AMERICAN INSTITUTE OF PHYSICS

JOURNAL OF APPLIED PHYSICS

CODEN: JAPIAU
ISSN: 0021-8979

Editor

Steven J. Rothman
Argonne National Laboratory
Argonne, IL

Associate Editors at Argonne National Laboratory

Robert C. Birtcher
Gian P. Felcher
R. E. Holland
John N. Mundy
Simon R. Phillpot

Editorial Board

Term ending 31 December 1994
William R. Frensley (Univ. of Texas at Dallas)
Julia M. Phillips (AT&T Bell Labs, Murray Hill, NJ)
Paul M. Solomon (IBM, Yorktown Heights, NY)

Term ending 31 December 1995
Ulrich Gösele (Max Planck Inst., Halle, Germany)
William L. Johnson (Caltech, Pasadena, CA)
William F. Krupke (Lawrence Livermore Lab, CA)

Term ending 31 December 1996
Gene F. Dresselhaus (MIT, Cambridge, MA)
Allen M. Goldman (Univ. Minnesota, Minneapolis)
Klaus H. Ploog (Paul Drude Inst., Berlin, Germany)
Robert Sinclair (Stanford Univ., Stanford, CA)

Joan Eigo, *Production Editor*

The *Journal of Applied Physics* (ISSN: 0021-8979) is published semimonthly by the American Institute of Physics, 500 Sunnyside Blvd., Woodbury, NY 11797-2999. Second-class postage paid at Woodbury, NY, and additional mailing offices. POSTMASTER: Send address changes to *Journal of Applied Physics*, AIP, 500 Sunnyside Blvd., Woodbury, NY 11797-2999.

© 1994 by the American Institute of Physics.

The *Journal of Applied Physics* is the American Institute of Physics' (AIP) archival journal for significant new results in applied physics. The journal publishes articles that emphasize understanding of the physics underlying modern technology. There are two issues per month. The subject coverage includes, but is not limited to, experimental or theoretical physics applied to all aspects of materials: for example, charge and mass transport, superconductivity, magnetism; surfaces, interfaces, thin films, crystal lattice defects; electrical, optical, magnetic, and structural properties; processing; ion implantation. Materials covered include semiconductors, superconductors, metals and alloys, amorphous materials, and oxides. Other important topics are: electrical, optical, and magnetic devices; optics and lasers; nonlinear optics; electrical discharges; acoustics. The Proceedings of the Annual Conference on Magnetism and Magnetic Materials is a regular feature. *Applied Physics Reviews* is a series of occasional review articles on similar subjects.

Submit manuscripts (3 copies) to Editor, *Journal of Applied Physics,* Argonne National Laboratory, Bldg. 203, Room R-127, 9700 South Cass Avenue, P.O. Box 8296, Argonne, IL 60439-8296.

Subscription Prices* **(1994)**	U.S.A. & Poss.	Can., Mex., Central & S. Amer. & Caribbean	Foreign Surface Mail	Air Freight — Europe, Asia, Africa & Oceania	Optional Air Freight — Europe, Asia, Africa & Oceania
Members†	$190	$270	$270	——	$380
Nonmembers	$1655	$1735	——	$1845‡	——

*The journal is available on microfiche at $190 per year to members and $1655 per year at the nonmember rate.
†AIP Member and Affiliated Societies. ‡Includes air freight service.

Back-Number Prices: 1994 single copies: $80. Prior to 1994 single copies: $24 for members; $80 for nonmembers. Prices for conference supplements available on request.

Subscription, renewals, and address changes should be addressed to *AIP Circulation and Fulfillment Division (CFD), 500 Sunnyside Blvd., Woodbury, NY 11797-2999.* Allow at least six weeks advance notice. For address changes please send both old and new addresses and, if possible, include a mailing label from a recent issue.

Claims, Single Copy Replacement and Back Volumes: Missing issue requests will be honored only if received within six months of publication date (nine months for Australia and Asia). Single copies of a journal may be ordered and back volumes are available in print or microform. Members—contact AIP Member Services at (516) 576-2288; (800) 344-6901. Nonmember subscribers—contact AIP Subscriber Services at (516) 576-2270; (800) 344-6902.

Page Charge and Reprint Billing: Contact: AIP Publication Page Charge and Reprints—CFD, 500 Sunnyside Blvd., Woodbury, NY 11797-2999; (516) 576-2234; (800) 576-6909.

Copying Fees: Copying of articles beyond that permitted by the Fair Use provisions (Sections 107 and 108) of the U.S. Copyright Law requires payment of fees. The code at the bottom of the first page of each article gives the fee for each copy of the article. Fees should be paid through the *Copyright Clearance Center (CCC), 222 Rosewood Drive, Danvers, MA 01923.* Persons desiring to photocopy materials for classroom use should contact CCC's Academic Permissions Service.

The item-fee code for this publication is 0021-8979/94 $6.00.

Permission For Other Use: Permission is granted to quote from the journal with the customary acknowledgment of the source. To reprint a figure, table, or other excerpt requires in addition the consent of one of the original authors and notification to AIP. Reproduction for advertising or promotional purposes, or republication in any form, is permitted only under license from AIP, which will normally require that the permission of one of the authors also be obtained. Direct inquiries to: Office of Rights and Permissions, American Institute of Physics, 500 Sunnyside Blvd., Woodbury, NY 11797-2999.

Document Delivery: For information on obtaining copies of individual articles, contact AIP Circulation and Fulfillment Division, 500 Sunnyside Blvd., Woodbury, NY 11797-2999; phone: (516) 576-2277; (800) 344-6908; fax: (516) 394-9704; E-mail: elecprod@pinet.aip.org.

Online Availability: Abstracts of journal articles published by the AIP and its Member Societies are available in bibliographic databases on major online hosts. The abstracts are also available in the SPIN database via the AIP online service, PINET (Physics Information Network). PINET also offers Advance Abstracts, a current awareness service with abstracts of research papers up to three months prior to their publication in AIP or Member Society Journals. Call (800) 874-6383 or (516) 576-2262 for further information.

All papers in this volume, and in previous Proceedings of the Conference on Magnetism and Magnetic Materials published in this series, have been reviewed for technical content. The selection of referees, review guidelines, and all other editorial procedures are in accordance with standards prescribed by the American Institute of Physics.

