ABSTRACT

As the sophistication of acoustic sensor and communication systems related to unmanned underwater vehicles (UUV) has increased, the requirement for greater volume and higher speed data transfers has emerged. Fiber optic technology provides an effective means for high bandwidth communications with a UUV while minimizing weight and space criteria aboard the UUV. Increase in data transmission speed has permitted real time processing of data on the launch platform when using large high powered computing systems. Maximum system reliability at advanced performance levels can also be realized. By designing and developing a full scale system comprised of the UUV, remote control and command platform, and data handling and routing electronics, fiber optic tethered UUV technology was demonstrated in lab and field tests. This three year venture culminated in a series of successful in-water tests that proved the feasibility of fiber optic tethered UUVs and warranted the continuation of research on remotely operated UUVs.

CHAPTER 1

INTRODUCTION

With the use of a single fiber as the communication link between the UUV and launch platform, the success of the overall system relies partially on accurately converting all communicated information into a serial data stream. The data stream will then be transmitted optically over the fiber. The task of converting the serial data stream into data that is useable by the subsystem electronics is accomplished by additional custom electronics that can multiplex/demultiplex and interface effectively to the processing and control equipment.

This thesis will discuss the development of a system that utilizes an optical medium for data communications, and more specifically the design development and integration of the data handling electronics on either side of the optical subsystem.

1.1 Fiber Optic Tethered Vehicles

A tethered UUV is an underwater vehicle capable of performing various missions without having in-water personnel [1]. Tethered UUVs can operate in hazardous conditions or in bad weather. They can operate in areas that are dangerous, confined, or otherwise not suited for manned vehicles. Because it is unmanned, the UUV is fearless and does not have to provide support for man or extensive equipment [2].

Tethered UUVs are used for operations as search and recovery, underwater construction, assembly, and inspection. They are best suited for large seafloor area coverage, single task missions, and are clearly superior for hazardous circumstances.

1.2 Fiber as a Data Transmission Medium

The goal of the fiber optic tether is to provide a simple error free link that will interface different equipment and tolerate the varying communication losses in the system [3]. The link is the lifeline, communicating real time data and control to and from the UUV. The communication link must be able to handle high speed data and large volumes of data [4]. Additionally, its supporting electronic interfaces must be able to maintain the link through proper use and respect for the maximum link bandwidth.

Fiber is an unequaled communication link. For an individual single mode fiber, an unlimited bandwidth-length product is theoretically possible, but not practical. Viable transmission distance is affected by two parameters, dispersion and attenuation [5]. Current links operate at less than 5 GHz. As a transmission media, links can be realized that communicate greater than 250 km without repeaters [6]. Additionally, optical transmitters of different wavelengths can use the same fiber simultaneously without interference. Being able to use the same fiber simultaneously multiplies the carrying capacity by the number of wavelengths used.

The optical link offers the great advantage of very high speed and simultaneous bidirectional data communications. Fiber has the additional advantages

of a) electrical isolation, b) no short circuits, c) wide bandwidth with low attenuation, d) transmission security, e) no crosstalk, and f) no fire hazards [5]. Fiber is also small in size and light weight. A typical fiber for deployment could be less than 1mm in diameter and weigh 1 kg/km, while a coaxial cable with a comparable bandwidth could be 30 mm in diameter and weigh 1110 kg/km [6]. For UUVs, a fiber link's size and weight translates to extended mission lifetime and enhanced packing density for the spooled fiber.

1.3 Data Handling

In order to accommodate the data flow across the optical link, typically, custom electronics are designed. The design is custom because the type and quantity of interfaces can vary greatly and the interface to the optics is user specified.

Interfacing systems can exist in different forms; two common structures are the pipeline and bus structure. In a pipeline configuration, data will pass through each function (or interface) one at a time to arrive at the final destination (optical interface). The throughput of the system is limited by the slowest interface. In a bus configuration, all of the functions are tied to a common point, a bus type structure. A bus is a communications backplane that is shared for intercommunications among bus modules. Limitations on the configuration are dependent on the bus bandwidth and availability, since all data transfers to an alternate interface must pass through the common bus. The bus can only support one data transfer path at any given instant.

The choice of the system utilized in this thesis was obviously directed at a central bus configuration because of the non-pipelining organization of the system processing. For reasons to be discussed in detail later, the VME (Versa Module Eurocard) bus was chosen. All interfacing within the two unique subsystems (UUV and launch platform) is accomplished using the VME bus structure complete with commercial and custom designed circuit cards.

The objective of the data handler is to provide a transparent interface that joins the two separate subsystems. If it was possible to keep all of necessary electronics inside of the UUV, the data flow for the system would be very different. Recorded data could be routed to the recorders, acoustic data could be channeled directly through the array processors, and command and control information would be local to the UUV and provide immediate decisions on processed data. This was not the situation developing for this system; data would not only exist in the UUV but also at a remote location that also required the data. The design of this system was not simply a demonstration of a tethered vehicle, but needed to provide the computational power required for the experiment.

A powerful processing system had to be transferred to the launch platform where there were no restrictions on space. Effectively this required the splitting of the system electronics and the addition of a communication link between them that would not effect the overall system characteristics or operation. This required additional electronics evolved into the development of the Fiber Optic-VME Interface board (FO-VME I/F) and the associated optics.

1.4 Thesis Objectives

The research presented in this thesis is part of a much larger system that was involved with the complete system development of a fiber optic tethered UUV. This system's successful completion took several years and involved the hard work of many engineering disciplines. This thesis will discuss one specific development within the system, the engineering of the electronic data handler (FO-VME I/F) on either side of the optics.

Objectives

- Evaluate, through field testing, the reliability and performance of operating a fiber optic tethered UUV communication link. Determine what performance can be expected and how it can be improved.
- Evaluate the use of fiber optics as a medium for a simultaneous bidirectional data link connecting the UUV to the launch platform.
- Provide real time access to data on either side of the optical link via custom electronics that can interface easily to commercial equipment.
- Provide a semi-transparent split of the system data processing electronics (UUV and launch platform) via a bidirectional data path to the optics.
- Ensure the custom electronics provides data availability and integrity.

All the objectives listed above were achieved and will be discussed in this thesis. Completion of the objectives support the reliability and existence of a fiber optic tethered UUV, and justify the further development of this technology. Additionally, this communication system allows real time data to be processed remotely from the vehicle. The processing also permits a more robust system for the remote equipment to accomplish complex tasks.

1.5 Thesis Summary

Chapter 2's discussion of technological and space constraints will illustrate why a fiber optic tethered UUV was needed, and will reinforce the advantage of such an approach. A look at the optics and payout fiber is included since this represents the basis for the remote processing. The thesis will discuss the background of a tethered UUV system and the major components that comprise the system and relate to data handling and routing.

In Chapter 3, the design and configuration of the data handler that is called the Fiber-Optic VME Interface (FO-VME I/F) is covered. Its design and development is discussed. Chapter 4 focuses on the testing process. Through laboratory and field test results, the entire system, and specifically the FO-VME I/F and fiber optic link, were tested thoroughly to ensure reliable operation. Important test configurations are discussed and some unique data analysis is provided.

Chapter 5 discusses the newer technology and how it can be integrated into the system to create a more dynamic system. The system did have a few operational

errors. These are listed in Chapter 6 in order to indicate the source of each problem and the strategies that can or could be used to correct the problems.

CHAPTER 2

BACKGROUND & SYSTEM OVERVIEW

Many of today's research and development programs rely on the availability of a standard UUV test bed for testing. This shell of a test bed system is expanded and modified to accommodate the recorders, electronics, batteries and miscellaneous test equipment that will aid in the program's objectives. Modification and expansion is not needed in the fiber optic tethered vehicle, thus reducing UUV space and weight, and restrictions on computing hardware.

The advantages offered by the fiber optic tethered UUV are slightly diminished by the custom electronics required to support the link. When the link is used, the UUV must house the optical transmitter and receiver to drive the fiber, but it must also contain the electronics that interface with the acoustic array for data and control, plus to the UUV electronics for controlling UUV movement in the water. Topside, the electronics must interface to the processing and recording equipment. Typically these use industry standard interfaces.

2.1 Necessity of a Fiber Optic Tethered UUV

There are two major reasons why tethering of a UUV makes sense and can be beneficial. They are based on the premise that the tether allows the system processing electronics to be relocated from the UUV to the launch platform. This

relocation creates a space savings internal to the UUV without the need for specialized electronics, and permits the use of virtually any size electronics equipment on the dry side of the tether.

The amount of electronic equipment that can go on-board a UUV is limited by available space and the maximum weight allowable for deployment of the UUV. The constraint on space is made worse by the fact that a UUV is typically small, making custom fit hardware the rule. The addition of the fiber optic link partially removes this constraint. Most of the added electronics can be removed and placed on the launch platform, leaving room for a fiber spool and the associated optics and electronics. Also, the additional space eliminates the necessity of form-fitting hardware in the UUV and the launch craft provides relatively boundless space for housing processing electronics. In addition, there is a cost saving because the need for special, rugged, or modified equipment is reduced. Standard commercial products can be utilized effectively.

Besides the savings in space within the UUV, the data processing electronics on the launch platform can now be larger and more complex due to the removal of the size constraint. As data processing computers evolve, more power is put into much more compact a space; however, the high end processing computers, of any generation, have always been large. The relocation of the processing computers from the UUV to the launch craft makes it possible to use the best possible processor (within budget) to meet the objectives of the project. For example, the initial remote processing system presented in this thesis utilized a μ VAX 3800 workstation and a

full size 15-slot VME chassis for data processing and command and control. Including the power supplies and fans needed for this equipment, this equals approximately 12 ft³ of computer equipment. To fit all of this computing power inside the UUV would add nearly six feet to the UUV's length. At the time this system was designed there were no alternatives that could easily fit inside the UUV. The opportunity to place processing electronics on the launch craft permitted the use of standard, unmodified laboratory equipment for remote processing.

2.2 Tethered UUV Subsystems

Figure 2.1 shows the main subsystem blocks needed to create a tethered UUV system. There are four unique subsystems that, when combined, form a system capable of remotely processing UUV data and controlling UUV actions. The subsystems are a) fiber optics, b) UUV electronics, c) launch platform processing electronics and data recording, and d) data handling and routing electronics. The following sections discuss each subsystem block.

2.2.1 Fiber Optic Link

An objective of a previous fiber optic link study was to prove that a reliable connection could be maintained between a UUV and a launch platform [7, 8]. The objective was established for long fiber lengths and high UUV speeds. The success of this study provided a strong impetus for the use of fiber optics used for remote

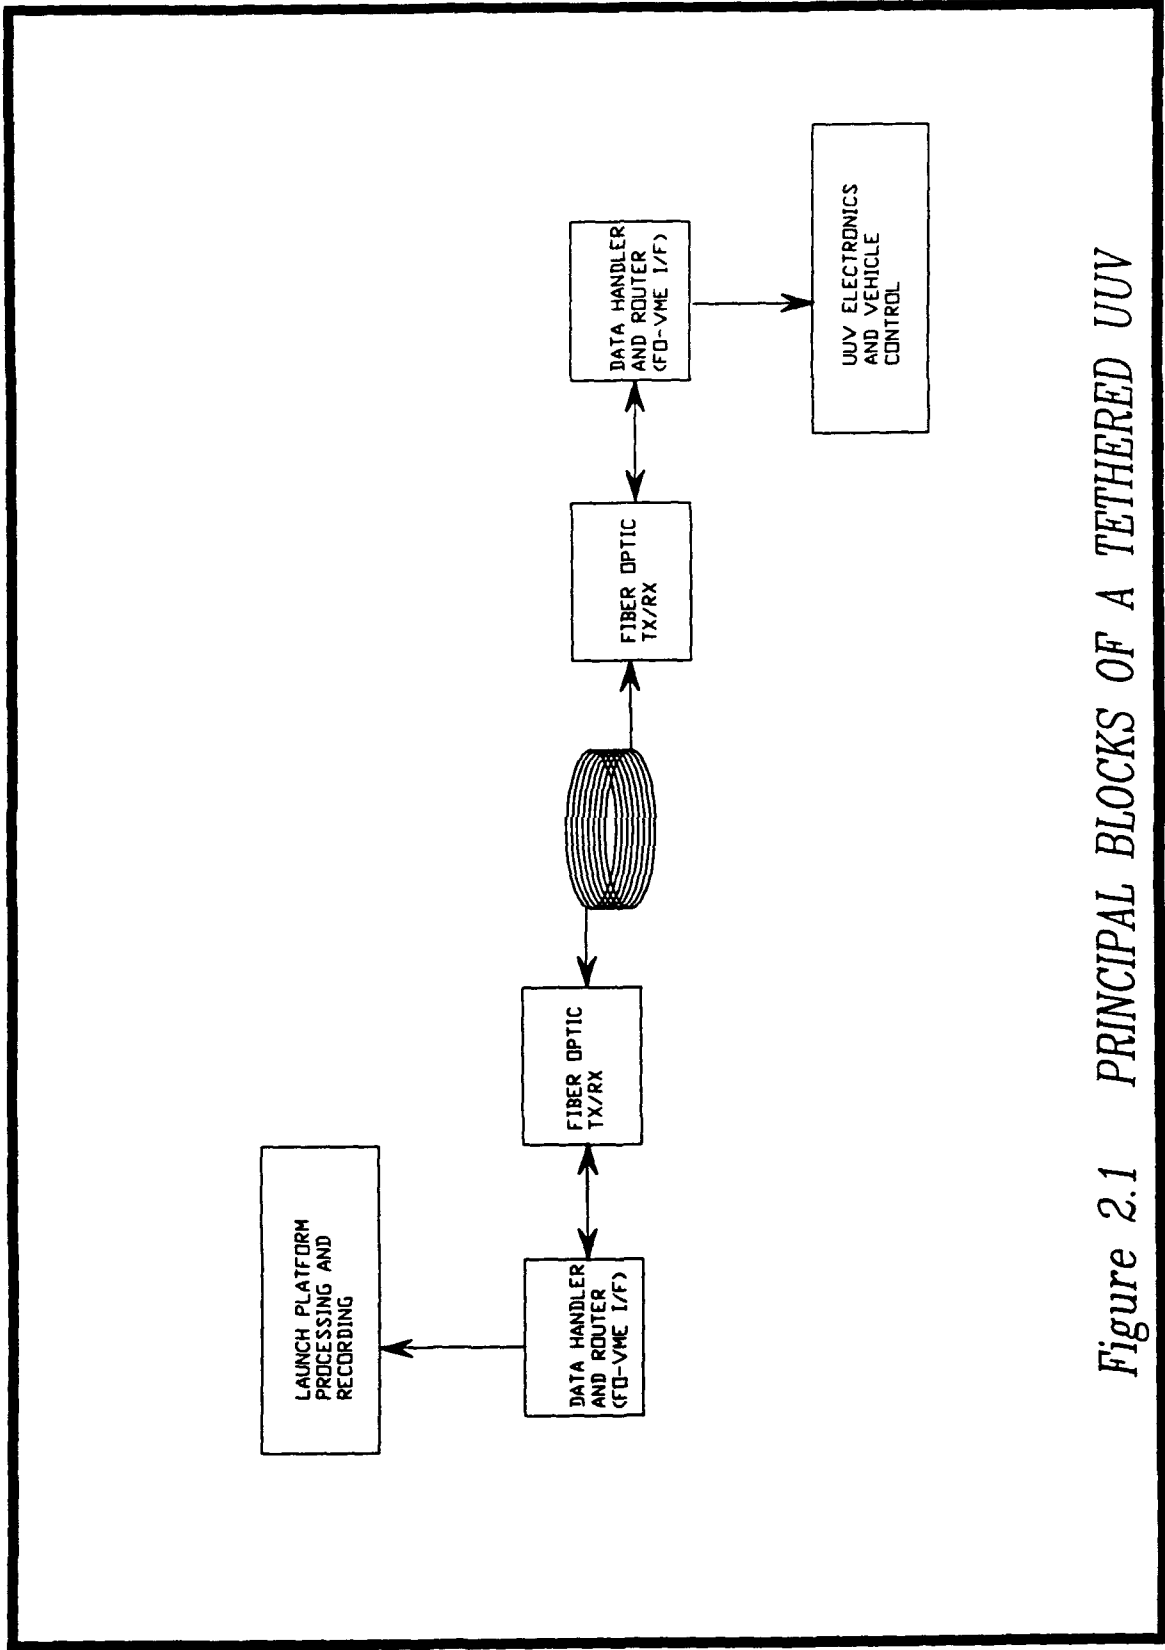

Figure 2.1 PRINCIPAL BLOCKS OF A TETHERED UUV

control and command processing, and for continued research into optically tethered UUVs.

