In a gross sense, increasing range to the test area appears to cause a shift to the right in the cumulative histogram. The net result of such a shift is to decrease the extremes of contrast within the test area that could, in turn, lead to less apparent target signatures. All of this could be explained by the large range cell volume averaging concept discussed earlier. When one combines a strong target signature with a larger number of worker background signatures, the resulting average tends toward the weak background levels.

CUMULATIVE HISTOGRAMS

HIST_TYP=w/otargets

Figure 13. Cumulative histograms showing range effect

The final observation in this section on statistical perspectives is that the data collected at Fort Hunter Liggett do appear to be quite repeatable. Figures 14 and 15 show the histograms of tests whose target arrays were located at about the same position relative to the radar but whose data were collected at different times of the day varying from predawn to the middle of the afternoon. This clearly shows, also, that environmental factors such as air temperature and relative humidity changes within reasonable limits have little effect on radar measurements taken during MSFD. There is some temptation to attribute the differences between the histograms shown in Figures 14 and 15 to gross differences in weather conditions, as the data represented on Figure 14 was collected during heavy fog

CUMULATIVE HISTOGRAMS

HIST_TYP=w/otargets

Figure 14. Cumulative histograms showing repeatability (heavy fog)

CUMULATIVE HISTOGRAMS

HIST_TYP=w/otargets

Figure 15. Cumulative histograms showing repeatability (moderate weather conditions)

conditions and those shown on Figure 15 to a more moderate set of relative humidity conditions. However, the magnitudes of the data do not support that contention. Water will tend to absorb and forward scatter the radar energy. If moisture was the controlling factor in the difference between these two groups of tests, then the data in Figure 14 should be shifted to the left of the data in Figure 15, and that is not the case. The range effects noted above seem to be the best argument for the differences.

4 Backscatter Modeling and Discussions of Terrain Effects

A Simple Backscatter Prediction Model

The second approach taken in these studies of characterizing the interaction of the MSFD test site backgrounds with the radar sensors was to develop and exercise a simple backscatter prediction model to qualitatively assess the impact of terrain geometry on measured data. In other words, "How much of the radar return can be predicted by some reasonable knowledge of the test site surface geometry?" This was thought to be a particularly relevant question for the MSFD because of the relatively clean environment of the tests compared with what might exist at test sites in other temperate parts of this country or in western Europe, or even Central America.

The backscatter model developed consisted of the following elements that are schematically drawn on Figure 16. First of all, available 25-m terrain elevation data were converted into a three-dimensional finite element surface of triangular facets for which vectors normal to each facet are easily computed. Next, a point light source was positioned at the location of the radar system (either the high site or the low site), and the angle, ϕ , between the light source and the normal vector to each terrain facet was computed. Under the assumption of Lambertian scattering, the intensity (or power) of the backscattered light was calculated to be proportional to the cosine of this angle.¹ A ray-tracing scheme was developed to ensure that terrain facets that could not be seen by the radar would not produce a returned signal. Because none of the available Geographic Information System packages available at WES possessed a finite range point light source simulation capability, this software package was developed by the first author.

The point light source simulation of a radar is reasonable, because light energy and radar energy are the same physical phenomenon; they differ only in frequency. The Lambertian assumption for scattering is not unreasonable, because at the frequency of operation of this radar system, the terrain surface is certainly rough. Ultimately, the acid test for this model is its comparison with real data. Results indicate a strong correlation between the two.

Representative results for this simple backscatter prediction model are shown on Figures 16-18. First of all, Figures 16 and 17 show the terrain backscatter predictions for the entire areas within which MSFD tests were conducted, with Figure 16 depicting the radar located at the high site (Site 8)

¹ M. Born and E. Wolf. (1980). *Principles of optics*. 6th Edition (with corrections), Pergamon Press, Inc., Oxford, UK.