JOURNAL OF APPLIED PHYSICS

Vol. 75, No. 10, 15 May 1994

CODEN: JAPIAU ISSN: 0021-8979

Micromagnetics and Hysteresis

5475	Monte Carlo simulations of remanent magnetization decay driven by interactions	M. E. Matson, D. K. Lottis, E. Dan Dahlberg
5478	The Preisach model with stochastic input as a model for aftereffect	Isaak D. Mayergoyz, Can E. Korman
5481	The measurement of irreversible magnetization and activation volumes	R. Cammarano, P. G. McCormick, R. Street
5484	A phenomenological differential-relation-based vector hysteresis model	A. Bergqvist, G. Engdahl
5487	Master equation approach to anhysteresis of noninteracting particles	Ivo Klik, Ching-Ray Chang, J. Lee
5490	Scaling aspects of domain wall dynamics and Barkhausen effect in ferromagnetic materials	G. Bertotti, G. Durin, A. Magni
5493	Monte Carlo simulations of the magnetocaloric effect in superferromagnetic clusters having uniaxial magnetic anisotropy	L. H. Bennett, R. D. McMichael, H. C. Tang, R. E. Watson
5496	A phenomenological magnetomechanical hysteresis model	A. Bergqvist, G. Engdahl
5499	Reversible transverse susceptibility of particulate recording media	Jing Ju Lu, Huei Li Huang, Ching-Ray Chang, Ivo Klik
5502	Efficient Preisach demagnetization algorithm and its experimental testing	A. A. Adly, Y. J. Zhao
5505	Interpreting logarithmic decay	Ivo Klik, Ching-Ray Chang, J. Lee
5508	Magnetization processes in Co–Cr submicron samples: Hall measurements and micromagnetic simulations	M. van Kooten, S. de Haan, J. C. Lodder, Th. J. A. Popma
5511	Frequency dependence of hysteresis curves in conducting magnetic materials (abstract)	D. C. Jiles

Spin Glasses and Other Disordered Systems

5512	Hierarchical scaling: An analytical approach to slow relaxations in spin glasses, glasses, and other correlated systems (invited)	J. Souletie
5517	Exchange stiffness of Ca-doped YIG	I. Avgin, D. L. Huber
5520	Random-exchange to random-field crossover breaking in $Mn_{0.35}Zn_{0.65}F_2$	F. C. Montenegro, J. C. O. de Jesus, A. Rosales-Rivera
5523	Order by disorder in an anisotropic pyrochlore lattice antiferromagnet	S. T. Bramwell, M. J. P. Gingras, J. N. Reimers
5526	A new scheme to percolation thresholds	Serge Galam, Alain Mauger
5529	Heat capacity and magnetic properties of $CoCl_2 \cdot H_2O$	J. A. Lukin, S. A. Friedberg, S. Chardarlapaty, W. W. Brubaker, C. C. Cinquina, G. C. DeFotis
5532	Perturbative approximation scheme for isolated impurity bonds in the two-dimensional spin-$\frac{1}{2}$ Heisenberg antiferromagnet	P. Schlottmann
5535	Magnetic properties of a new amorphous magnet	C. P. Landee, C. M. Wynn, A. S. Albrecht, W. Zhang, G. B. Vunni, J. L. Parent, C. Navas, M. M. Turnbull
5538	The influence of heat treatments on order–disorder phenomena in a naturally occurring manganese-ferrite	Cherie R. Bluncson, B. J. Evans
5541	Remanent magnetization in the diluted Ising antiferromagnet $Fe_{0.6}Zn_{0.4}F_2$	C. Djurberg, J. Mattsson, P. Nordblad
5544	Freezing transition in the Z_3 gauge glass	Ronald Fisch

(Continued)

Particulate Recording Media

5547	Reptation and viscosity in particulate recording media in the time-limited switching regime	W. D. Doyle, L. Varga, L. He, P. J. Flanders
5550	Ferromagnetic resonance spectra of oriented barium ferrite tapes	Yuwu Yu, J. W. Harrell, W. D. Doyle
5553	Angular dependence measurement of individual barium ferrite recording particles near the single domain size	Thomas Chang, Jian Gang Zhu
5556	Co-Sn substituted barium ferrite particles	X. Z. Zhou, A. H. Morrish, Zheng Yang, Hua-Xian Zeng
5559	Magnetic properties of modified Ba-ferrite particles	H. Sadamura, N. Sugita, M. Maekawa, N. Nagai
5562	H_c enhancement of Co-adsorbed γ-Fe_2O_3 particles via surface treatment with sodium polyphosphate	F. E. Spada, F. T. Parker, A. E. Berkowitz, T. J. Cox
5565	Coercivity enhancement in γ-Fe_2O_3 by surface treatment with phosphate ions	David E. Nikles, Martin R. Parker, Elizabeth M. Crook, Terry M. Self
5568	Electrochemical evaluation of the effect of binder additives on iron corrosion	J. Carlos Arroyo, Hassan M. Saffarian, Garry W. Warren
5571	Molecular dynamics of magnetic particulate dispersions	P. A. Deymier, C. Jung, S. Raghavan
5574	A computer simulation of the microstructure of a particulate dispersion	G. N. Coverdale, R. W. Chantrell, A. Hart, D. Parker
5577	The effect of dc bias fields on the switching speed in magnetic particulate media (abstract)	W. D. Doyle, L. He
5577	Preparation and magnetic properties of Al-modified acicular α-Fe particles (abstract)	C. H. Lin, P. C. Kuo, S. C. Chen, C. S. Hsih
5578	Studies into the use of waterborne coating formulations for the preparation of magnetic tape (abstract)	Stacy Barrom, Ashley Bray, Song Cheng, John Elike, Hong Fan, Alan M. Lane, David E. Nikles
5579	Rheo-optical measurements on suspensions of magnetic recording particles (abstract)	Hyoung J. Choi, Yoon D. Park, Paul L. Frattini, Myung S. Jhon