The original fiber optic link used in the above study was designed to utilize:

- 1300 nm and 1550 nm wavelengths to provide simultaneous bidirectional optical communication
- a dispersion shifted, single mode fiber
- fiber lengths of 5 Km to 20 Km
- commercially available parts
- a 16 MHz data rate
- modular and upgradeable components

Because of the low data rate, dispersion was not of concern and the design was centered around the flux budget. The flux budget represents the total attenuation experienced from transmitter to receiver. Using the maximum attenuation ratings for all the components, a system loss of greater than 30 dBm was calculated [9, 10]. Figure 2.2 is the block diagram of this communication scheme and Table 2.1 lists all of the components used with optical and mechanical parameters. The component selection did not change dramatically for the new system built around remote processing. Similar optical devices were used but were packaged in less than half the space. Parameters and tradeoffs that drive this optical tether design are data rate, cost, UUV capacity, distance, deployment cost, and repair frequency [3, 11, 12].

Figure 2.2 FIBER OPTIC BLOCK DIAGRAM

2.2.1.1 Transmitter/Receiver (Tx/Rx) Pair

To accommodate the requirement for long data link, a distributed feedback laser (DFB) was selected. Its small FWHM added a margin of safety against dispersion problems that were not necessarily of concern because of the low data rates used. Overall the Tx/Rx pairs were over specified to compensate for uncertainty in attenuation fluctuations due to fiber payout. The DFB lasers chosen are readily available commercial parts and were purchased as a pair for each wavelength used, 1300 nm and 1550 nm.

The Tx/Rx components provide a full function, high-speed fiber optic link. Both operate at NRZ rates of up to 500 Mbytes/sec. Our application was 16 Mbytes/sec and the components were tuned for that frequency. Data I/O for each is ECL 10K compatible. The Tx module incorporates circuitry for monitoring and controlling the optical power and temperature. The optical receiver employs a temperature compensated Ge-APD (Avalanche Photo Diode) which provides the high sensitivity required. Additionally, the Rx incorporates automatic gain control (AGC) which enables operation over a wide range of optical loss budgets.

2.2.1.2 Wavelength Division Multiplexers

To operate the bidirectional link simultaneously, a different light wavelength is transmitted in each direction along the fiber. A wavelength division multiplexer (WDM) injects, extracts, and isolates outgoing and incoming wavelengths over a

single fiber. Additionally it isolates the light signals between the local transmitter and receiver. Features of the WDMs include:

- bidirectional transmission with greater than 80 dB directivity
- wide spectral channels for use with Fabry Perot or DFB lasers without tight wavelength selection or control
- less than -40 dB back reflection.

2.2.1.3 Payout Fiber

In the past, remote underwater systems have had a communication bottleneck. Acoustic communication transmitted through the water eliminates fiber problems, but is severely limited by bandwidth and real time data availability. An expendable FO link based on a small diameter cable offers the best trade-off for this application [6]. An optimally designed cable incorporates single mode fiber with minimal diameter growth over wire. Fiber is relatively inexpensive, reliable, has high bandwidth and can support bidirectional communication over great distances [13, 14]. Features of the payout fiber used include:

- inexpensive in production quantity
- low attenuation: < 0.5 dB/km @ 1300 nm and 1550 nm wavelengths
- high tensile strength: 100 lbs ultimate; 30 lbs working
- anti-abrasion jacket

- continuous length up to 20 km
- small bend radius and excellent optical performance at 1550 nm because of dispersion shifted properties
- tolerance to temperature and pressure fluctuations

2.2.2 Underwater Vehicle Subsystem

Figure 2.3 shows the UUV system layout and configuration. The forward section of the UUV generally consists of the system specific hardware of a particular project, while the aft section of the UUV contains the mechanics that comprise the UUV. The first section is the acoustic array with a small ballast section, followed immediately by the electronics section.

Within the electronics section are battery packs to power acoustic transmits, acoustic array electronics, and the interface unit. In the upper forward compartment, the interface unit resides, this is made up of a VME chassis containing six circuit boards, three commercial, and three custom designs. One card contains all of the optical components for communication. This is also the unit that is responsible for the data handling and routing and is discussed in detail in chapter 3. In general, the batteries provide energy for approximately thirty minutes of testing; however, in the laboratory, bench power supplies can be substituted for continuous testing and troubleshooting.

The propulsion batteries and the fiber optic (FO) cable section are located behind the electronics section. The battery section is composed of a large bank of

Figure 2.3 UUV CONFIGURATION

silver-cell batteries that are required for propulsion and maneuverability of the UUV. The FO cable section houses a pressure vessel that holds the spool of FO cable. This vessel is flooded while the UUV is submersed. This optical link design connects the fixed end of the FO cable to a pressure penetrator leading to the optics on the dry side of the UUV and allows the other end to freely payout from the pressure vessel through the remaining sections of the UUV exiting from the top stabilizer fin at the aft most section.

Next is the control section that contains the autopilot, motion sensors, and electronics for UUV control. Two electrical links exist between the autopilot and the interface unit and from the autopilot to the transmitter battery box. These links provide system independence and are the only two electrical connections between the UUV test bed and unique system electronics and are dedicated to test initiation and safety. Finally, aft of the control section is the UUV afterbody which consists of the motor and propulsion mechanics.

2.2.3 Launch Platform Subsystem

The remote subsystem residing on the platform has two configurations. The configuration in use today encompasses the functionality of the original; however, because the original configuration was used for such extensive data collection, it will be discussed briefly. The original subsystem was used for remote control of the UUV in the initial field tests. A block diagram of this entire system is shown in figure 2.4.

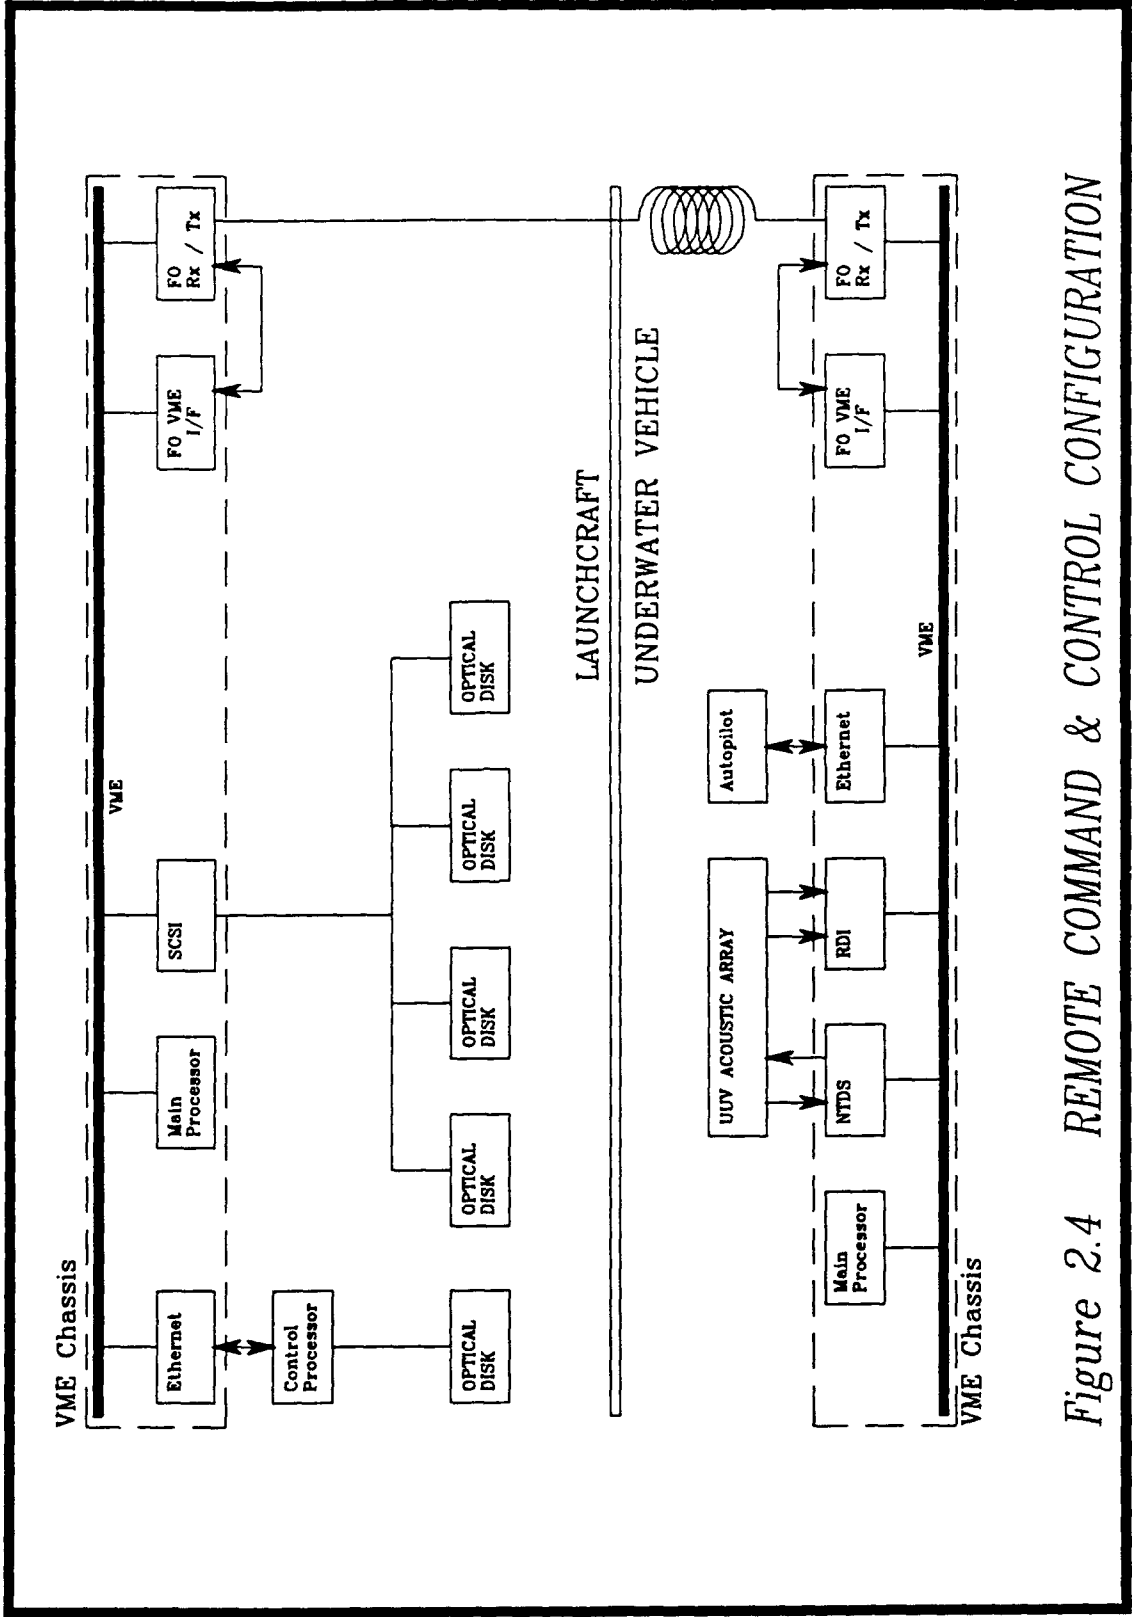

Figure 2.4 REMOTE COMMAND & CONTROL CONFIGURATION

The original subsystem on the launch craft contained two ruggedized units. One unit contained the μ VAX, which is the control computer, and two optical disk recorders, one used for startup and recording of control data, and another used to store raw data. The second unit, a VME chassis, contained an interface unit and three additional raw data optical disk recorders. The launch platform interface unit contained the optical transmitter and receiver complementary to those within the UUV and is connected to the other end of the FO link. A monitor is also included for viewing the vehicle parameters such as position and speed.

Figure 2.5, in a similar manner, portrays a remote processing system that was tested in late 1992 and early 1993. The new remote processing setup replaces both ruggedized chassis with one ruggedized VME chassis containing a μ VAX on a VME card, and a personal computer as an interface for human intervention. Although the system is now configured to accommodate real time remote processing of data, simple tests requiring only remote control of the UUV and no intervention can still be performed. In either subsystem, remote control or remote processing, the UUV configuration remains unchanged.

2.2.4 Interface Unit

The functionality of a tethered system lies within the interface unit (IU). The IU, in its different configurations, controls the interfacing of several hardware components within the system. These components are the acoustic array and the autopilot in the UUV and the tactical computer and the optical drive located on the