Figure 16. Schematic of the backscatter model

and Figure 17 showing results for the radar located at the low site. There is a black dot on each figure at the location of the radar, and 40-ft contours are superimposed on the figures. The simple model predicts intensities that vary between 0.0 and 1.0 in magnitude. These results were then converted to a 40-db range (which is comparable with the range of measured data) and displayed with the same color bar used for the displays of target feature metric calculations shown in the previous chapter. Even on the gross scale of these figures, it is readily apparent that the model behaves correctly in the sense that steep slopes visible to the radar cause strong backscatter returns and that terrain that cannot be seen by the radar is placed in shadows (white background on these figures to facilitate viewing of the elevation contours).

But the real question is whether or not the model can qualitatively simulate the measured data at each test site, thereby establishing that surface geometry is a major contributor to the test results at MSFD. Returning once again to the same test for which results have already been discussed in previous chapters, Figure 18 contains a comparison between measured data and predicted results using the simple backscatter model. When viewing these images, keep in mind that the measured data were displayed on a rectangular format, while the outline on the simulation results depicts the polar nature of the radar operation. A similar set of figures is shown in Appendix A for each MSFD test. They all demonstrate a strong correlation between predictions based on simple surface geometry and reflectance models and the actual data measured by the radar. For example, note that on Figure 18 strong returns were measured by the radar and displayed on the lower right hand area of the range-azimuth plot that could not be attributed to the presence of any man-made objects. The simple backscatter model predicted the same area of strong returns because of the fact that the terrain surface is nearly normal to the radar at that location. In fact, most of the significant features of the test site radar response are

Figure 17. Backscatter model predictions for the high site location

qualitatively simulated by this simple reflectance model. Hill slopes facing the radar are illuminated, and shadows exist where depressions in the terrain have been measured.

Vegetation Overlays

Also shown on Figure 18 is a 10-ft contour map with a vegetation overlay. This was produced by enlarging a set of aerial photographs of the MSFD test areas taken within the next year after the demonstration was conducted to the same scale as the measured data and prediction displays. A contour map was generated on a transparency and laid over the aerial photo. As can be seen by the site photographs contained in Appendix A, the crowns of the trees and other significant vegetation are easily recognized and were simply colored in on the transparency. Such an overlay would probably be most useful for those test sites where the terrain geometry was not such a strong contributor to the backscatter signal as is true for MS6603.

5 Summary and Recommendations

In an attempt to develop a scene characterization methodology for long-range (2 to 7 km), low-grazing angle (less than 10 deg) active millimeter wave radar systems, a twofold approach was taken. First, slant range versus azimuth maps of radar backscatter measurements were filtered using the target feature metric technique to collect statistics on the occurrence of target-like features and to relate those signatures to natural terrain conditions. Second, a prediction of radar returns from the terrain was modeled by a point light source at the radar location and the assumption of Lambertian scattering from the terrain facets. Model predictions were combined with overlays of vegetation at each test site and compared qualitatively with the measured data to assess the impact of terrain conditions on backscatter response.

Application of these analysis tools to the Martin Marietta radar data collected during the MSFD resulted in the following observations:

- a. Man-made targets within the terrain backgrounds found at Fort Hunter Liggett are reasonably easy to locate in range-azimuth "images" when their positions are known, but might not be easily found by automated methods applied to either raw data or filtered data because of the strong target-like returns from the terrain at some test sites.
- b. Not enough data on different types of target backgrounds are available from the MSFD trials to develop an effective statistical tool for quantifying background conditions for differing terrain conditions. The use of cumulative histograms for achieving this objective is still a potential tool, but more data from different backgrounds and collected with the same radar system is needed to pursue this train of thought.
- c. A simple point light source model with assumed Lambertian scattering qualitatively correlates very well with observed data. Vegetation overlays serve to enhance that correlation. This implies that for the type of terrain offered by the Fort Hunter Liggett test sites, even crude surface geometry models and vegetation overlays will explain much of the background response.
- d. Many questions about the impact of terrain on radar returns under the conditions stated above remain unanswered in part because of insufficient supporting data. Future tests in which radar data will be closely studied must include more comprehensive ground truth measurements. For example, had it been known prior to the execution of the MSFD that a detailed look at the radar data was going to be taken, a complete set of low-altitude, oblique, high-resolution color photography and video of all of the test sites could have been collected (from at least two of the

cardinal directions). This would have answered any questions about vegetation conditions or about the occurrence of man-made clutter and such natural features as rock outcroppings.