Thin and Ultrathin Films

5580	Growth and magnetic dynamic scaling of ultrathin ferromagnetic films: Fe/Au(001)	Y.-L. He, Y.-F. Liew, G.-C. Wang
5583	Mössbauer investigation of the magnetic hyperfine field distribution in Fe(100)/Ag(100) structures	P. J. Schurer, Z. Celinski, B. Heinrich
5586	Magnetization reversal processes in epitaxial Fe/GaAs(001) films	C. Daboo, R. J. Hicken, D. E. P. Eley, M. Gester, S. J. Gray, A. J. R. Ives, J. A. C. Bland
5589	Surface magnetization processes investigated by the combined surface magneto-optical Kerr effects in Fe/Cu(100) thin films	Z. J. Yang, S. D. Healy, K. R. Heim, J. S. Drucker, G. G. Hembree, M. R. Scheinfein
5592	The initial phases of epitaxy of fcc Fe/Cu(100): Supersurface and subsurface island formation	S. D. Healy, K. R. Heim, Z. J. Yang, G. G. Hembree, J. S. Drucker, M. R. Scheinfein
5595	Effect of surface layers on ferromagnetic resonance in thin Fe films: Ni, Co, Si, and $YBa_2Cu_3O_{7-\delta}$	P. Lubitz, M. Rubinstein, D. B. Chrisey, J. S. Horwitz, P. R. Broussard
5598	Magneto-optical Kerr effect study of ac susceptibilities in ultrathin cobalt films	A. Berger, S. Knappmann, H. P. Oepen
5601	Ferromagnetic resonance determination of fcc→hcp structural change in epitaxial Co/Mn superlattices	K. Ounadjela, Y. Henry, M. Farle, P. Vennegues
5604	Magnetization of thin Gd films on W(110) near the Curie temperature	M. Farle, W. A. Lewis

(Continued)

High Frequency and Nonlinear Phenomena

5607	Origin of the fine structure of subsidiary absorption in tangentially magnetized YIG films	A. V. Pomyalov, I. Laulicht
5610	Instability mechanism of collective spin wave oscillations in finite-size ferrite samples	A. N. Slavin, G. Srinivasan, S. S. Cordone, V. B. Cherepanov
5613	Controlling spin-wave chaos	S. M. Rezende, F. M. de Aguiar, A. Azevedo
5616	Spin-wave chaotic transients	F. M. de Aguiar, S. M. Rezende, F. C. S. da Silva
5619	Magnetoelastic interaction in yttrium iron garnet films with magnetic inhomogeneities through the film thickness	Yu. V. Gulyaev, A. G. Temiryazev, M. P. Tikhomirova, P. E. Zil'berman
5622	Nonlinear statics and dynamics of highly anisotropic magnets	V. S. Ostrovskii
5625	Applications of ferrites and ferromagnets in tuning rf cavities for accelerators	S. M. Hanna
5628	Forward volume wave microwave envelope solitons in yttrium iron garnet thin films: Peak profiles and multisoliton signatures (abstract)	M. A. Tsankov, M. Chen, C. E. Patton
5629	Microwave magnetic envelope solitons: Threshold powers and soliton numbers (abstract)	J. M. Nash, M. Chen, M. A. Tsankov, C. E. Patton
5630	Self-channeling of magnetostatic waves in ferromagnetic film (abstract)	J. Boyle, S. A. Nikitov, A. D. Boardman, A. Moghadam, K. M. Booth, J. G. Booth
5631	Spin wave solitons in an antiferromagnetic film (abstract)	A. D. Boardman, S. A. Nikitov, N. A. Waby
5632	Brillouin light scattering study of spin wave instability magnon distributions in yttrium iron garnet thin films (abstract)	P. Kabos, G. Wiese, C. E. Patton
5633	Nonlinear surface spin waves (abstract)	A. L. Sukstanskii, S. V. Tarasenko

Magnetic Properties: Tunneling

5634	Thermal equilibrium noise with $1/f$ spectrum and temperature-dependent magnetic viscosity in the amorphous alloy DyNi	B. Barbara, A. Ratnam, A. Cavalleri, M. Cerdonio, S. Vitale
5637	Time-dependent phenomena at low temperature in magnetic digital compact cassette tape	X. X. Zhang, J. Tejada
5639	Low-temperature magnetic relaxation of organic coated $NiFe_2O_4$ particles	R. H. Kodama, C. L. Seaman, A. E. Berkowitz, M. B. Maple
5642	Quantum tunneling across a domain wall junction (abstract)	Bernard Barbara, Leon Gunther
5642	Macroscopic quantum tunneling in antiferromagnetic horse-spleen ferritin particles (abstract)	J. Tejada, X. X. Zhang
5643	Magnetism of thin magnetic layers with strong anisotropy and quantum tunneling (abstract)	P. Perera, M. J. O'Shea

Magnetoelastic Behavior of Films and Crystals

5644	Magnetic and structural modifications in Fe and Ni films prepared by ion-assisted deposition	William A. Lewis, Michael Farle, Bruce M. Clemens, Robert L. White
5647	Magnetostrictive hysteresis in nickel polycrystalline thick films	Isabelle Brard, Roland Georges, Gilles Le Blevennec
5650	Method for determining both magnetostriction and elastic modulus by ferromagnetic resonance	R. D. McMichael
5653	Multitarget sputtering of high magnetostrictive Tb-Dy-Fe films	E. Quandt
5656	Magnetostriction, elastic moduli, and coupling factors of composite Terfenol-D	L. Sandlund, M. Fahlander, T. Cedell, A. E. Clark, J. B. Restorff, M. Wun-Fogle
5659	Structure and magnetic properties of mechanically alloyed $SmFe_2$	Clive D. Milham

(Continued)

5662 High pulsed field magnetostriction in RMn_2 (R=Gd, Tb, Nd, and Y) — M. R. Ibarra, C. Marquina, L. Garcia-Orza, Z. Arnold, A. del Moral

5665 An ultrasonic study of the Néel transition in dilute Cr-Al alloy single crystals — H. L. Alberts

5667 Magnetostriction of polycrystalline Co-Pd alloys — S. U. Jen, B. L. Chao

5670 Hysteretic and other relationships between technical magnetostriction and magnetization — I. J. Garshelis

5673 Micromagnetic model for the influence of biaxial stress on hysteretic magnetic properties — M. J. Sablik, L. A. Riley, G. L. Burkhardt, H. Kwun, P. Y. Cannell, K. T. Watts, R. A. Langman

5676 Modeling the effects of stress on magnetization in ferromagnetic materials (abstract) — D. C. Jiles

Hysteresis and Micromagnetics

5677 Interpretation of hysteresis curves and Henkel plots by the Preisach model (invited) — V. Basso, M. Lo Bue, G. Bertotti

5683 Experimental testing of applicability of the Preisach hysteresis model to superconductors — G. Friedman, L. Liu, J. S. Kouvel

5686 2D vector Preisach models and rotational hysteretic losses — I. D. Mayergoyz

5689 Demagnetized-state dependence of Henkel plots. I. The Preisach model — Ferenc Vajda, Edward Della Torre, R. D. McMichael

5692 Demagnetized-state dependence of Henkel plots. II. Domain wall motion — R. D. McMichael, Ferenc Vajda, Edward Della Torre

5695 Model calculations of rotational hysteresis for ferromagnetic particles with competing anisotropies — Y. Yoshida, T. L. Templeton, A. S. Arrott