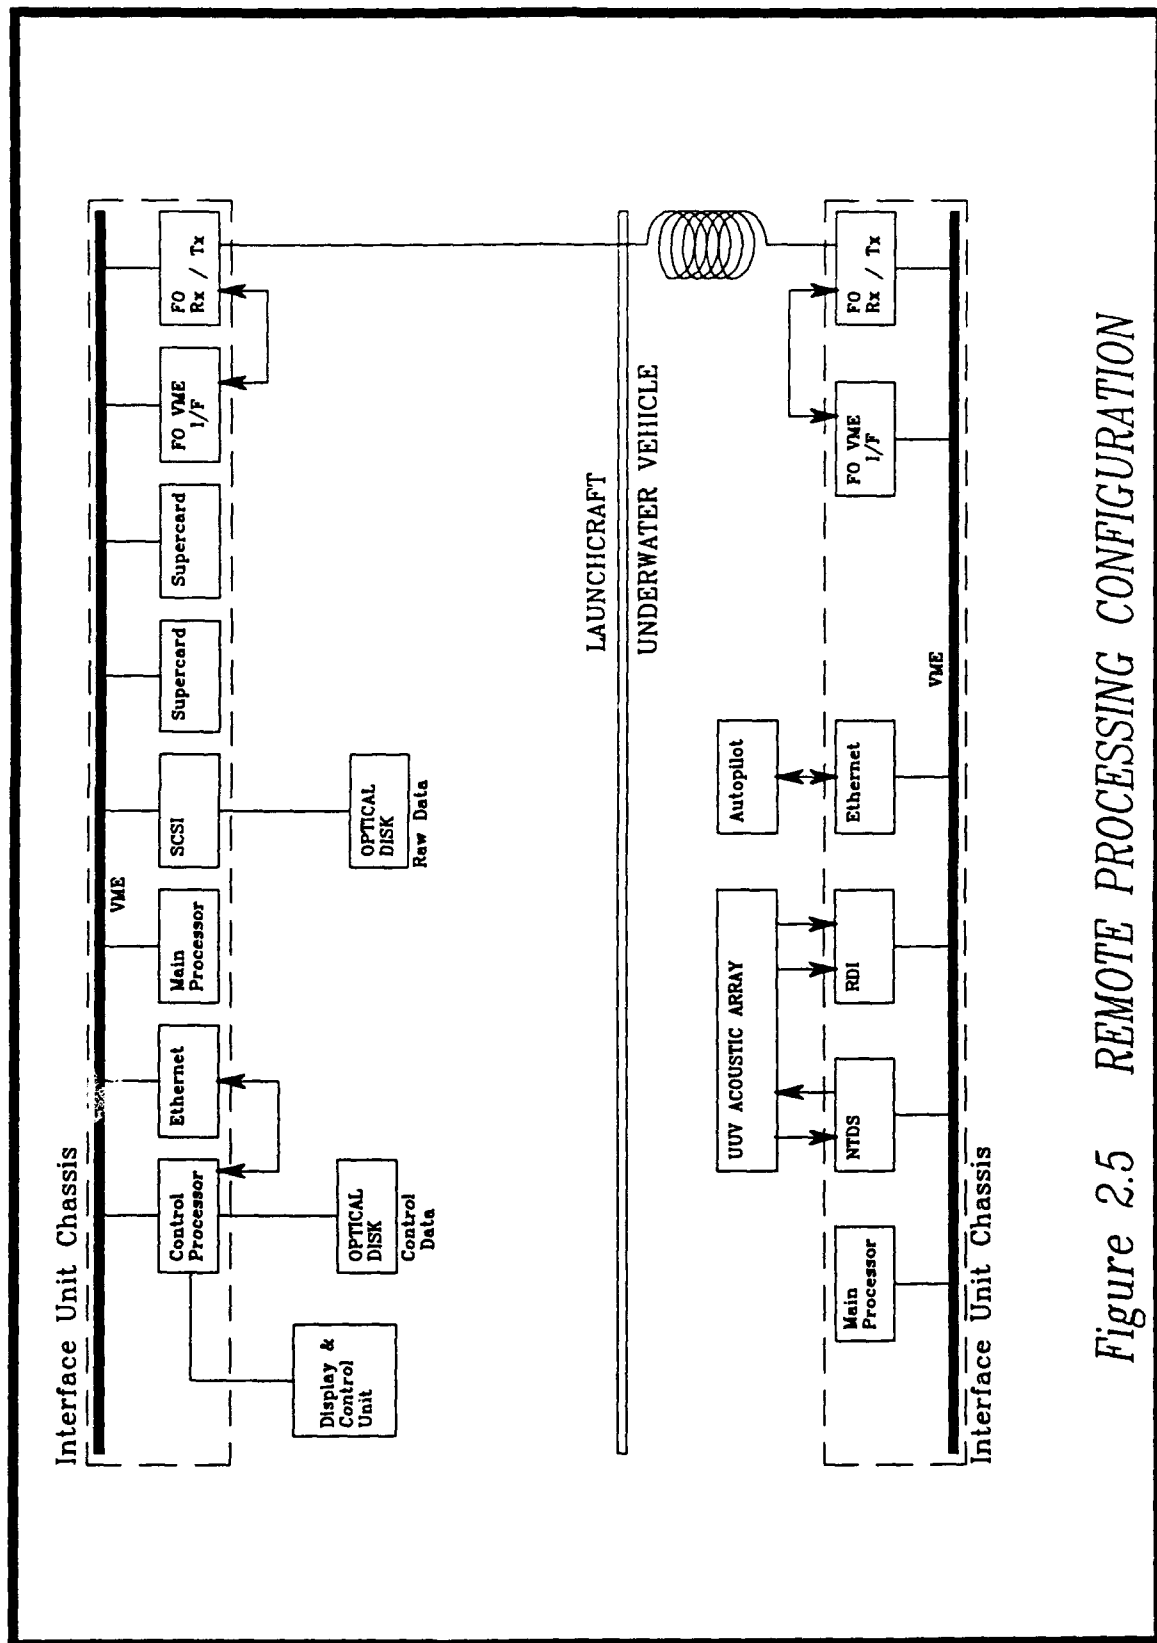

Figure 2.5 REMOTE PROCESSING CONFIGURATION

launch craft. In addition to its interfacing responsibilities, the IU maintains the fiber optic communication link between the launch platform and the UUV IU. The system on the launch platform also contains two vector processing boards that handle the signal processing tasks.

The following sections introduce the boards and the interface unit configurations. For this thesis, the board of particular interest is the Fiber Optic VME Interface (FO VME I/F). This board is responsible for bridging the VME based systems on either side of the optical link. The design of the FO VME I/F will be discussed in detail in chapter 3.

2.2.4.1 Interface Unit Board Definitions

Each board within the IU has a specific function and was designed or purchased to meet those unique requirements. Table 2.2 lists the boards and some of their technical highlights.

TABLE 2.2
INTERFACE UNIT BOARD HIGHLIGHTS

Board Name	Model #/Manufacturer	Highlights
VME Controller/Main Processor	PME68-33/Radstone	25 MHz 68030 CPU VSB Interface 40 MBytes/sec Data Transfers

CHAPTER 3

DESIGN OF THE FIBER-OPTIC VME INTERFACE

The design of the Fiber-Optic VME interface (FO-VME I/F) splits one VME backplane into two distinct backplanes. The two backplanes are often located many kilometers apart, but can communicate through the FO-VME I/F and over the optical link to share real time information. This integral board in the system's interface unit is extremely crucial for the success of the fiber optic link. It allows the link to operate at a high data rate while keeping the data accessible on an industry standard VME backplane. Without the development of the FO-VME I/F board, interfacing to powerful commercial electronics necessary on either side of the link could have proved to be a more difficult task. A multitude of interfaces (ie. NTDS, Ethernet, and SCSI) are required to have access to the interface units located at the opposite ends of the link. The FO-VME I/F provides a common point for data transfers and does not require customized interfacing among separate modules. Figure 3.1 is a functional block diagram of the FO-VME I/F board and provides a reference to functions discussed throughout the chapter.

3.1 Design Goals and Objectives

The objectives stated in chapter 1 are system oriented goals and are meant to disclose where the FO-VME I/F fits into system success. When these objectives are

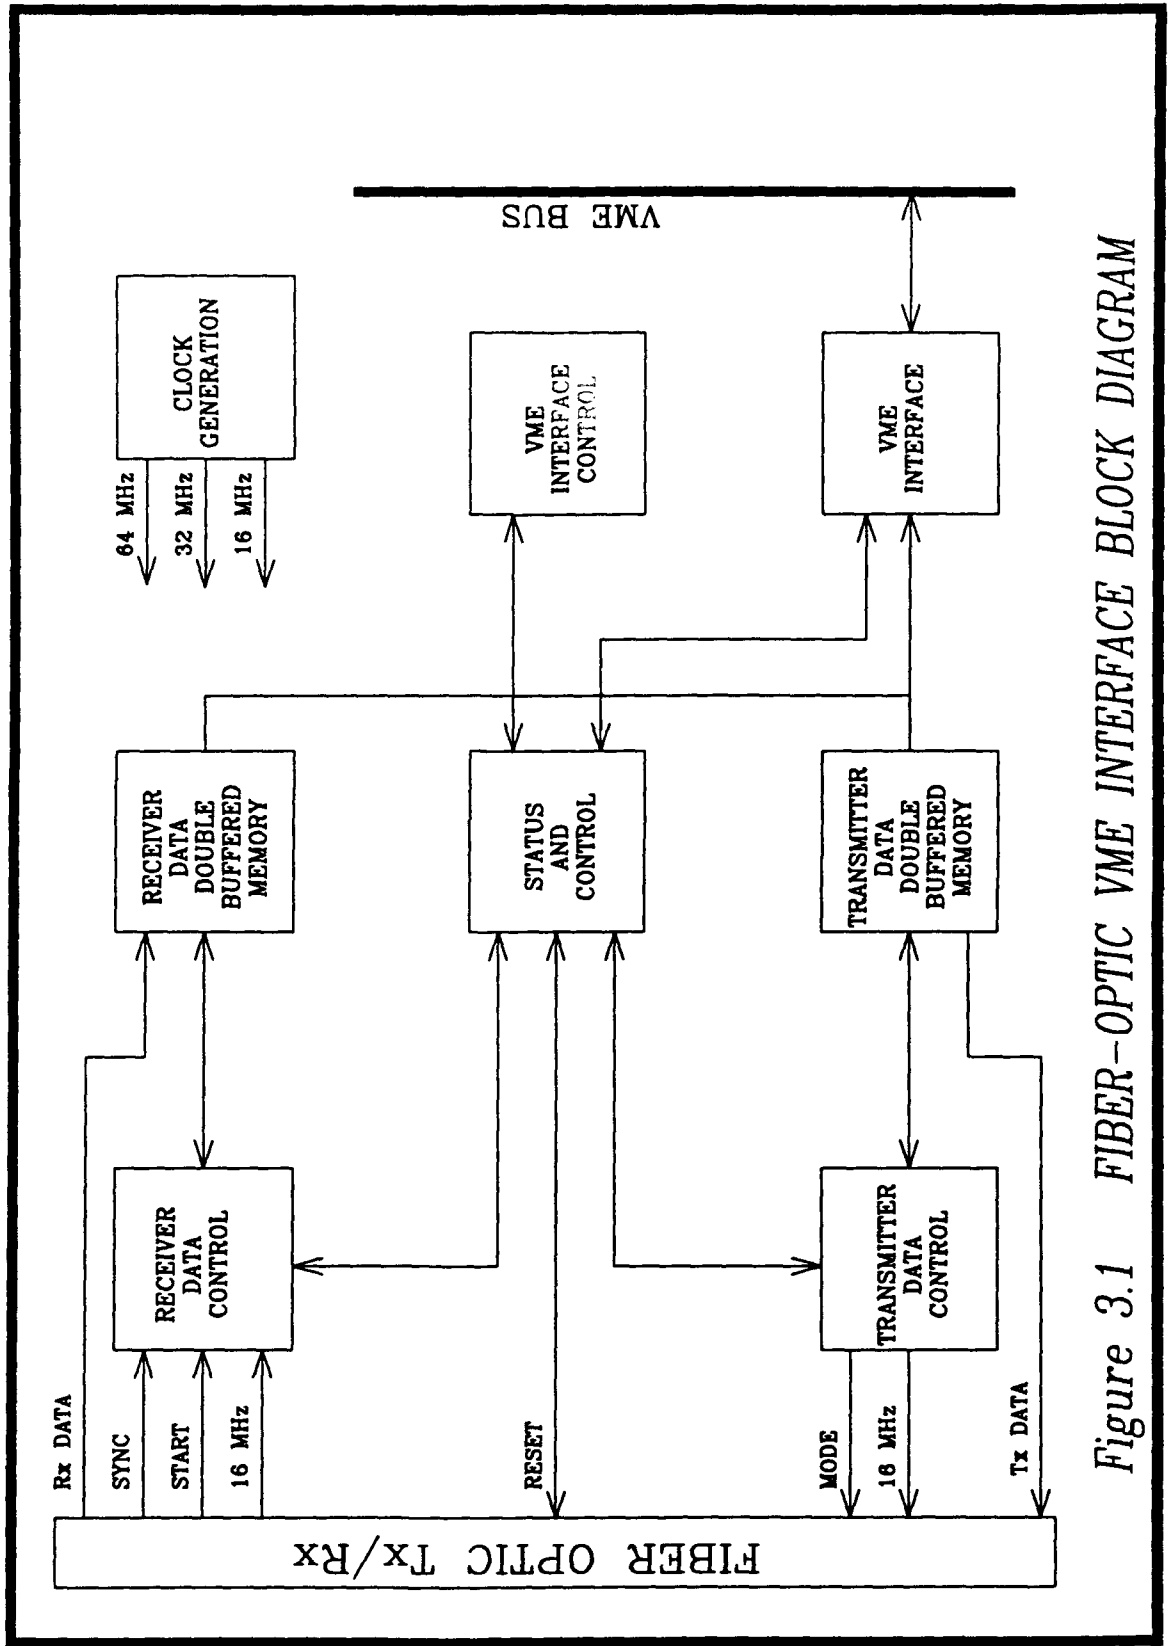

Figure 3.1 FIBER-OPTIC VME INTERFACE BLOCK DIAGRAM

translated into hardware design, they allow the designer to understand what steps are needed to accomplish system requirements within one part of the system.

3.1.1 Physical Constraints

The interface unit resides in two locations, the UUV and the launch platform, with the UUV being the more physically restricting of the two. Because of the UUV size constraint and the need for conformance at the two locations, the UUV restrictions drove the design on both sides. Even though the launch craft presented no space restrictions, it was designed with UUV requirements for several reasons: a) hardware could be swapped between UUV and launch platform interface units with no modifications, b) portions of the interface unit could be integrated into one unit before adding the communication link and, c) only one custom hardware version was needed to be built instead of specific versions for the UUV and launch platform.

The size constraint aboard the UUV posed another problem, lack of redundancy. Data transmitted within the UUV and especially up the link, was vulnerable to corruption. In addition, any complete failure of a component or board could terminate a successful test. The lack of redundancy in the system was compensated for in two different fashions. Designs were integrated into the FO-VME I/F board that included an overriding control by the user. This meant that a fatal error could be averted by resetting and reconfiguring the board. Also through the use of status registers, anomalies could be identified and recorded. In the case of a fatal error, an organized and safe system shutdown would occur.

The second attempt to compensate for no redundancy was by extensive testing for reliability. As will be shown in chapter 4, thorough testing of the boards and eventually the system, were performed to significantly decrease the chance of a system error during actual testing. This method of testing proved worthwhile by exposing problems early in the design.

3.1.2 Data Reliability

When data is transferred over the VME backplane, it is assumed that transfers will be made reliably. This is true for the VME backplane since it is a proven and tested standard that has succeeded in the electronics community. For the design of the FO-VME I/F board, this same data reliability was needed. Reliability should be expected when good electronic design practices are followed. Again, through the use of comprehensive tests, known data patterns can travel through the entire system, thus verifying system and FO-VME I/F reliability.

3.1.3 Testability

For board level and system testing, the FO-VME I/F is required to have a testable design. At the board level, this translates to well placed components and signal traces that are accessible for instrumentation during troubleshooting. Also, simple VME control was placed on the board that could put the board into different modes depending on the tests performed. Finally, the use of status registers allowed for monitoring during use and for the isolation of problem areas.

3.1.4 Compatibility

Because the function of the card is to bridge the VME bus to a fiber optic transmitter, both sides must be well defined. The board is designed to be compliant with VMEbus specification ANSI/IEE STD1014-1987 IEC 821 and 297. This specification is distributed by VITA, VMEbus International Trade Association. Compatibility with this specification makes the FO-VME I/F compatible with all other VME products using this specification.

The serial channel to the optics must also be compatible with the data rate, format, and electrical levels needed for the transmitter and receiver circuit. The design permits the use of newer optical components for future upgrades.

3.1.5 Data Availability and Integrity

The need for data in real time adds the need for data availability. The delay that could be added to transmitted data had to be minimized. Design of the FO-VME I/F board incorporates double buffering of transmitted and received data to permit continuous and uninterrupted use of the optical link. When data is made available, it is transmitted in a continuous bit stream with no data gaps. The double buffering permits the interface controller to transmit or receive data on one buffer while the opposite function is simultaneously occurring without the need of controller assistance. The VME controller determines data priority for real time communications with the interface unit on the other side of the link. This scheme grants complete data availability to the user.

Integrity also occurs because the VME controller is left out of the transmission except when needed. Data is accessed from the FO-VME I/F at a rate 12.5 times faster than the optical link. This means to sustain the link at maximum bandwidth, the controller only dedicates 8% of its time for service of the FO-VME I/F board.

3.2 The VME Bus

In 1981, the VME bus was made available to the electronics community. Its design was started years earlier and was meant to provide a solid 16/32 bit bus standard that would be monitored by an independent organization [15]. The initial players in the game were Motorola, Phillips/Signetics, and Mostek. Their efforts created one of the most commonplace bus structures used today.

3.2.1 Mechanical Benefits

As stated earlier, the placement of electronics inside the UUV imposed a size restriction on their design. The actual usable space varied as the system design progressed, but the goal of a compact electronics package remained strict. Other bus structures considered for their size and popularity were the STD Bus, IBM-PC Bus, and Multibus. However, some of the mechanical attributes of these alternate busses pose problems. The dimensions of both the IBM-PC Bus and Multibus are too large. The IBM-PC Bus, though smaller in area than the VME bus card, has a length that makes it awkward to fit it into the allotted area. Another problem involves the use of copper fingers for connection to the backplane as opposed to the pin and socket

connection used by VME. The copper finger arrangement does not make as good of a connection and degrades more quickly over time especially as the card is removed and replaced.

An advantage offered by all of the bus structures is mechanical modularity. Since each board is designed to a standard, it can be placed and used in any system utilizing that standard. This modularity extends from standard board dimensions to connector pinouts. Table 3.1 [15] shows a comparison of the bus structures considered for this subsystem along with other popular choices.

3.2.2 Electronic Benefits

Besides its excellent mechanical attributes, VME is also an excellent electronic choice. This long standing and well supported bus structure offers a high data speed backplane. The backplane functions at a variety of data widths (8, 16, 24, and 32 bits) and address widths (16, 24, and 32 bits). When operating at the full data bus width of 32 bits, a theoretical transfer speed of 40 MBytes/second is possible [16]. Most applications will fall short of this limit, but can still easily achieve speeds in excess of 30 MBytes/sec. Table 3.2 [15] lists features of the VMEbus standard.