Having developed the data management and analysis tools for this study, it would be relatively easy to test other higher order target feature metrics. In fact, a database now exists for this one set of terrain conditions to take a closer look at existing target detection algorithms or to develop and test new ones. One very straightforward task that could be undertaken and that would require nothing more than to revisit these existing data would be to examine the impact of averaging multiple azimuth sweeps or comparing results from different elevation settings as suggested in Chapter 2.

In the area of modeling, it appears from the simple exercise conducted within this study that modifications of the point light source model could yield a valuable tool for predicting terrain signatures. Examples of such modifications would include more realistic scattering assumptions from grass-covered terrain and a coupling of tree and bush spatial information with a separate module for estimating an average backscatter from each species.

Appendix A

Scene Metric Statistics

The following pages contain a summary of common statistics for the log-scale histograms associated with each of the 24 MSFD radar scenes. There is a table for data that represent the total power returned to the radar receiver (BAND=total power) as well as a table for the power measured on the right receive-right transmit channel (BAND=polarization RR) and for power measured on the left receive-right transmit channel (BAND=polarization LR). Each of these tables has, in turn, separate sheets for each radar target feature metric (METRIC=measure of power, METRIC=signal to clutter, METRIC=variance). The final table summarizes results for the polarization ratio metric (BAND=LR/RR, METRIC=polarization ratio).

Appendix B

Target Metric Statistics

In an attempt to make this document as useful as possible, statistics on radar feature metrics as they relate to the actual targets were compiled and are included in this appendix. The procedure for compiling these statistics was the following. First of all, a mask was created for each scene that served two purposes. One was to remove the influence of a man-made target on the radar return by effectively removing from the scene a portion of one or more azimuth slices that was centered on the likely location of each target. The other purpose was to identify the strongest return from that segment as the target return, or metric value. The target metric value was then compared with the target-free background to produce the global target prominence for that target that is defined in Chapter 3 of the main text.

As with the previous appendix, data are presented in terms of both the type of received signal considered (total power, right receive-right transmit (RR) polarization power, left receive-right transmit (LR) polarization power) and the metric being considered (measure of power, signal-to-clutter, variance, and polarization ratio).

TARGET RADAR METRICS

Appendix C

Relevant MSFD Test Site Data and Analysis Results

Contained within this appendix is all of the information used to study the radar returns from each of the 24 MSFD test sites for which good data were available. Arranged in numerical order by test number, each packet of information contains a test summary sheet, Charge Coupled Device B&W oblique photographs (if available), a B&W down-looking aerial photo and a 10-ft contour map, both two-dimensional and three dimensional (3-D) linear scale representations of total measured power, slant range-azimuth representations of measured data and filtered data from the target feature metric exercises, range-azimuth representations of backscatter modeling results, and another site contour map with vegetation overlays. The approximate locations of targets for each test are shown as circles on the backscatter prediction results.

13. ABSTRACT (Maximum 200 words) In an attempt to develop a scene characterization methodology for long-range (2 to 7 km), low-grazing angle (<10 deg or .17 radians) active millimeter wave radar systems, a twofold approach is taken. First, slant range versus azimuth maps of radar backscatter measurements are filtered to collect statistics on the occurrence of target-like features and to relate those signatures to natural terrain conditions. Second, a prediction of radar return from the terrain is modeled by a point light source at the radar location and the assumption of Lambertian scattering from the terrain facets. Model predictions are combined with overlays of vegetation at each test site and compared qualitatively with the measured data to assess the impact of terrain conditions on backscatter response. These approaches are applied to a set of test site K _a -band radar measurements made at Fort Hunter Liggett during the winter of 1988.