5698 A hysteresis model with interactions — J. Planès

5701 Simulation of magnetization reversal in two-phase exchange coupled nanocrystalline materials — E. H. Feutrill, P. G. McCormick, R. Street

5704 Activation volume of a pair of magnetostatically coupled particles — A. Lyberatos

5707 Parameter template in local magnetic measurements — R. Kaczmarek, M. Dautain, S. Defoug

5710 3-D micromagnetic modeling of domain configurations in soft magnetic materials — Zhenzhou Guo, Edward Della Torre

5713 Magnetization in current carrving iron whiskers (abstract) — A. S. Arrott, J.-G. Lee

Magnetic Semiconductor

5714 Spin-dependent confinement in DMS-based heterostructures (invited) — A. Petrou, L. P. Fu, W. Y. Yu, S. T. Lee, B. T. Jonker, J. Warnock

5719 Optical transitions in (ZnCo)Se and (ZnFe)Se: Role of an effective p–d exchange (invited) — Chee-leung Mak, J. Bak, R. Sooryakumar, M. M. Steiner, B. T. Jonker

5725 Coexistence of Brillouin and Van Vleck spin exchange in $Zn_{1-x}Mn_xSe/Zn_{1-y}Fe_ySe$ spin superlattice structures — B. T. Jonker, H. Abad, L. P. Fu, W. Y. Yu, A. Petrou, J. Warnock

5728 Magnetic study of the diluted magnetic semiconductor $Sn_{1-x}Mn_xTe$ — P. J. T. Eggenkamp, C. W. H. M. Vennix, T. Story, H. J. M. Swagten, C. H. W. Swüste, W. J. M. de Jonge

5731 Magnetic behavior of $(CuIn)_{1-x}Mn_{2x}Te_2$ — P. M. Shand, P. A. Polstra, I. Miotkowski, B. C. Crooker

5734 Relaxation of magnetization in $Cd_{1-x}Mn_xTe$ diluted magnetic semiconductors under illumination — M. Smith, A. Dissanayake, H. X. Jiang, L. X. Li

5737 Theory of magnetization in IV–VI based diluted magnetic semiconductors — R. L. Hota, G. S. Tripathi, P. K. Misra

(Continued)

5740	Effects of oxygen vacancies on magnetic properties of Ca-substituted yttrium iron garnet (abstract)	Y. J. Song, R. E. Bornfreund, G. B. Turpin, P. E. Wigen

Magnetic Recording: Frequency, Spatial, and Tribological Effects

5741	Tribological studies of silicon for magnetic recording applications (invited)	Bharat Bhushan, Vilas N. Koinkar
5747	Mathematical modeling of lubrication for the head-disk interface using incompressible fluids	Paul R. Peck, Myung S. Jhon, Ralph F. Simmons, Jr., Thomas J. Janstrom
5750	Wear and stiction regimes of thin-film magnetic disks	Arlen Bowen
5753	Recording medium properties and capacity bounds	J. A. O'Sullivan, D. G. Porter, R. S. Indeck, M. W. Muller
5756	Direct imaging of track edge fringing fields on recorded media	R. D. Gomez, I. D. Mayergoyz, E. R. Burke
5759	Computation of magnetic fields from recording surfaces with multiple tracks	E. R. Burke, R. D. Gomez, R. Madabhushi, I. D. Mayergoyz
5762	Micromagnetic modeling and experimental study of transition noise correlation in thin-film media	Jian-Gang Zhu, Haiyun Wang, Thomas C. Arnoldussen
5765	Noise correlations in dibit recording	Gang Herbert Lin, H. Neal Bertram, Ralph Simmons
5768	Magnetic viscosity in high-density recording	Pu-Ling Lu, Stanley H. Charap
5771	Friction and wear of ultrahigh-density magnetic tapes	Bharat Bhushan, Steven T. Patton
5774	Analysis of write and read spacing loss for perpendicular recording (abstract)	Yoichiro Tanaka, Tomoko Komai, Takashi Hikosaka
5775	Experimental Preisach analysis of the Wohlfarth relation (abstract)	Ferenc Vajda, Edward Della Torre

Soft Magnetic Materials and Applications I

5776	Magnetic fine structure of domain walls in iron films observed with a magnetic force microscope	Roger Proksch, Sheryl Foss, E. Dan Dahlberg, Gary Prinz
5779	Influence of rf magnetron sputtering conditions on the magnetic, crystalline, and electrical properties of thin nickel films	M. S. Miller, F. E. Stageberg, Y. M. Chow, K. Rook, L. A. Heuer
5782	Molecular magnets V(tetracyanoethylene)$_x \cdot y$(solvent): Applications to magnetic shielding	B. G. Morin, C. Hahm, Joel S. Miller, A. J. Epstein
5785	Soft magnetic properties of nanocrystalline Fe-Hf-C-N films	J. O. Choi, J. J. Lee, S. H. Han, H. J. Kim, I. K. Kang
5788	Electrical characteristics of spiral coil planar inductors using amorphous alloy ribbons as magnetic layers	K. Tanigawa, H. Hirano, T. Sato, N. Tanaka
5791	Bending stresses and bistable behavior in Fe-rich amorphous wire	M. Vázquez, C. Gómez Polo, J. Velázquez, A. Hernando
5794	Relaxation in magnetic continua	V. L. Sobolev, I. Klik, C. R. Chang, H. L. Huang
5797	Generalized equations for domain wall dynamics	Vladimir L. Sobolev, Huei Li Huang, Shoan Chung Chen
5800	Magnetic induced uniaxial anisotropy in NiFe and NiFeCr films (abstract)	Terry Torng, Simon H. Liao
5800	Structural and magnetic properties of rf-sputtered iron nitrides using NH_3 (abstract)	John Q. Xiao, C. L. Chien
5801	Nucleation of the nanocrystalline phase in $Fe_{73.5}Cu_1Nb_3Si_{13.5}B_9$ (abstract)	J. D. Ayers, V. G. Harris, J. A. Sprague, W. T. Elam

Symposium: Magnetic Circular Dichroism

5802	Validity and the applicablity of magnetic-circular-dichroism sum rules for transition metals (invited)	Ruqian Wu, Dingsheng Wang, A. J. Freeman

(Continued)

5807 X-ray magnetic circular dichroism studies of multilayered thin films of 3d transition metals (invited) (abstract) — D. Weller, M. G. Samant, J. Stöhr, Y. Wu, B. D. Hermsmeier, G. Held, C. Chappert

5807 Physical information in polarized x-ray absorption spectroscopy and x-ray photoemission spectroscopy (invited) (abstract) — Bernard Theodoor Thole