In order to achieve such data rates, the backplane must be electrically sound. Years of refinement have developed a backplane that is both immune to modest external noise levels as well physically designed to prevent excessive crosstalk between traces when functioning at high speeds.

Table 3.1 FEATURES OF SYSTEM BUSSES

Bus	Sync(S) or Async (A)	Multiplexed	Data bus width (bits)	Address width (bits)	Interrupts (levels)	Multiprocessing	Card size (mm)	Connector style	Governing body

Table 3.2 VMEBUS FEATURES

Item	Specification	Notes
Architecture	Master/slave	
Transfer mechanism	Asynchronous, non-multiplexed, opt. multiplexed (†)	No central synchronization clock
Addressing range	16-bit (short I/O) 24-bit (standard) 32-bit (extended) 64-bit (long) (†)	Address range selected dynamically
Data path width	8, 16, 24 or 32-bit 64-bit (†)	Data path width selected dynamically
Unaligned data transfers	Yes	Compatible with most popular microprocessors
Error detection	Yes	Using BERR* (optional)
Data transfer rate	0 - 40 Mbyte/sec 0 - 80 Mbyte/sec (†)	
Interrupts	7 levels	Priority interrupt system with STATUS/ID
Multiprocessing capability	1 - 21 processors	Flexible bus arbitration
System diagnostic capability	Yes	Using SYSFAIL* (optional)
Mechanical standard	Single height Double height	160 X 100 mm eurocard 160 X 233 mm eurocard DIN 603-2 connectors
International standards	Yes	IEC 821, IEEE 1101 IEEE 1014

(†) Denotes proposed VMEbus enhancement.

Finally there is the issue of independence among VME modules in a common backplane. The bus functions only when information is transferred among modules and will not inhibit their independent functions. A VME module can process data or interface to an external device at any speed without using the backplane. A functional block diagram of the VMEbus architecture is shown in figure 3.2 [15].

3.3 Design

After it was determined where the FO-VME I/F board would fit in the system layout, some design issues were resolved. A list of electronic requirements was made to guide the design. These requirements had to provide:

- slave compatibility with the VME interface specification
- 32 bit wide data block transfers over the backplane
- a serial transmit stream to optical transmitter in a Manchester encoded format
- reception of a serial data stream from the optical receiver
- double buffering for transmitted and received data so that both could function independently and simultaneously
- flexibility in board addressing and interrupt levels
- status registers that could be monitored to ensure proper board functioning
- a writable register for dynamic board control

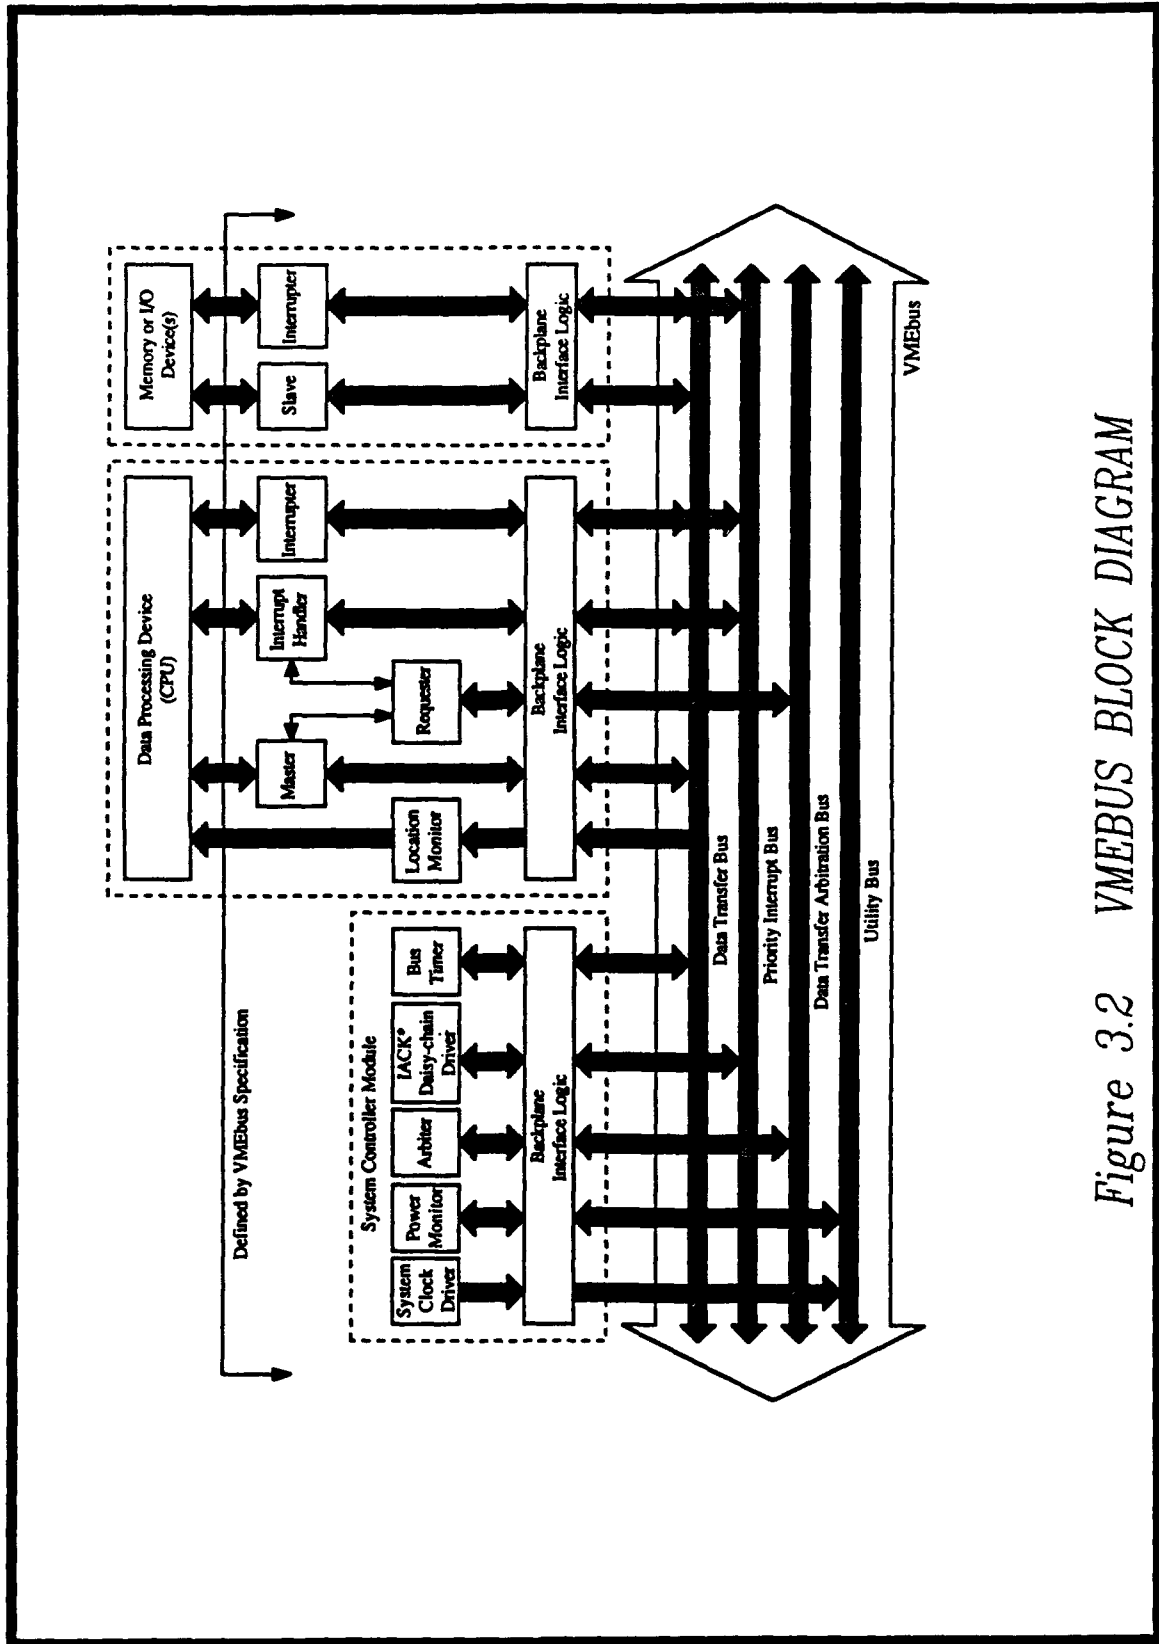

Figure 3.2 VMEBUS BLOCK DIAGRAM

3.3.1 VME Interface

The FO-VME I/F interface to the VME consists of the Cypress VIC068 chip and its transceivers [17]. The VIC068 is a complete VME interface that adheres to the VME specification revision C.1. The VME interface is simplified with the use of this chip, but because of the VIC068 complexity, there is a learning curve before its use will pay off. The VIC068 is a programmable interface and must be initialized upon power up for proper operation for its specific application. One of the most difficult aspects of using the VIC068 is that it needs a 64 MHz clock to achieve its full potential. Although a clock speed of this frequency can often cause crosstalk problems, this high frequency was handled delicately during PCB layout and no problems were identified.

The final design that centered around the VIC068 achieved data rates of 25 MBytes/second across the backplane when performing block transfers. This data rate is more than adequate for servicing the optical link and does not provide a significant burden on the main controller in the backplane. In other words, it allows the link to operate continuously at 16 MBits/second while not requiring a large percentage of the VME controller's time for maintenance

3.3.2 Data Formats

3.3.2.1 Link Data Format

The serial data transmitted on the link is encoded into a Manchester format. A Manchester format for serial data involves the mixing of the data and the clock at the

source so that both can be recovered at the receiver. Figure 3.3 displays how binary data is encoded to form Manchester data. As shown in the figure, the Manchester data contains a transition in the middle of every data cell that is extracted to form a clock when the data is decoded. Also, consecutive 1's or 0's show up as a clock thus providing constant transitions and an indication that the link is active. One benefit of this form of encoding is that the clock can be recovered and used for the clocking of the data through the rest of the design. Because the link is a connection between two independent subsystems, it can not be guaranteed that they are using precisely the same clocking frequency or that the clocks are in phase. Once received data is recovered and stored, it can be reclocked out at the local subsystem's clock rate.

Another benefit for Manchester encoding is the transmitted data is continuously transitioning. Each data cell contains a data transition which makes it simple to determine whether or not the link is active by the appearance of data transitions even when communications are idle.

A disadvantage to Manchester encoding is that the entire link bandwidth is needed for this transmission. As figure 3.3. shows, the actual data needed to be transmitted is half the frequency of the Manchester encoded data. In other schemes such as NRZ (non return to zero), the data does not contain clock data and thus runs at half the bandwidth. NRZ encoding can double the available bandwidth of the serial link. However, NRZ is difficult to synchronize because of its non-periodic transitions.

Figure 3.3 MANCHESTER DATA FORMAT

The actual serial data format is shown in figure 3.4. Each packet takes 16.384 ms for transmission, where 4 us are required for link synchronization. Serial packets can occur non-stop and can utilize 100% of the link bandwidth. Data packets can also be transmitted at a much slower pace from transmit buffer to receive buffer, but the link always operates at 16 MHz.

3.3.2.2 Buffer Packet Format

Each individual transmit and receive buffer on the FO-VME I/F board is 32 kbytes in size, organized 8k x 32 bits. Selection was made on the 32 bit data width for ease in interfacing to the VME data path without the need for additional demultiplexing. Also, the size of the memory integrated circuit, an 88 pin slim DIP package, occupies very little board space. The buffer size is known as the principal data packet and contains the formatted data for every transmission on the link. Figure 3.5 shows the breakdown of the contents of a principal data block. Its division allocates specific portions for raw acoustic data and control data (primarily ethernet data). Also a preamble is used that contains a user defined 64 bit sync word that, when decoded, indicates the start of a principal block.

Although the same format is used for either direction on the link, not all the allotted areas will always be used. For example, there is no raw acoustic data that is passed from the launch platform to the UUV; that portion of the principal block can be ignored even though it is still transmitted. It is also not required to be read by the controller when received in the receive buffer.

Figure 3.4 LINK DATA FORMAT

3.3.3 FO-VME I/F Memory Map

All modules present in a VME backplane are configured to occupy a specific address range. In a VME system, there are multiple address ranges, each representing the number of address bits and data bits being used [16]. For example, A32/D32 in a VME system means that a board will respond with 32 bit data to data requests that require 32 address bits. Figure 3.6 is a memory map of the FO-VME I/F board. It shows the selectable A16/D8 and A32/D32 address space on this board and what is contained in these ranges if they are accessed. It is important that the address ranges are selectable because different VME controllers cannot always access any VME location at a given VME address and data width. For example, a controller may only perform A32/D32 transfers in the lower half of VME space, therefore a board would need to be set for an acceptable address in that range.

3.3.4 Optical Tx/Rx Interface

One function of the FO-VME I/F board is to interface with the optical transmitter and receiver. As stated earlier, the serial data interface is Manchester encoded before transmission on the fiber, and it is the function of the FO-VME I/F to provide the encoding and decoding.

The task is accomplished easily since a high clock frequency of 64 MHz resides on the board. The encoding is simply the 'exclusive NOR' of a 16 MHz clock and the data, re-clocked at 32 MHz for stability. Decoding is simpler yet with the use of a commercial Manchester decoder.