5808 Element specific magnetic hysteresis curves of Fe/Cu/Co multilayers (invited) (abstract) — Y. U. Idzerda, H.-J. Lin, G. Ho, G. Meigs, A. Chaiken, G. A. Prinz, C. T. Chen

5809 Core-level magnetic circular dichroism in 3*d* and 4*f* magnetic systems (invited) (abstract) — T. Koide

5810 Soft x-ray magneto-optical Kerr effect (invited) (abstract) — C. C. Kao, C. T. Chen, E. D. Johnson, Y. U. Idzerda, J. B. Hastings

Cooperative Phenomena: Critical Phenomena and Disordered Systems

5811 Application of the spreading of damage technique to the $S=1/2$ Ising thin film — I. V. Rojdestvenski, U. M. S. Costa

5814 Quantum renormalization of the *XY* model — Alessandro Cuccoli, Valerio Tognetti, Paola Verrucchi, Ruggero Vaia

5817 Magnetization and static structure factor behavior in a first-order helix-fan phase transition — E. Rastelli, S. [illegible] lazzari, A. Tassi

5820 Magnetic properties in the Ising mixed spin-1/2–spin-1 superlattice — E. F. Sarmento, J. C. Cressoni, R. J. V. dos Santos

5823 Monte Carlo calculation of the correlation range for the $S=\frac{1}{2}$ isotropic Heisenberg ferromagnetic thin film — I. V. Rojdestvenski, M. G. Cottam, I. A. Favorski

5826 Static critical properties of disordered ferromagnets studied by superconducting quantum interference device magnetometry and small-angle neutron-scattering techniques — S. Pouget, M. Alba, M. Nogues

5829 Thermodynamical properties of a Heisenberg model with Dzyaloshinski–Moriya interactions — F. Lacerda, J. Ricardo de Sousa, I. P. Fittipaldi

5832 A unified effective-field renormalization-group framework approach for the quenched diluted Ising models — Douglas F. de Albuquerque, I. P. Fittipaldi

5835 Critical behavior of the anisotropic Heisenberg model by effective-field renormalization group — J. Ricardo de Sousa, I. P. Fittipaldi

5838 Random decorated antiferromagnetic Ising model with mixed spins — Vanêssa M. Correia, Roberto J. V. dos Santos

5841 Phase diagrams of diluted ferromagnetic Ising films in a transverse field — J. C. Cressoni, J. W. Tucker, E. F. Sarmento

5844 Relaxation dynamics in a reentrant (FeNi)Mn ferromagnet: A percolation analysis — D. Li, R. M. Roshko, G. Yang

5847 Spin glasses with cubic anisotropy — Z. Domański, T. K. Kopeć, F. Pázmándi, P. Erdös

5850 Macroscopic random magnetic anisotropy constant in crystalline $Dy_xY_{1-x}Al_2$ ($x=0.3$, 0.4) — A. del Moral, M. Ciria, J. I. Arnaudas, J. S. Abell, Y. Bi

5853 Temperature dependence of the hyperfine field distributions in the $Fe_{93.5-x}Nd_xZr_{6.5}$ ($x=0$, 2) amorphous alloys — G. K. Nicolaides, M. Pissas, D. Niarchos, R. D. Taylor, K. V. Rao

5856 Blocking of logarithmic temporal relaxation of magnetic remanence by piezomagnetically induced domains in $Fe_{1-x}Zn_xF_2$ — J. Kushauer, C. Binek, W. Kleemann

5859 One-dimensional antiferromagnetic behavior in $AVOPO_4$ ($A=NH_4$, Na) prepared from hydrothermal conditions — Charles J. O'Connor, Victoria Soghomonian, Robert C. Haushalter, Zhanwen Wang, Jon Zubieta

5862 ac susceptibility on the dilute antiferromagnet $Mn_xZn_{1-x}F_2$ close to the percolation threshold (abstract) — F. L. A. Machado, F. C. Montenegro, E. Montarroyos, J. C. O. de Jesus, A. Rosales-Rivera, S. M. Rezende

(Continued)

5862	The frequency dependence of the ferro-to-spinglass transition of amorphous Fe-rich Fe-Zr (abstract)	J. Nogués, K. V. Rao
5863	Cooperative spin-crossover transition: Effects of the antiferro- and ferri-ordered phase (abstract)	Benjamin G. Vekhter

Small Particles

5864	Nanocomposite formation in the Fe_3O_4-Zn system by reaction milling	Laszlo Takacs, Martha Pardavi-Horvath
5867	Fe-Al_2O_3 nanocomposites prepared by high-energy ball milling	Søren Linderoth, Michael S. Pedersen
5870	Synthesis and properties of α''-$Fe_{16}N_2$ in magnetic particles	Xiaohua Bao, Robert M. Metzger, Massimo Carbucicchio
5873	Magnetism and spin dynamics of nanoscale FeOOH particles	M. M. Ibrahim, G. Edwards, M. S. Seehra, B. Ganguly, G. P. Huffman
5876	Magnetic properties of microemulsion synthesized cobalt fine particles	J. P. Chen, K. M. Lee, C. M. Sorensen, K. J. Klabunde, G. C. Hadjipanayis
5879	Magnetic properties of carbon-coated rare-earth carbide nanocrystallites produced by a carbon arc method	B. Diggs, A. Zhou, C. Silva, S. Kirkpatrick, N. T. Nuhfer, M. E. McHenry, D. Petasis, S. A. Majetich, B. Brunett, J. O. Artman, S. W. Staley
5882	Magnetic properties of carbon-coated, ferromagnetic nanoparticles produced by a carbon-arc method	E. M. Brunsman, R. Sutton, E. Bortz, S. Kirkpatrick, K. Midelfort, J. Williams, P. Smith, M. E. McHenry, S. A. Majetich, J. O. Artman, M. De Graef, S. W. Staley
5885	Structural and magnetic properties of ultrafine Fe-Pd particles	L. Yiping, G. C. Hadjipanayis, C. M. Sorensen, K. J. Klabunde
5888	Fine structure and magnetic properties of Mn- and Co-doped nanocrystalline γ-Fe_2O_3	Ming-Cheng Deng, Tsung-Shune Chin, F. R. Chen
5891	Elongated superparamagnetic particles	Amikam Aharoni
5894	Interactions between single domain particles	Roger Proksch, Bruce Moskowitz
5897	Temperature dependence of switching field distribution	Jiang-Ching Lin, I. Klik, C. J. Chen, Ching-Ray Chang
5900	Dynamics of fine particles observed in zero-field neutron scattering	M. Hennion, C. Bellouard, I. Mirebeau, J. L. Dormann, R. Ober
5903	Magnetic properties of fine Ni particles coated with Pd (abstract)	Makoto Yamaguchi, Yoshichika Otani, Hideki Miyajima
5903	Nuclear magnetic resonance studies on the surface magnetism of vanadium ultrafine particles (abstract)	Yukihiro Hirayama, Tomoki Erata, Eiji Kita, Akira Tasaki