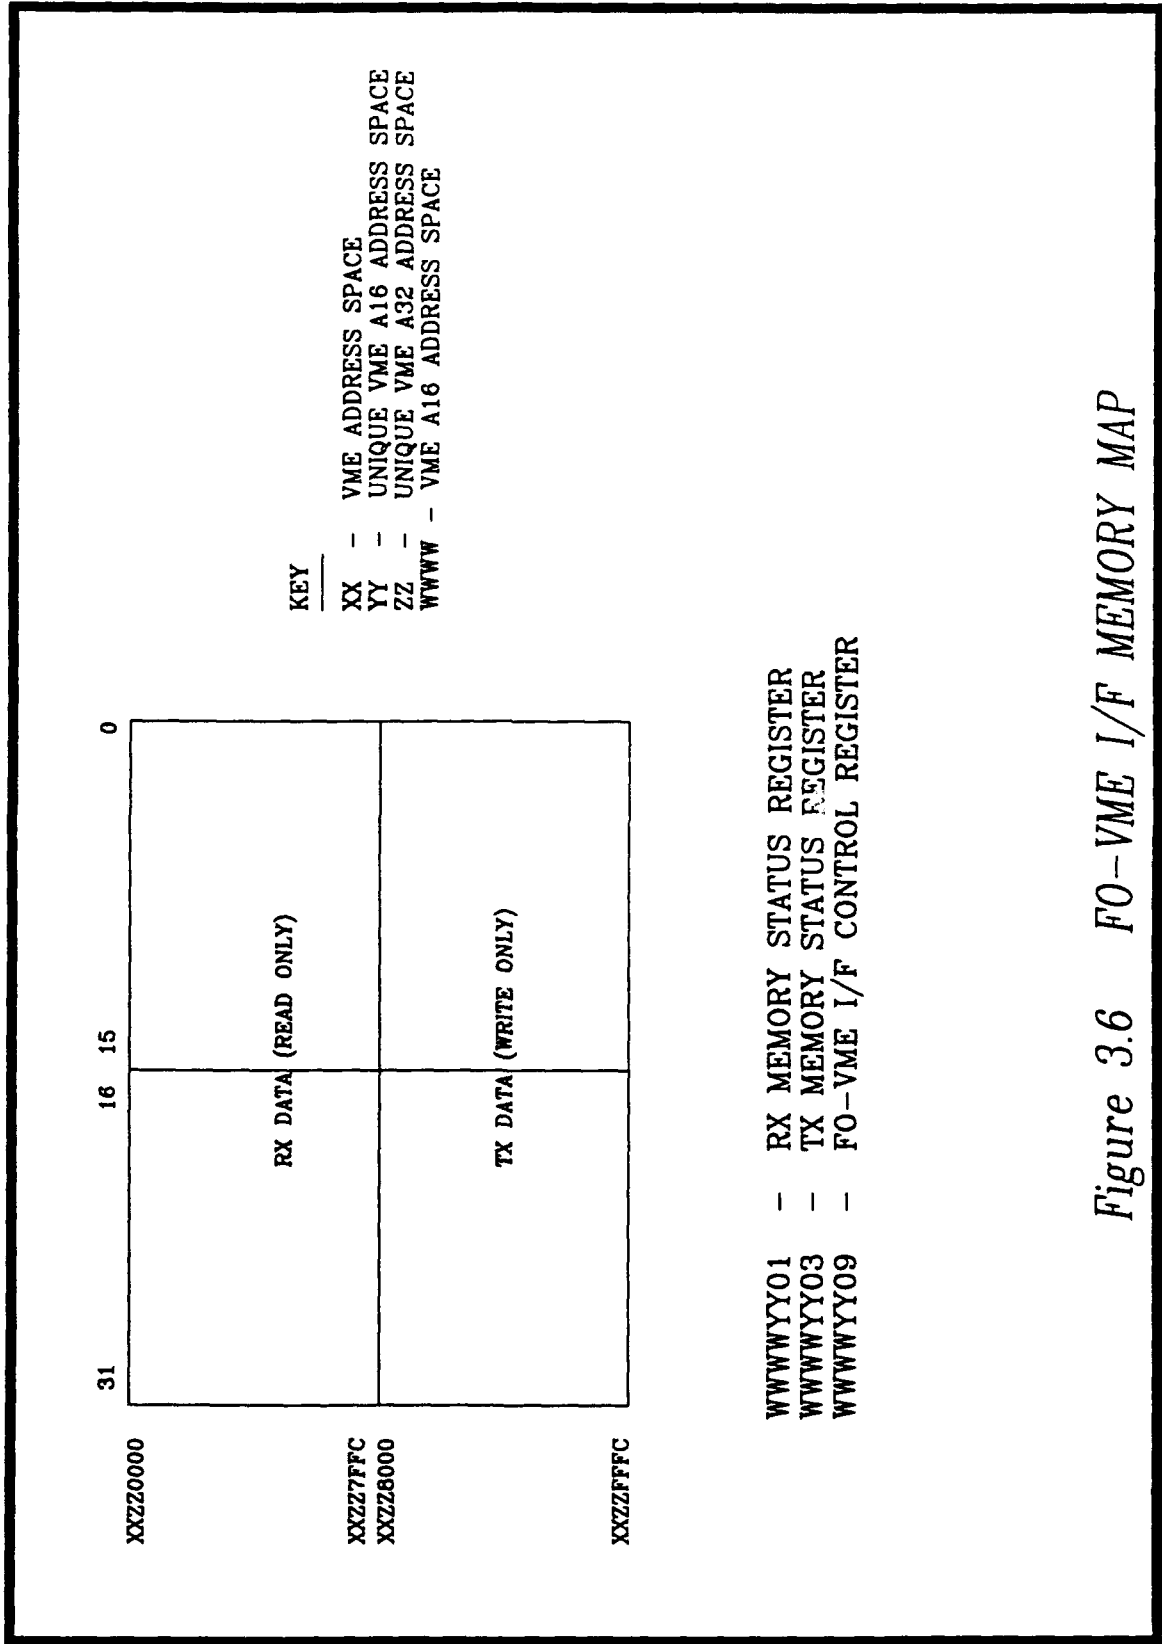

Figure 3.6 FO-VME I/F MEMORY MAP

Data on the FO-VME I/F is handled as 32 bit words and translated to serial for interfacing with the optics. Figure 3.7 steps through the serial data to buffer storage routine. Manchester encoded data is decoded and translated to 16 bit words. In this form it is stored in 32 bit wide locations in memory. When a new sync is decoded, the present buffer is no longer written and is marked as full.

3.3.5 Dual Double Buffer Memories

Each buffer on the FO-VME I/F board is a 8k x 32 bit RAM. Separate I/O is provided for independent input and output connections. The same address lines are used for both the read write functions, thus simultaneous reads and write are not possible. The board has two banks of memory, transmit and receive and each is operated independently from the other; data can be received by the board while the VME controller is transmitting data. Each bank is comprised of two memories and they are in the same location in VME address space. When the controller completes the writing of a transmit buffer, it can continue to write the next block in the same address space. It appears to the controller as if it is writing over the previous data, but in fact it is writing the next transmit buffer while the first one is being transferred to the optics for transmission over the fiber. Overall, the toggling of memories is transparent to the user. A similar scenario happens on the receive side where the VME controller can be reading received data while the second receive buffer is reading data from the optical receiver. This function of toggling memories makes the card simple to use and easy to integrate into a system program.

Figures 3.8a & b represent the logical flow of the double buffered memories. This particular flowchart follows the transmission of data from the VME backplane to the optical transmitter. The logic is identical for received data coming from the optical receiver and being read across the VME backplane. At the start of a transmit, the status register reveals that TxA is empty and can be written. Initially no data is in either Rx buffer so no data can be read to the optical transmitter. The VME controller begins writing to TxA until it is full. Then a status read will reveal a readable buffer that will immediately be transmitted without further intervention by the VME controller. It will also show that TxB can be written for the next transmission while TxA is currently being transmitted. At this point in the flowchart, the reading and writing of buffers becomes independent. If there is an empty buffer, it can be written with data to be transmitted; likewise any full buffer will be immediately transmitted. If at any time both transmit buffers are full, they will be transmitted one after another with no time delay between buffers and no data can be written from the VME controller to a Tx buffer until at least one Tx buffer is empty.

This controller independent toggling of buffers allows for maximum link bandwidth utilization while requiring minimal VME controller service. The data flow for received data can use this same flowchart with the exception that data is being written from the optical receiver and read by the VME controller. The transmit and receive buffers are also independent of each other allowing for simultaneous operation of each buffer pair.

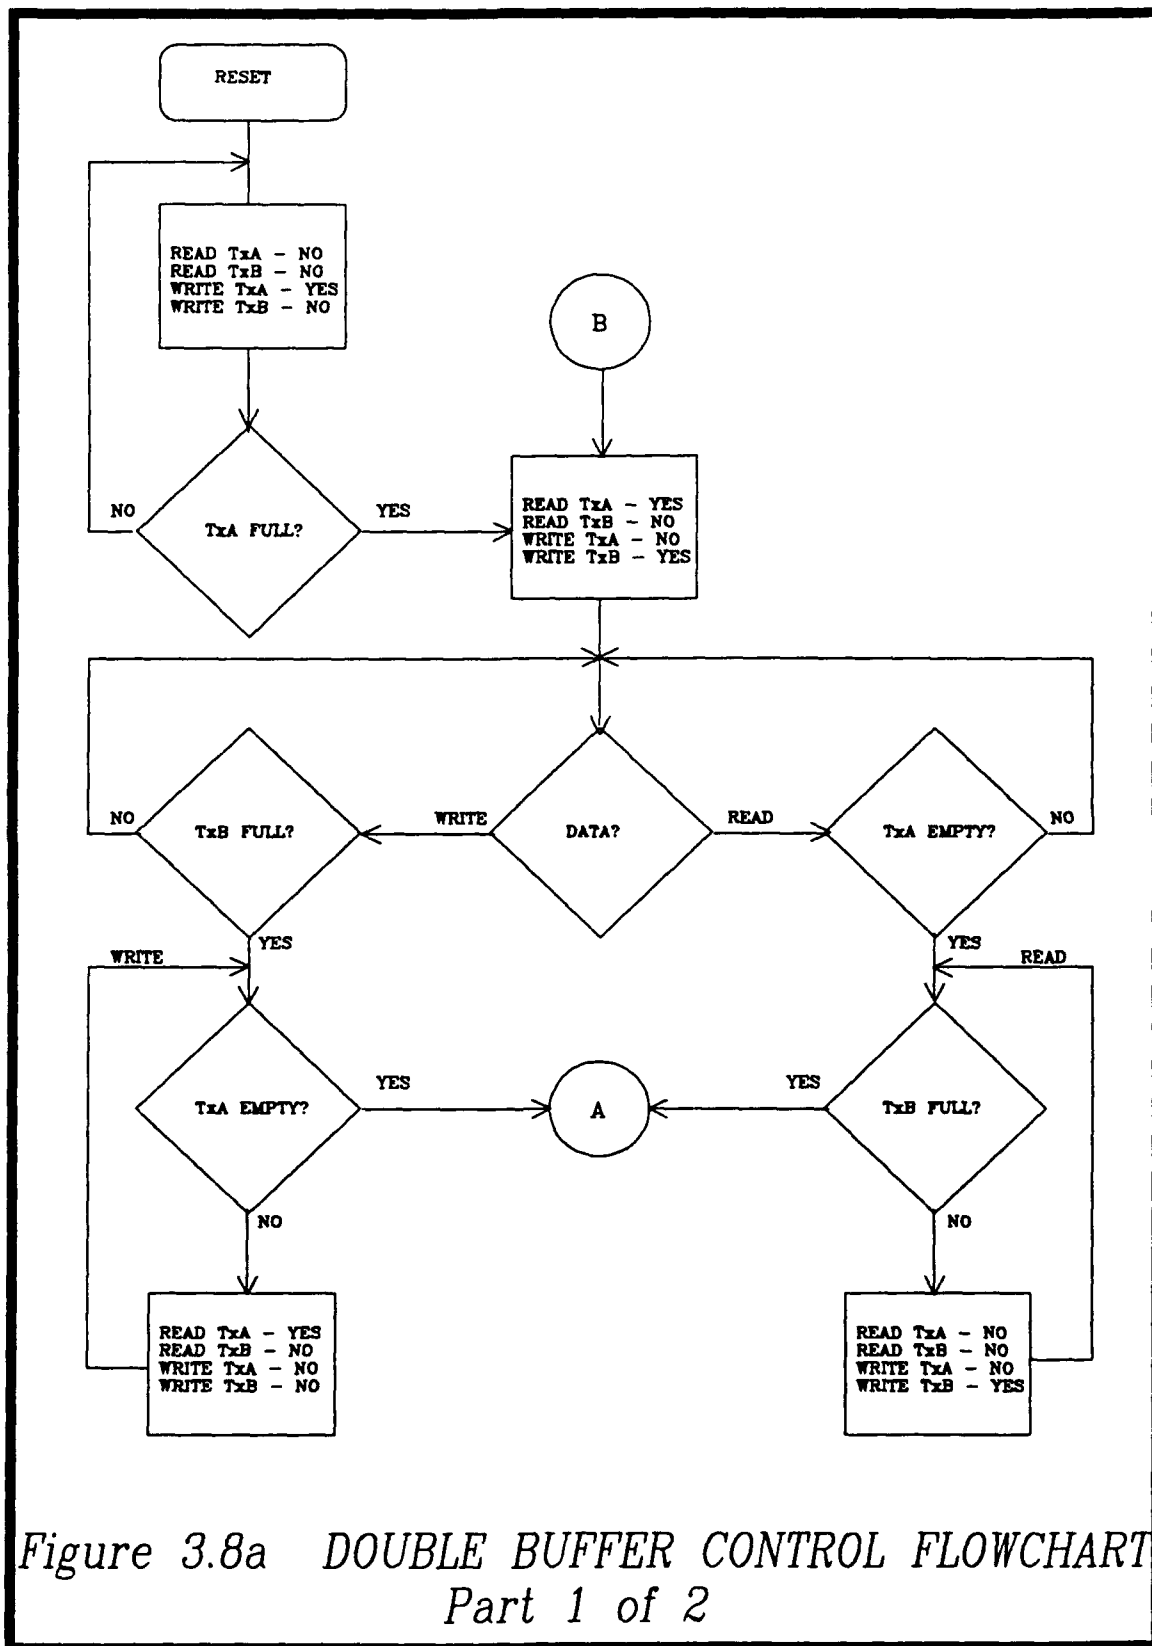

Figure 3.8a DOUBLE BUFFER CONTROL FLOWCHART
Part 1 of 2

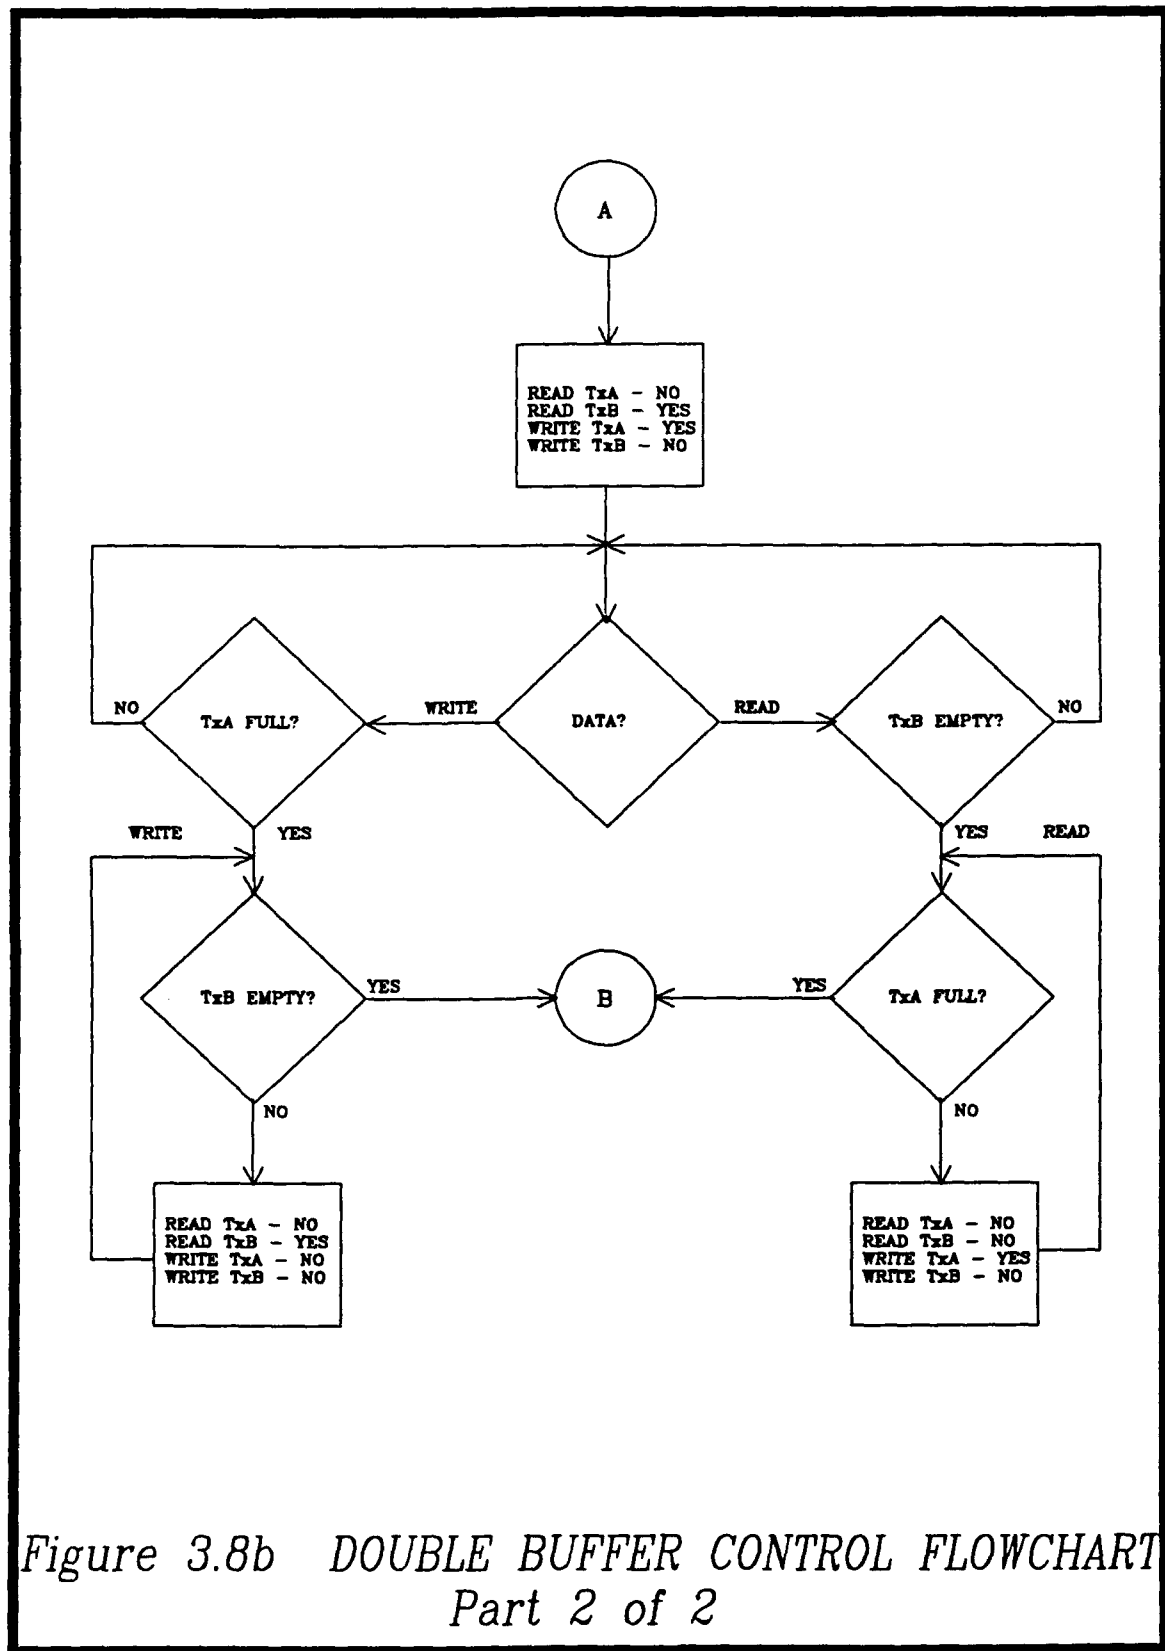

Figure 3.8b DOUBLE BUFFER CONTROL FLOWCHART
Part 2 of 2

3.3.6 Time Delay of Fiber Optic Interface

For transparent link operation, the system user should not be able to discern the delay added to the data packets due to traversing the link. Ideally, in a non-link supported system, data would be transferred directly among modules and not travel any unnecessary paths. For this system; however, the data needs to be formed into packets, transmitted to the opposite end of the link, and the disassembled before reaching its destination.

For some paths, the extra delay is of no consequence. For example, data that is transmitted up the link for recording will not be affected by additional delay; the only concern is to handle the data in real time so that it is recorded as fast as it is created. Some data paths; however, depend heavily on available data. The most restricting requirement comes from raw acoustic data that is processed to form new UUV commands. In this scenario, raw acoustic data from the UUV needs to be processed in powerful array processors located on the launch platform. Decisions from this processing are formulated and then transmitted back down the link for control of the UUV. The hardware allows for real time transmission of all the data, but adds a handling delay that can be determined.

This delay is easily calculated as a sum of the hardware delays of the FO-VME I/F and fiber.

$$\text{Total Delay} = t_{\text{WRITE BUFFER}} + t_{\text{XMIT BUFFER}} + t_{\text{FIBER DELAY}} + t_{\text{READ BUFFER}} \quad (3.1)$$

where:

$t_{\text{WRITE BUFFER}}$ = time required by the VME controller to write to a transmit buffer

$t_{\text{XMIT BUFFER}}$ = time required to read a transmit buffer serially to the link

$t_{\text{FIBER DELAY}}$ = optical delay added by fiber

$t_{\text{READ BUFFER}}$ = time required by the VME controller to read a receive buffer

Using the following characteristics of the FO-VME I/F and fiber:

VME read and write speed = 25 MBytes/second

Buffer size = 32 kBytes

Link Speed = 16 MBits/second

Fiber Length = 20 km

Refractive Index (n) = 1.476

The solution to equation 3.1 is the following.

$$19.09 \text{ ms} = 1.31 \text{ ms} + 16.384 \text{ ms} + 98.3 \text{ us} + 1.31 \text{ ms}$$

The time delays created from the buffer operations are easily calculated by dividing buffer size by speed to obtain time. Finally, the delay added by the fiber is approximately equal to the length of the fiber (l) divided by the speed of light (c)

multiplied by the refractive index (n) as shown in equation 3.2. This result is expressed in seconds.

$$t_{\text{FIBER DELAY}} = (l * n)/c \quad (\text{secs}) \quad (3.2)$$

This total delay of 19.09 ms is for a one way transmission across the link. For the example stated above for UUV control, the total delay would be a minimum of 38.18 ms from the time raw acoustic data resides in the UUV VME controller to the time a decision based on this data resides in the same VME controller in the UUV. For this application, this calculated delay was negligible.

3.3.7 Status and Control

The FO-VME I/F board contains three registers: two status and one control. Their function is to provide the VME controller with information about the board during use. The status registers contain information on memories such as full or empty, and which of the dual buffers is ready or in progress for reading and writing. Information of this kind can be used by the VME controller to determine if a transmit can occur, and in the case of an error, determine which memory is failing and reset its conditions in an attempt to continue its use.

In addition to the status registers designed and added to the board, the VIC068 contains over fifty registers that are shared between the FO-VME I/F board and the VME controller. These additional registers contain VME related information and are

used for configuration of the board so it can be used in a specific VME system. The sharing of these registers allows the circuitry on the FO-VME I/F board to exchange information related to VME activity without the need for additional custom designed hardware on the FO-VME I/F board.

Finally, there is one write-only control register unique to FO-VME I/F board. This register permits the VME controller to have limited control over some of the board's functions. For example, the control register can put the board into a reset mode that clears and resets the dual buffers or it can prohibit data from leaving or entering the board. The addition of this control register aids in a board recovery in the event of a critical error.

3.3.8 Operation Modes of the FO-VME I/F

Independent of VME activity, the FO-VME I/F board has three modes internal to its design that are always functioning. These three modes are a) status and control update, b) interrupt generation, and c) VME accesses. The interdependence of the mode operations is displayed in a flowchart in figure 3.9.

The first mode updates the status and control registers unique to the FO-VME I/F board. The VIC chip provides a programmable local timer that can function as a tick timer to initiate local activity. On this board the timer is set at 1000 Hz and is used to interrupt the board so that the status and control registers can be updated. As shown in figure 3.9, this mode has the highest board priority. While the board cycles

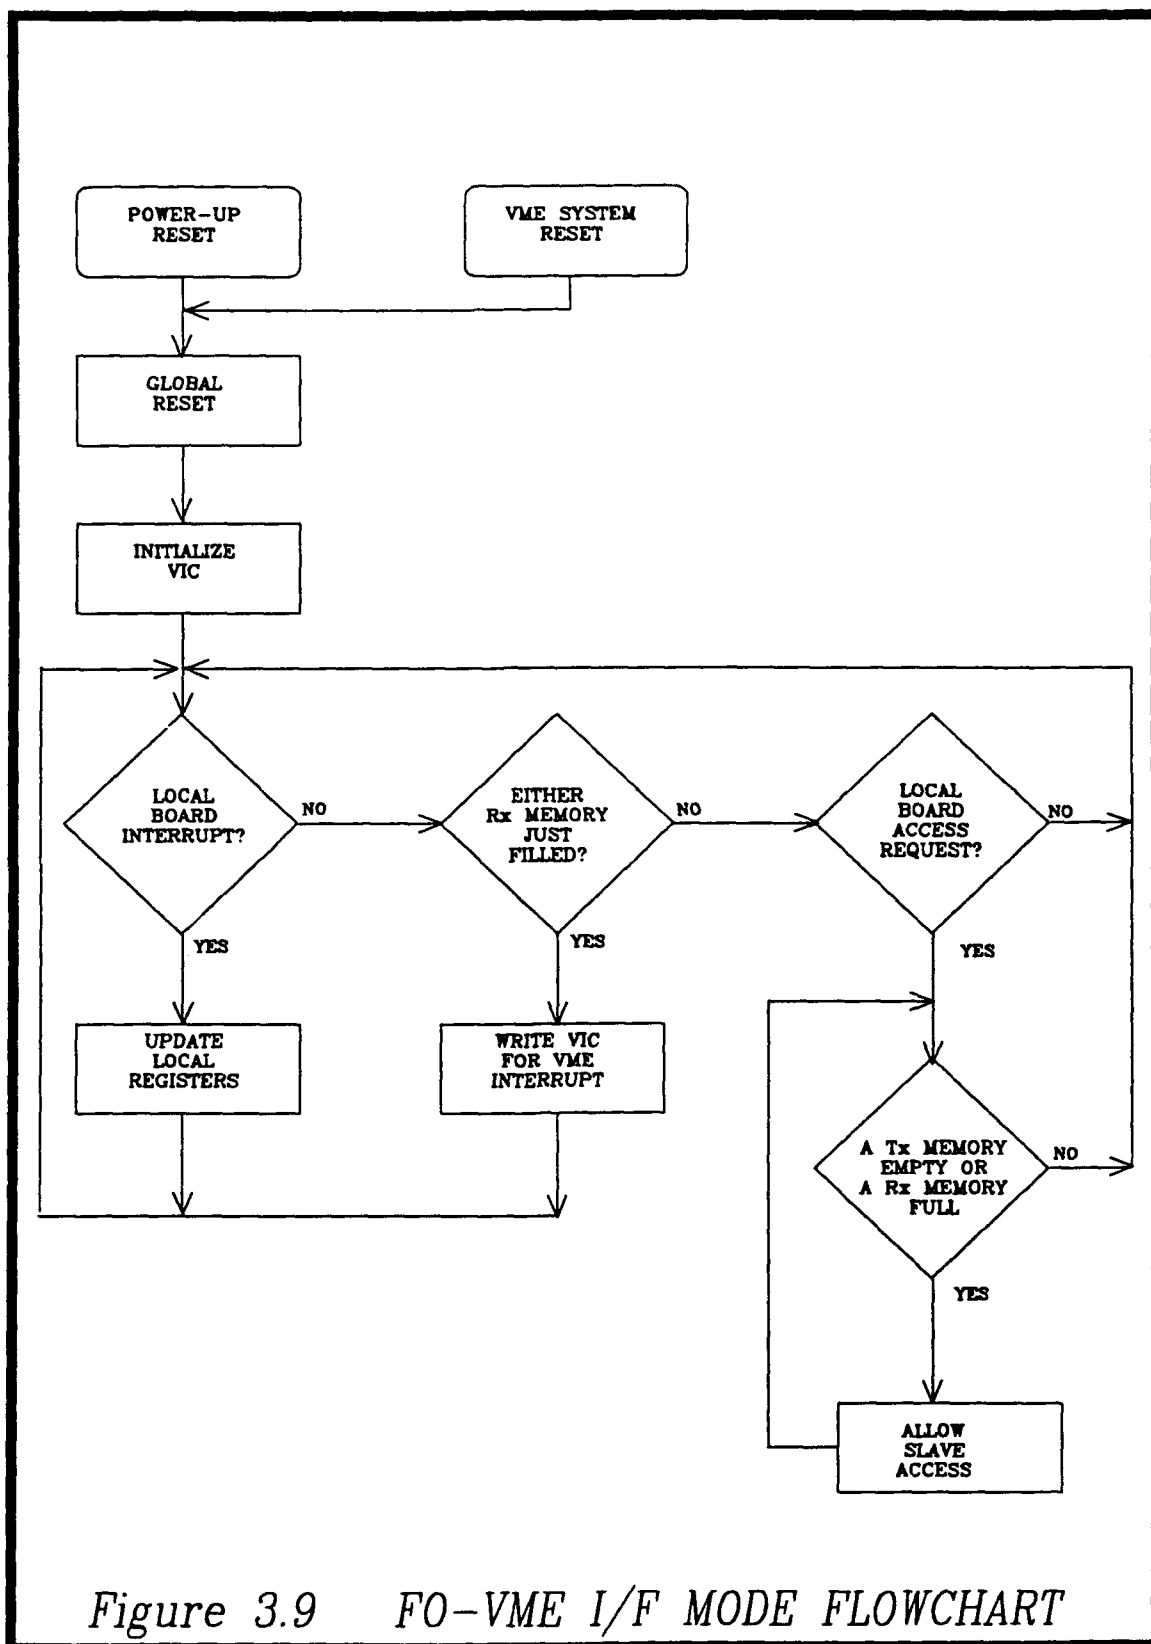

Figure 3.9 FO-VME I/F MODE FLOWCHART

through its modes, it checks for the arrival of a 1000 Hz tick first before checking the need for a different mode. The reason for this priority is twofold. First the time required for a status update is small in comparison to a VME access so timely status is always available. Second, because access to the registers will override the other two modes, it is possible for the VME controller to access a board that is failing and possibly reset the board before a critical failure occurs. Any other priority could hinder timely status updates and potentially put the board into a "lock up" state without a software capability to determine status.

The second mode pertains to generating interrupts on the VME backplane. Whenever a Rx buffer is filled with new received data from the link, the FO-VME I/F must let the VME controller know so that the data can be removed before the buffer is needed again by the link. By generating an interrupt that is broadcast to the controller, the board is requesting service. It is then the responsibility of the VME controller to read all of the relevant data from the buffer and then free up space for the next alternate receive packet. If data is not removed and both buffers are filled, new data received from the link will be lost.

The last mode provides slave accesses for reading and writing Rx and Tx buffers. Although this last mode has the lowest priority on the board, it plays the most significant role. When the VME controller wants to access the FO-VME I/F board, it issues a local bus request that is decoded by the board to be accessed. The board will enter the slave access mode and then check to see if there is a buffer that can be read or written; if not, it will not grant access. If access is granted, the local

bus on the FO-VME I/F is opened to the VME bus and data transfers can occur. The largest transfer that can occur is 256 transfers of 32 bit words (1 kByte). After a transfer of any size, the access is lost and must be reinstated between the controller and the FO-VME I/F.

CHAPTER 4

TESTING

Thorough testing, both in the laboratory and in the field, was undertaken to prove the feasibility of a UUV with remote command and control provided over a fiber optic link. The tests were performed in stages that steadily increased in complexity, culminating in actual complete system tests performed in an underwater environment. Although it is not an objective of this thesis to determine a bit error rate (BER) for the optical and electronic subsystems, enough data was gathered to confirm the effectiveness of this technology for undersea use.

To aid in all facets of testing, electronic and optical test equipment was used. For this research a optical power meter and optical time domain reflectometer (OTDR) were obtained. The test equipment was extremely valuable for laboratory and ultimately field testing. Their presence is very helpful for optical link development.

4.1 Laboratory Test

Before going to the field for final testing and analysis, a series of tests were performed in the laboratory to ensure reliable and safe operation of the UUV electronics. Specifically, three tests - loopback, ramp data, and puretone - scrutinized the system and allowed for an almost flawless system performance in the field.

4.1.1 Loopback Test

Testing of only the hardware that contained the fiber optic link (FO) related components was done to ensure the integrity of the transmission path from the VME bus to the VME bus on the opposite side. The first was the loopback test. As seen in Figure 4.1, the test set was made up of two VME chassis, each only containing a VME controller/processor (PME-63) and the FO boards, the FO-VME I/F and the the optics. Connecting the two VME chassis, via the FO boards, was a 20 km spool of fiber. The Sun workstation acted as the monitor to initialize testing and to view results.

The test was written in Ada and loaded into PROMs located on the two PME-63s. One PME-63 was the master, the other the slave. Initiation of the test sent 32 kbyte (the size of a FO-VME buffer) packets of known 32-bit long data words up the link from the master. The slave read the packet from the FO-VME I/F, incremented values by one, and then returned the packet. When received back, the master checked the values for the correct increment, incremented them by one, and sent the new packet back up the link. The test was varied by changing the number of packets to be sent (up to 2^{32}) and the speed (up to 100% link utilization) at which they were sent.