New Instrumentation and Measurement Techniques

5904	Polyphase eddy current testing	I. Marinova, S. Hayano, N. Ishida, Y. Saito, Y. Hirama, M. Yamamoto
5907	Defect recognition in conductive materials by local magnetic-field measurement	T. Doi, S. Hayano, I. Marinova, N. Ishida, Y. Saito
5910	Component-resolved imaging of surface magnetic fields	R. D. Gomez, E. R. Burke, I. D. Mayergoyz
5913	Measurement of Young's moduli for film and substrate by the mechanical resonance method	Y. H. Lee, Y. D. Shin, K. H. Lee, J. R. Rhee
5916	A new structure of torque sensors using thin pickup head—Use of mutual coupling modulation	I. Sasada, F. Koga
5919	A microwave transmission spectrometer	Carlo Waldfried, Scott Wadewitz, G. Dewar

5922	Measurements of intrinsic magnetic properties of materials from surface inspection (abstract)	Z. J. Chen, D. C. Jiles
5922	Three component magnetic field measurements using cubic anisotropy in (111) YIG films (abstract)	A. Ya. Perlov, A. I. Voronko, P. M. Vetoshko, V. B. Volkovoy
5923	Magnetoresistive characterization of thin-film structures by a gradient-field method (abstract)	P. L. Trouilloud, F. Suits, C. V. Jahnes, M. A. Russak, E. J. Spada, J. W. Chang
5924	Dispersivity measurement of magnetic powders using the magnetic noise method (abstract)	V. M. Vasilyev
	Symposium: Environmental Magnetism	
5925	Contributions of fine-particle magnetism to reading the global paleoclimate record (invited)	Subir K. Banerjee
5931	Collection, measurement, and analysis of airborne magnetic particulates from pollution in the environment (invited)	Philip J. Flanders
	Critical Phenomena	
5937	Dynamics of the one-dimensional spin-1 Heisenberg antiferromagnet with exchange and single-site anisotropy	Shu Zhang, Yongmin Yu, V. S. Viswanath, Joachim Stolze, Gerhard Müller
5940	Ferromagnetism of single crystal $Fe[S_2CN(C_2D_5)_2]_2Cl$	G. C. DeFotis, W. W. Brubaker, S. Chandarlapaty, K. L. Beers, G Coffey
5943	Spin-1/2 Heisenberg antiferromagnet on the square and triangular lattices: A comparison of finite temperature properties	N. Elstner, R. R. P. Singh, A. P. Young
5946	Disorder-driven first-order phase transformations: A model for hysteresis	Karin Dahmen, Sivan Kartha, James A. Krumhansl, Bruce W. Roberts, James P. Sethna, Joel D. Shore
5949	Magnetic properties of the two-dimensional "triangles-in-triangles" Kagomé lattice $Cu_9X_2(cpa)_6$ (X=F,Cl,Br)	Sanchit Maruti, Leonard W. ter Haar
5952	Magnetic properties of two copper (II)-halide layered perovskites	N. Sivron, T. E. Grigereit, John E. Drumheller, K. Emerson, R. D. Willett
5955	Can the universal jump be observed in two-dimensional XY magnets?	S. T. Bramwell, P. C. W. Holdsworth
5958	Strong thermal fluctuation effects on the dynamics of Bloch walls (abstract)	M. Hartl, D. Garanin, J. Koetzler
5959	Depth-dependent magnetic correlation length in terbium (abstract)	P. M. Gehring, K. Hirota, C. F. Majkrzak, G. Shirane
	Thin Film Recording Media I	
5960	Ba-ferrite thin-film media for high-density longitudinal recording (invited)	T. L. Hylton, M. A. Parker, M. Ullah, K. R. Coffey, R. Umphress, J. K. Howard
5966	Microstructural investigations of barium ferrite longitudinal thin-film media	B. Y. Wong, X. Sui, D. E. Laughlin, M. H. Kryder
5969	Low-temperature deposition of hexagonal ferrite films by sputtering	Akimitsu Morisako, Hiroaki Nakanishi, Mitsunori Matsumoto, Masahiko Naoe
5972	Surface roughness and magnetic properties of *in situ* heated and postannealed thin films of perpendicular barium ferrite	Kyusik Sin, John M. Sivertsen, Jack H. Judy
5975	Preparation of Co-Zn ferrite films at low substrate temperature by plasma-free dc sputtering for magnetic recording media	N. Matsushita, K. Noma, S. Nakagawa, M. Naoe
5978	Magnetic and crystallographic properties of Co-Cr-(Ta,Pt)/Cr films deposited by excimer laser ablation	A. Ishikawa, K. Tanahashi, Y. Yahisa, Y. Hosoe, Y. Shiroishi
5981	Transverse susceptibility and ferromagnetic resonance of Hi-8 metal-evaporated tape	C. Sürig, G. Zimmermann, K. A. Hempel

(Continued)

5984 Low-temperature sputter deposition of high-coercivity Co-Cr films for perpendicular recording — Naoki Honda, Kazuhiro Ouchi, Shun-ichi Iwasaki

5987 Improvement of anisotropy of perpendicular magnetic recording tape by Ta addition and Kr sputtering gas (abstract) — Kiyoshi Kuga, Hideaki Yoshimoto, Yoshiro Yoneda, Junji Numazawa, Masahiko Naoe

Emerging Hard Magnets Based on Interstitials

5988 High field magnetization measurements of Sm_2Fe_{17}, $Sm_2Fe_{17}N_3$, $Sm_2Fe_{17}D_5$, and Pr_2Fe_{17}, $Pr_2Fe_{17}N_3$ (invited) — O. Isnard, S. Miraglia, M. Guillot, D. Fruchart

5994 Comparative Mössbauer effect study of several R_2Fe_{17} and $R_2Fe_{17}N_x$ compounds — Gary J. Long, S. Mishra, O. A. Pringle, F. Grandjean, K. H. J. Buschow

5997 The effects of group IV B/V B/VI B additions on the magnetic properties of $Sm_{2+\delta}Fe_{17}$ carbonitrides — X. Chen, Er. Girt, Z. Altounian

6000 Phase transformation induced by gas phase reaction in $RFe_{10}SiC_x$ alloys — E. W. Singleton, G. C. Hadjipanayis, V. Papaefthymiou, Z. Hu, W. B. Yelon

6003 A detailed study of nitride precipitates in Nd_2Fe_{17} — C. C. Colucci, S. Gama, C. A. Ribeiro, L. P Cardoso

6006 Aligned high anisotropy $Pr(Fe,Co,Mo)_{12}N$ film samples — R. Rani, H. Hegde, A. Navarathna, F. J. Cadieu

6009 Anisotropy and flux density enhancement in aligned $ThMn_{12}$-type $NdFe_{11}Co_{1-y}Mo_yN$ film samples — A. Navarathna, H. Hegde, R. Rani, F. J. Cadieu

6012 Hydrogenation decomposition desorption recombination magnets based on $Sm_{2+\delta}Fe_{17}M_{0.4}$ carbonitrides (M=IVB/VB/VIB group elements) — X. Chen, Z. Altounian

6015 Nitriding of melt-spun Nd-Fe-Mo alloys — F. E. Pinkerton, C. D. Fuerst, J. F. Herbst

6018 Effect of milling on the magnetic and microstructural properties of $Sm_2Fe_{17}N_x$ permanent magnets — P. A. P. Wendhausen, B. Gebel, D. Eckert, K.-H. Müller

6021 Magnetic properties of $Y(Fe,Co)_{10}Mo_2$ alloys — Xie Xu, Roy Tucker, S. A. Shaheen

Field Computations

6024 Magnetic thin-film media response in presence of displacement eddy currents — A. Geri, A. Salvini, G. M. Veca

6027 On finite element implementation of impedance boundary conditions — I. D. Mayergoyz, G. Bedrosian

6030 Three-dimensional iterative solution for the multiconductor eddy current and free surface calculations — M. Ramadan Ahmed, K. F. Ali, Ibrahim Moustafa

6033 Modeling and analysis of electric and magnetic coupled problems under nonlinear conditions — A. Geri, M. La Rosa, G. M. Veca

6036 Transformation methods in computational electromagnetism — A. Nicolet, J.-F. Remacle, B. Meys, A. Genon, W. Legros

6039 The effects of various magnetic materials on lamination design for stator–rotor diecasting of induction motors for electric vehicle applications — N. M. Elkasabgy, C. Di Pietro

6042 An improved method for magnetic flux density visualization using three-dimensional edge finite element method — Vlatko Čingoski, Hideo Yamashita

6045 Optimum design of voice coil motor with constant torque coefficients using evolution strategy — Chang Seop Koh, Osama A. Mohammed, Jun-o Kim, Song-yop Hahn

6048 Three-dimensional eddy current solution of a polyphase machine test model (abstract) — Uwe Pahner, Ronnie Belmans, Vlado Ostovic

6049 Numerical methods and measurement systems for nonlinear magnetic circuits (abstract) — Axel Heitbrink, Hans Dieter Storzer, Adalbert Beyer

6050 Comparative analysis of two methods for time-harmonic solution of the steady state in induction motors (abstract) — Robrecht DeWeerdt, Kostadin Brandisky, Uwe Pahner, Ronnie Belmans

(Continued)

Spin Waves, Hyperfine Fields, and Resonance

6051 Selection of the ground state in $CsCuCl_3$ by quantum fluctuations — E. Rastelli, A. Tassi

6054 Scaling behavior of the homogeneous magnetization dynamics in the ferromagnetic state of EuS — R. Dombrowski, D. Görlitz, J. Kötzler, Chr. Marx

6057 Dynamical properties of quantum spin systems in magnetically ordered product ground states — V. S. Viswanath, Joachim Stolze, Gerhard Müller

6060 Magnons in ferromagnetic terbium under high pressure — S. Kawano, J. A. Fernandez-Baca, R. M. Nicklow

6063 Polarization analysis of magnons in $CsMnI_3$ — Z. Tun, T. C. Hsu, J-G. Lussier

6066 Orientation dependence of dipole gaps in the magnetostatic wave spectrum of Bi-substituted iron garnets — Ana K. Chernakova, Andrew Cash, Jose Peruyero, Daniel D. Stancil

6069 Polarization analysis of the magnetic excitations in $Fe_{65}Ni_{35}$ Invar — J. W. Lynn, N. Rosov, M. Acet, H. Bach

6072 Temperature dependence of the magnetic excitations in ordered and disordered $Fe_{72}Pt_{28}$ — N. Rosov, J. W. Lynn, J. Kästner, E. F. Wassermann, T. Chattopadhyay, H. Bach

6075 Theory of ferromagnetic resonance relaxation in very small solids — J. B. Sokoloff

6078 Crystallographic and magnetic properties of $Co_xFe_{1-x}Cr_2S_4$ — Chul Sung Kim, Min Yong Ha, Heung Moon Ko, Young Jei Oh, Heung Soo Lee, Sang Youl Lee, Jung Chul Sur, Jae Yun Park

6081 The effect of Co doping on spin cluster resonance in the one-dimensional Ising ferromagnet FeTAC — R. S. Rubins, T. D. Black, K. Ravindran, John E. Drumheller

6084 New perspective on the Green's function dipole-exchange spin wave theory for thin films (abstract) — Ming Chen, Carl E. Patton

6085 Ground state and spin dynamics in hexagonal antiferromagnet $CsCuCl_3$ (abstract) — E. P. Stefanovskii, A. L. Sukstanskii

Magnetic Bubble and VBL Memories

6086 Successive Bloch line write operation in a 1-μM bubble material — K. Matsuyama, T. Ohyama, H. Asada, K. Taniguchi

6089 Micromagnetic computation for wall and Bloch line coercivity in thin films with perpendicular anisotropy — H. Asada, K. Matsuyama, M. Gamachi, K. Taniguchi

6092 Phase transitions in bubble lattice under temperature lowering (abstract) — V. S. Gerasimchuk, Yu. I. Gorobets, K. De Ville

6093 An adaptive computational method for domain wall dynamics (abstract) — Sergey G. Osipov

Soft Magnetic Materials: Ferrites

6094 Wet-process preparation of amorphous Y-Fe oxide films ferromagnetic at room temperature — Q. Zhang, T. Itoh, M. Abe, M. J. Zhang

6097 Magnetic anomalies in single crystal Fe_3O_4 thin films — D. T. Margulies, F. T. Parker, A. E. Berkowitz

6100 An analysis of the high-temperature relaxation in polycrystalline magnetite — J. Castro, D. Martinez, J. Rivas, H. J. Blythe