The objective of this initial test was to debug the custom built hardware. The loopback test was very effective in revealing errors in timing and logic. It was used to eventually debug four sets of custom designed hardware. After correction of the identified problems, the test was re-run for about 24 hours and resulted in few or no

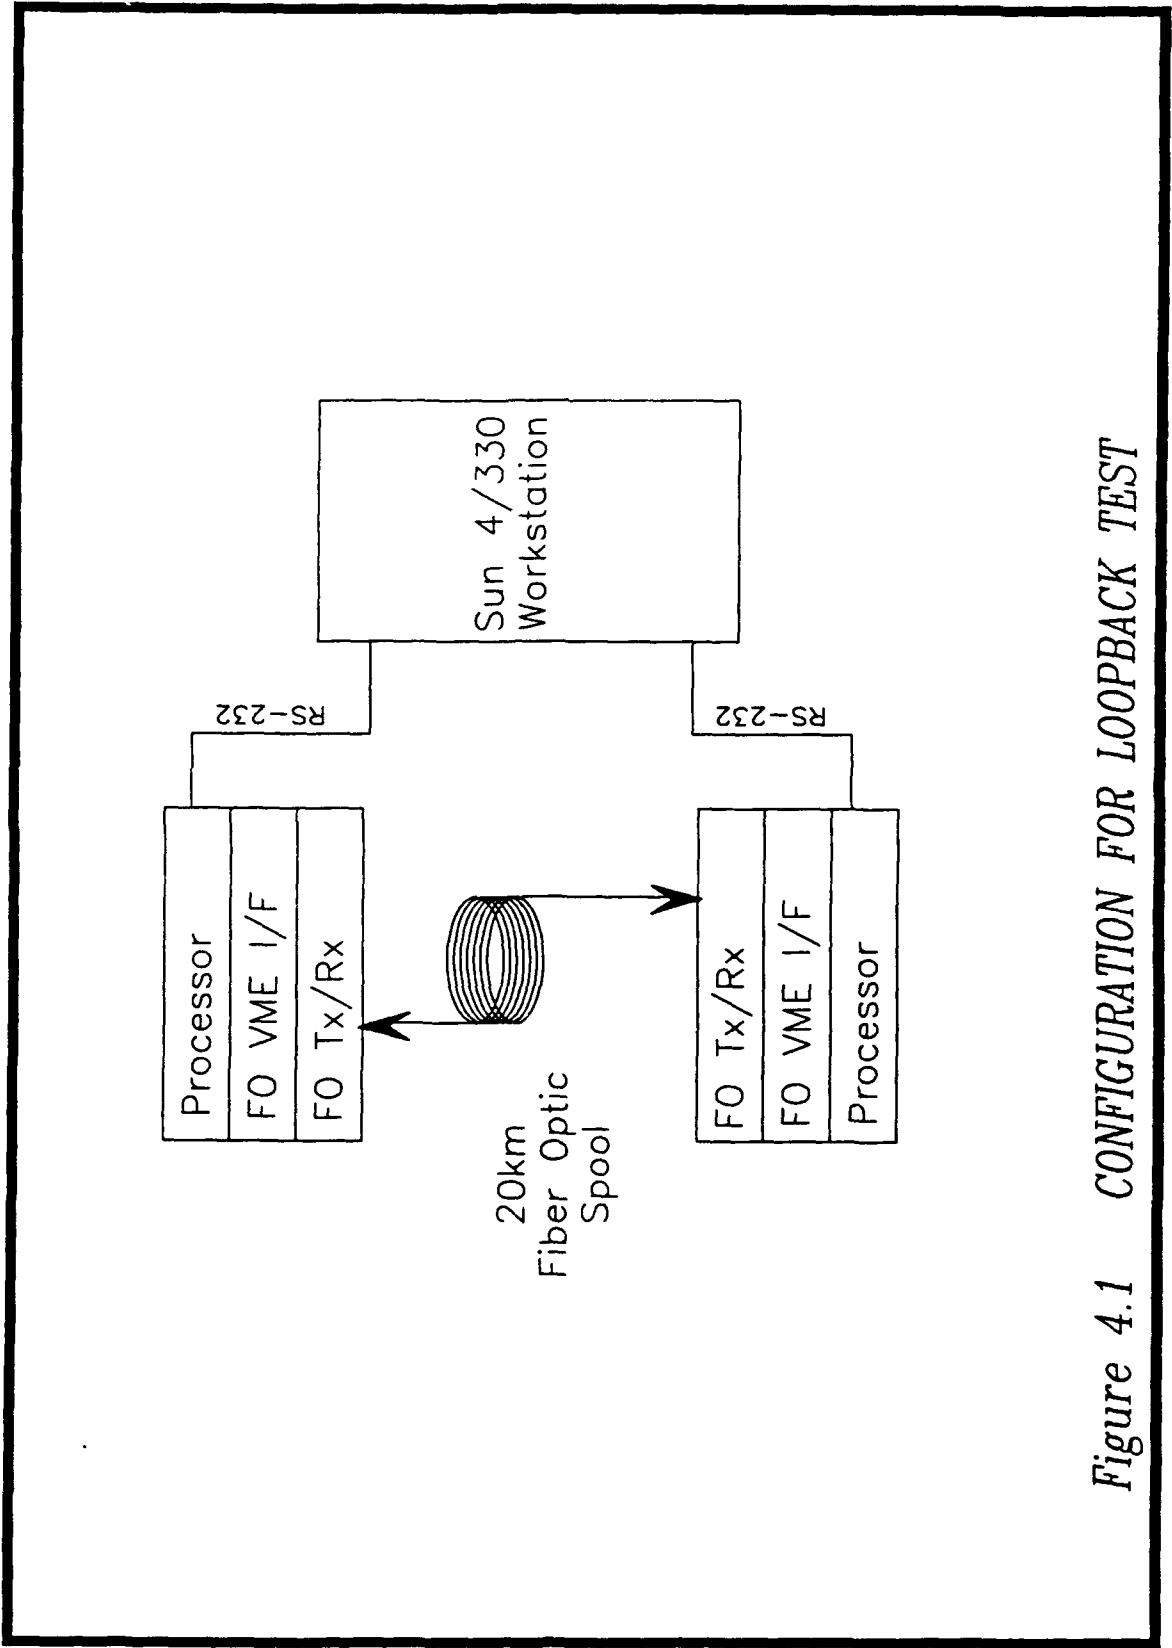

Figure 4.1 CONFIGURATION FOR LOOPBACK TEST

data errors. Because of the comparison done in the test, one error meant one long word was corrupt. The actual error could encompass from one to thirty-two bits. The nature of the loopback test did not warrant precise error handling or recording. As expected, the outcome only proved the fiber optic electronics and the optical link was sound for fast, simultaneous bidirectional data transfers.

4.1.2 Ramp Data Test

The custom FO boards were integrated into the system and the system was ready for the next level of test. A test fixture was constructed that functioned according to the specification of the actual acoustic array. Instead of providing acoustic type random data, it produced incremental data in the form of a ramp function. Its output data was continuous 16 bit parallel words, where each pair of data represented the real and imaginary components of actual data. Each data point was incremented by one over the previous data point. Figure 4.2 graphically displays the ramp data input. This test fixture allowed for a more thorough and realistic test. Figure 4.3 shows the setup for the ramp data test.

At this point the setup now contained portions of code to be included in the final system. Ramp data was injected into the system in place of acoustic data, and transmitted up its link via the PME-63 and FO-VME I/F board. Received data on the other side of the link was recorded onto optical disks via the PME-63 and SCSI boards. All test code is contained in the PME-63 and is bootable and commences on power up.

Figure 4.2 RAMP DATA INPUT

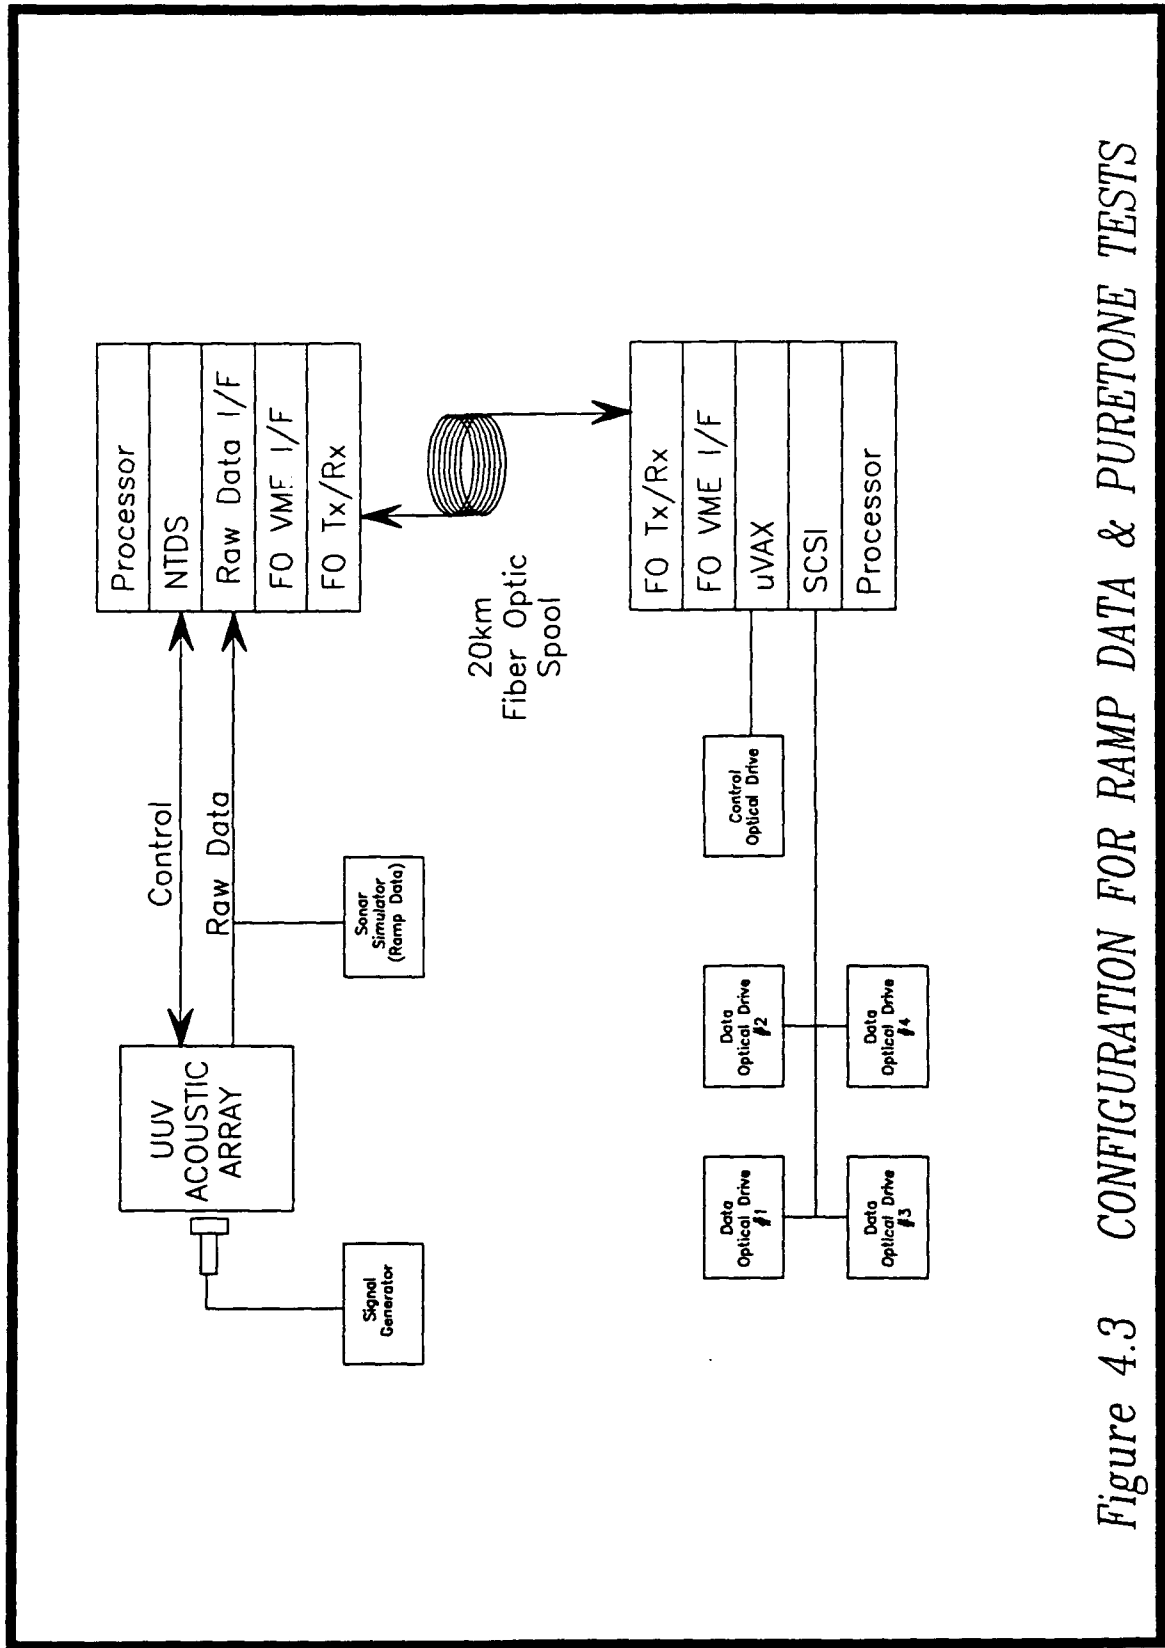

Figure 4.3 CONFIGURATION FOR RAMP DATA & PURETONE TESTS

Although in the test the FO link was running at full bandwidth, 16 Mbits/sec, only the acoustic data was checked for accuracy; this makes up 6.25 percent of the transmitted data. During the test; however, the controller was still sending and receiving full 32 kbyte packets of data. The data was extracted by reading the data and control disks. This combination of data and control information allowed for the formatted data to be located and recovered. The data was checked for incremental data one 16 bit longword at a time. Discrepancies were printed to the screen. Figure 4.4 shows a sample screen with correct data, and an induced error.

Table 4.1 shows the results of five ramp data tests, representing more than 250 MBytes of acoustic data. Assuming the BER of the optical link is equal to 10^{-9} , at most two bit errors should have occurred in this data sampling. As Table 4.1 portrays, no bit errors occurred, and this is a total system check, not just a test of the FO-VME I/F electronics and the optical link. Besides the optical link, the BER of the electronics transferring data on each side of the link in addition to the error rate of the optical recording medium used. In conclusion the system and the optical link performed satisfactorily and better than expected. The purpose of this test was not to derive the BER of the system, but rather to do a predictable whole system check that would reveal errors too large in magnitude to be accepted. Later field tests revealed no noticeable errors.

Table 4.1
Ramp Data Test Results

Test #	Quantity of Data	Bit Errors Recorded
1	55 Mbytes	0
2	54 Mbytes	0
3	55 Mbytes	0
4	55 Mbytes	0
5	54 Mbytes	0
Total	273 Mbytes	0

Fiber - Length = 19.8 km

Rx Input Power 1300 nm = -27.4 dBm (launch platform)
1550 nm = -25.5 dBm (UUV)

BER - Expected = 1.000×10^{-9}

4.1.3 Pure Tone Test

The laboratory testing satisfied only preliminary testing requirements, so a test was needed to test the entire system out of water. To accomplish this, an artificial stimuli was needed to form an input to the acoustic array. The objective of the test was to verify that the system was operating correctly and accurately from sensors to recording. Again, in figure 4.3 the test set up is shown. The setup is identical to the ramp data test setup, except for the removal of the test fixture and the addition of the

actual acoustic data interface. The stimuli to the sonar had to be predictable so analysis would be possible.

The puretone test consisted of a single frequency puretone injected into the sonar via a pressure transducer. Although the system would manipulate the received data by downconverting and filtering, the transfer function of the sonar was known and hence the recorded data could be calculated. The input puretone passed through many components, active and passive, so the test could not determine a BER. Rather, it was used to test the reliability of the electronics system and FO link. It was also easy to perform. The setup for the test differed very slightly from the final configuration, and a large subset of the data could be checked in about one hour.

Sections 4.1.3.1 and 4.1.3.2 describe two unique analyses performed on the tonal data to support system functionality and reliability. The analysis shifts from locating bit errors to locating holes in the data that could give invalid acoustic signal representation. In the complete system, random bit errors would most likely go unnoticed because of data manipulation such as averaging and smoothing algorithms.

4.1.3.1 Complex Data Visualization

Visualization of the puretone data made data analysis fast, accurate, and simple. Data from the sonar was in the form of two 16 bit words, one real and one imaginary. This complex data can be written as $e^{j(\omega + \phi)}$ or, converted to the trigonometric form, it is stated as $\cos(\omega + \phi) + j \sin(\omega + \phi)$, where ω is the input operating frequency and ϕ is the initial phase offset. The trigonometric equation is in

the form representing the radius of a circle, thus allowing a time sampling of the continuous complex data to assume a circular shape. Each plotted point will determine a point on the perimeter of a circle and the connected points will display a circle with a defined perimeter thickness. The thickness is derived from the sampling and input frequencies. Figure 4.5 displays an actual plot of puretone data with no missing data. The sampling frequency also defines the perimeter distance between two consecutive points and this is where the complex data visualization is important. As viewed in figure 4.6, a plotted point was intentionally omitted to portray the method. Because of the missing sample, the connecting line between two points is longer than expected and the circle shows a noticeable flaw that is the result of a missing data from the electronics subsystem.

This visual analysis is also preferred over FFTs for viewing the spectrum, because the system noise in a typical spectrum does not have a traceable source. Portions of the system noise were due to sonar filtering, but it is difficult to determine if any was due to the FO link. Each complex plot represented about 600 kbytes of data and about 10 such plots would exhaustively test all the recorded raw data from a short laboratory test.

The amount of missing data complex visualization could detect is one sample or four bytes; in addition, a corrupt MSB but would also be distinguishable. The puretone test was run several times before each field run, and never revealed a fault with the FO electronics.

Figure 4.5 TEST FREQUENCY SIGNAL PARAMETERIZED PLOT

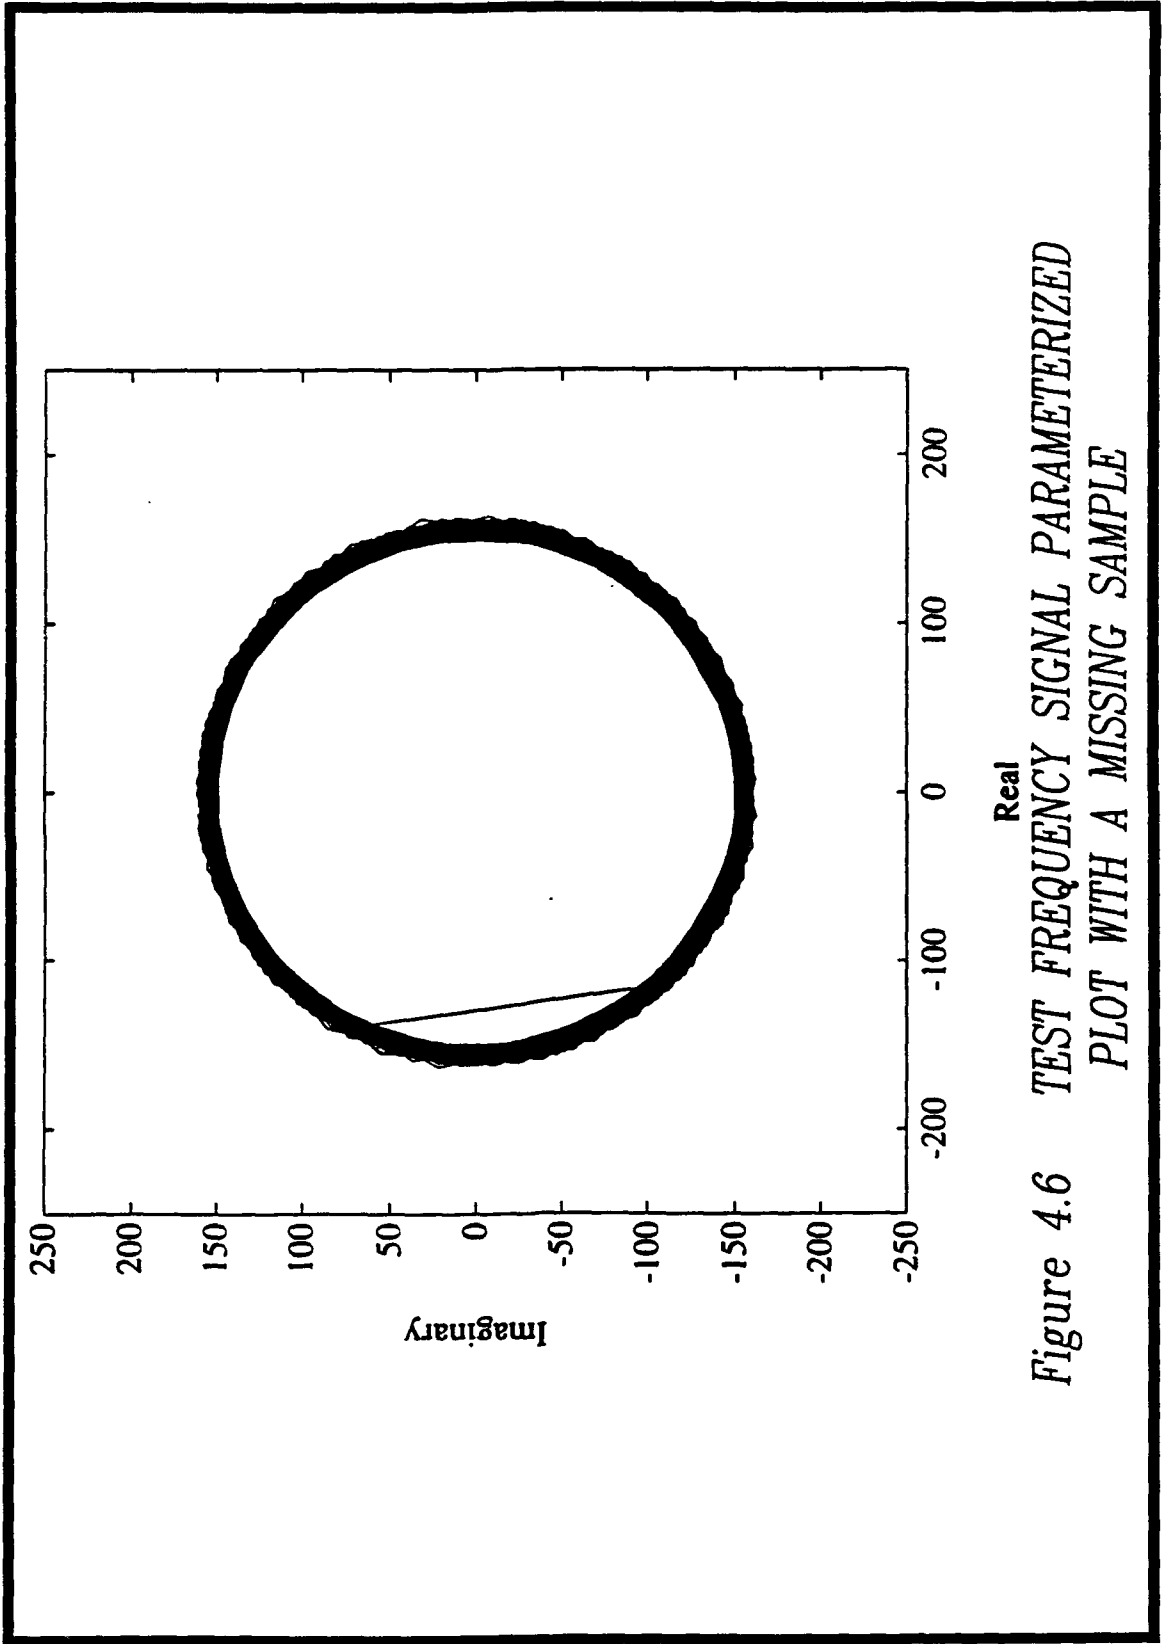

Figure 4.6 TEST FREQUENCY SIGNAL PARAMETERIZED
PLOT WITH A MISSING SAMPLE

4.1.3.2 Spectral Analysis

Much in the same manner field data was analyzed, laboratory test data could be analyzed by performing an FFT on the data and graphically displaying the results. The FFT has the following advantages over the complex visualization method: it checks system performance and verifies the frequency components of the test; and, by checking the frequency components, verifies that periodic data is not missing. It is possible that the complex visualization method would overlook missing periodic data because the remaining data could still produce a good circular plot.

Figures 4.7 and 4.8 show a sample input tone and a frequency plot of the recovered data after traversing the FO link. It is evident from the spectrum content that the signal stays intact. Also, the recovered time series displayed in figure 4.9 shows a reconstructed puretone. The jagged reconstruction is due to sampling.

4.2 Field Test

From the Fall of 1991 to early 1993, twelve in-water experimental tests were attempted that tested the reliability of the FO subsystem. Overall there was great system success, and system performance related to the remote control and operation of the UUV was outstanding. Table 4.2 lists the in-water tests attempted and their outcome. A tabulation of this run data shows:

2	-Fiber Breaks
10	-Run-as Planned
<hr/>	
12	-Total

Figure 4.7 INPUT FREQUENCY POWER SPECTRUM

Figure 4.9 RECOVERED OUTPUT FREQUENCY TIME SERIES

TABLE 4.2
IN-WATER RUN TEST RESULTS

	TEST DURATION	COMMENTS
1	2 min	Fiber break
2	--	Fiber Integrity Test at Launch Run-as Planned
3	--	Fiber Integrity Test at Launch Run-as-Planned
4	--	Fiber Integrity Test at Launch Run-as-Planned
5	10.5 min	Run-as-Planned
6	10.5 min	Run-as-Planned
7	51 sec	Fiber Break at launch
8	10.5 min	Run-as-Planned
9	10.5 min	Run-as-Planned
10	10.5 min	Run-as-Planned
11	12 min	Run-as-Planned
12	10 min	Run-as-Planned

The two fiber breaks will be discussed in Chapter 6. The 10 successful data runs netted about 350 MBytes of data. The data was broken down and divided into acoustic cycles. Each acoustic cycle contained acoustic blocks that were inspected for frequency content. The data for each acoustic block was FFT'd and inspected graphically. The level of FO subsystem electronics data integrity that could be determined from the test is limited. The smallest increment of missing data to be easily detected would be one sample (4 bytes). Missing one sample would create a true discontinuity and cause a phase shift that would be revealed in the FFT. For all ten valid runs, there were no obvious missing samples revealed in the data analysis. A certain BER is inherent to its system ($\sim 10^{-9}$ by optical component specifications) but its effects were not noticed in the different processes performed on the data.

Because of the complexity of the retrieved data, it is not possible for an FFT alone to verify the results; thus verification came in two forms. First, during any particular test, known signal sources were present in the water and their position relative to the UUV was monitored and recorded. The acoustic information gathered from these sources was verified to be contained in the data recorded through the link electronics.

A second verification of data retrieved through the FO link electronics occurred one year after the first field tests. Similar in-water runs were performed that did not use the fiber optic link and recorded data on optical drives internal to the UUV system. Because of the similarity of acoustic data collected, it was possible to perform comparisons to the FO link retrieved data. Comparisons concluded that the

data from 1991 were valid and was a true representation of the acoustic information present in the water. Discussion of this graphical analysis and comparison is complex and tedious, and is outside the scope of this thesis.

CHAPTER 5

FUTURE EXTENSIONS

5.1 The Future in Tethered Vehicles

UUVs with fiber optic payout capabilities have become increasingly popular in recent years. Companies like Optelecom, Northern Telecom, Sippican, and SAIC Maripro all offer variations or services based on this technology. Applications for this technology include: a) rapid deployment of communication links, b) tethered sonobouys, c) deployment of expendable oceanographic data acquisition equipment for measuring salinity, current, pressure, and depth, d) ordnance disposal, e) harborside security and, f) deep water search and salvage [1].

Our original fiber optic tethered vehicle was specifically designed and built for one project. All of its requirements were derived from goals set by this project, and from space occupied by the electronics and optics chosen. A fiber optic tethered UUV system would need to be more dynamic and adaptable to new applications. This may be accomplished by designing in more general purpose interfaces that could easily fit most users' applications.

The fiber optic spool could be housed in a permanent compartment within the vehicle. A new UUV layout would not be necessary if a project were to utilize the spool. In addition, an electronic interface will make the optics transparent to the user. The electronic interface would consist of a wide parallel word with a simple

asynchronous strobe or handshake. The bandwidth of the new link would be sufficient to meet any current or near future needs. The user only needs to strobe data, at virtually any rate, into the interface and the data will be available intact on the other end of the link. Each project has the requirement to multiplex and demultiplex its own data and interface with the link electronics. Again, all of the optics will be transparent to the user and will not affect UUV configurations. The following sections describe the new technology that will support this.

5.2 Opto-Electronics

Chip sets now exist to assist in GBit/second transmission. HP, Vitesse, AMCC and TriQuint offer such chip sets as standard product. With their availability, other manufacturers have developed standard links that use these chip sets. The standard products are aimed at the Fiber channel and HIPPI interface market, but their operation is generic enough for any use. Two such manufacturers are Finisar and Broadband Communication Products (BCP). The basis of the boards Finisar and BCP have developed is to remove the work of developing a fiber based system by hiding the optics. Two boards could be connected with a commercial fiber and then the user would have to strobe data into a wide bit word interface.

An immediate advantage, besides the lack of optical knowledge needed, is the user would work with a strobe rate that is 20-40 times slower than the serial link rate. This is a much simpler system rate to work with. As before, the development boards will offer full duplex operations using a single fiber.

5.3 VME Enhancements

In late 1992, another revision was completed towards the finalizing of a VME 64 specification. The most noticeable transitions to the new specification is the use of 64 address lines and 64 data lines. Theoretical VME transfers can now be as high as 80 MBytes/second and the address space increases to 16 exabytes (2^{64} bytes). Even at backplane speeds of this magnitude, a data link at a maximum of only 640 MBits/sec could be supported. A link of this bandwidth does not presently appear to have a function for a UUV. The data rate of 16 MBytes/second as discussed in this thesis would be sufficient for the tasks of this UUV system.

5.4 Summary

It is difficult to accurately predict all possible future configurations of UUVs. The parameters that define these systems are even more of an unknown. However, any proposed generic UUV FO link must cover the extremes of distance, speed, data bandwidth, and UUV size.

CHAPTER 6

CONCLUSION

6.1 System and Component Problems

6.1.1 Payout Fiber

Two of the twelve in-water runs involved a failure due to the fiber's breaking. The first of these breaks occurred because of improperly installed hardware. The cable broke at launch due to kinking in the hose that is meant to uncoil and protect the fiber at launch. This error did not point to the fiber as a source of blame, rather to the deployment setup. The deployment setup, however, is still part of task the required to use fiber as a transmission medium.

The other failure occurred at 51 seconds after launch (scheduled run time was 20 minutes). At this time, the remote vehicle sensed the loss of data from the launch craft, and shut down the system electronics. Because of the methods used in deployment, it is difficult to determine where the break occurred. After recovery of the UUV, there were significant lengths of cable still hanging from the UUV, indicating that the break was not in the vicinity of the UUV.

6.1.2 System Failures Summary

The two errors identified during field tests were repaired by trying to avoid the circumstances that led to them. This meant new procedures to identify potential

problems before they occurred. The system did perform exceptionally well with a success rate of 83% for the fiber optic subsystem electronics.

The use of pre-run test in the laboratory helped tremendously in avoiding additional errors. The complexity of the entire UUV and remote control system makes the possibility of a failure imminent; however, laboratory tests remove the oversights that can occur when the operator becomes too familiar with the system and this familiarity creates a false sense of security for in-water testing.

6.2 Thesis Summary

The results presented in this thesis culminated from a three year R & D project for which a major objective was to utilize a fiber optic data communication link to provide a remote command and control platform. System operation during in-water testing combined with laboratory testing demonstrated the tethered UUV met all of its technical requirements cited in section 1.4.

Presently, most payout applications use optical fibers and cables manufactured for other applications. With a wide growth of this application area, we can expect to see more fiber and cable developed that will be optimized for these areas. These include stronger fibers with a thinner buffer for high speed payout and cables ruggedized for the harsh undersea environment. The other components used for the success of this research are generally commercial off-the-shelf parts without specific tolerances for undersea use. This is easily acceptable since their working environment is dry and reasonably controlled.

The operation of the optical, payout, and remote command and control systems was excellent. As expected, all of the processing equipment, recorders, and commercial and custom boards performed exceptionally well and as expected. The fiber optic tether operated reliably at all speeds and maneuvers.