6103 $Dy_3Fe_5O_{12}$ garnet thin films grown from sputtering of metallic targets — J. Ostoréro, M. Escorne, A. Pecheron-Guegan, F. Soulette, H. Le Gall

6106 Enhanced coercivity due to a local anisotropy increase — J. A. Jatau, M. Pardavi-Horváth, E. Della Torre

6109 The microwave absorbing and resonance phenomena of Y-type hexagonal ferrite microwave absorbers — H. J. Kwon, J. Y. Shin, J. H. Oh

6112 Effect of Er_2O_3 addition on microstructure and physical properties of Mn–Zn ferrites for high-power use — C. S. Liu, J. M. Wu, C. J. Chen, M. J. Tung

(Continued)

6115	Dispersion observed in electrical properties of titanium-substituted lithium ferrites	Bijoy Kumar Kuanr, G. P. Srivastava
6118	Electrical conductivity of Mn–Zn ferrites	D. Ravinder, K. Latha
6121	Composition dependence of the elastic moduli of mixed lithium–cadmium ferrites	D. Ravinder
6124	Deposition and properties of $NiFe_2O_4$ thin films (abstract)	R. B. van Dover, E. M. Gyorgy, J. M. Phillips, J. H. Marshall, R. J. Felder, R. M. Fleming, H. O'Bryan, Jr.
6124	Studies of stoichiometric variations of epitaxially grown $Fe_{3-\delta}O_4$ (abstract)	E. Lochner, K. A. Shaw, R. C. DiBari, D. Hilton, D. M. Lind, S. D. Berry
6125	Cation distribution of Li-Ti mixed ferrites (abstract)	M. Bhagavantha Reddy, P. Venugopal Reddy

Thin Film Recording Media II

6126	Magnetic and microstructural properties of CoCrPt/CoCrPtSi dual-layered magnetic recording media	N. Inaba, Y. Matsuda, M. Suzuki, A. Nakamura, M. Futamoto
6129	Bicrystal advanced thin-film media for high density recording	Tai Min, Jian-Gang Zhu
6132	AFM structure and media noise of SmCo/Cr thin films and hard disks	E. M. T. Velu, D. N. Lambeth, J. T. Thornton, P. E. Russell
6135	Modeling of thin-film media with advanced microstructure for ultrahigh density recording	Xiao-Guang Ye, Jian-Gang Zhu
6138	Evaluation of the CoCrTaPt alloy for longitudinal magnetic recording	Yuanda Cheng, Mojtaba Sedighi, Irene Lam, Richard A. Gardner, ZhiJun Yang, Michael R. Scheinfein
6141	Analysis of the electronic properties of CoCrPt thin films using parallel electron energy loss spectroscopy (PEELS)	Pawel Glijer, John M. Sivertsen, Jack H. Judy
6144	Noise properties and microstructure of oriented CoCrTa/Cr media	R. Ranjan, W. R. Bennett, G. J. Tarnopolsky, T. Yamashita, T. Nolan, R. Sinclair
6147	Effects of oxide addition on magnetic and structural properties of CoNiPt alloy films	A. Murayama, S. Kondoh, M. Miyamura
6150	Comparison of reproduce signal and noise of conventional and keepered CoCrTa/Cr thin film media	Kyusik Sin, Juren Ding, Pawel Glijer, John M. Sivertsen, Jack H. Judy, Jian-Gang Zhu
6153	Process temperature dependence of ∂M plots on Co alloy media on amorphous carbon substrates	Masago Kuwabara, Haydee Saffari, Mark R. Visokay, Hidetaka Hayashi, Motoharu Sato
6156	Friction and wear of ion-implanted diamondlike carbon and fullerene films for thin-film rigid disks	Bharat Bhushan, B. K. Gupta
6159	Thin film disks for high density recording with textured underlayers (abstract)	Mohammad Mirzamaani, Michael A. Russak, Christopher V. Jahnes
6160	A study of the structural properties of sputtered CoCrPt based on x-ray diffraction, small angle x-ray scattering, XAFS, and transmission electron microscopy measurements (abstract)	S. Yumoto, N. Ohshima
6161	Multinuclear nonmagnetic resonance studies of perfluoro poly ether lubricants (abstract)	K. V. Viswanathan
6162	The durability of new rigid disks by molded plastic substrates (abstract)	Osamu Morita, T Sano, Yasuyuki Imai, Naoko Hisayama, Hiroshi Takino

Coupling Through Nonmagnetic Layers

6163	Temperature-dependent non-Heisenberg exchange coupling of ferromagnetic layers (invited)	R. P. Erickson

(Continued)

6169	Photo-induced antiferromagnetic interlayer coupling in Fe superlattices with iron silicide spacers (invited)	J. E. Mattson, Eric E. Fullerton, Sudha Kumar, S. R. Lee, C. H. Sowers, M. Grimsditch, S. D. Bader, F. T. Parker
6174	An alternate route to giant magnetoresistance in MBE-grown Co–Cu superlattices (invited)	Roy Clarke, Darryl Barlett, Frank Tsui, Baoxing Chen, Ctirad Uher
6178	Magnetic profile as a function of structural disorder in Fe/Cr superlattices	Michael J. Pechan, J. F. Ankner, C. F. Majkrazk, David M. Kelly, Ivan K. Schuller
6181	Temperature dependence of the exchange coupling in the Fe(001) whisker/11 ML Cr/20 ML Fe structure	M. From, L. X. Liao, J. F. Cochran, B. Heinrich
6184	Anisotropy studies of AFM coupled MBE grown Co/Cu(001) superlattices	K. Bröhl, S. Di Nunzio, F. Schreiber, Th. Zeidler, H. Zabel
6187	"Loose spins" in Fe/Cu/Fe(001) structures	B. Heinrich, Z. Celinski, L. X. Liao, M. From, J. F. Cochran
6190	Interlayer coupling and spin polarization of the nonmagnetic layers in Fe/Cu and Fe/Ag CMFs	Y. B. Xu, M. Lu, Q. Y. Jin, C. Hu, Y. Z. Miao, Y. Zhai, Q. S. Bie, H. R. Zhai, G. L. Dunifer, R. Naik, M. Ahmad
6193	Growth temperature dependence of biquadratic coupling in Fe/Cr(100) superlattices studied by polarized neutron reflectivity and x-ray diffraction (abstract)	M. Schäfer, J. A. Wolf, P. Grünberg, J. F. Ankner, A. Schreyer, H. Zabel, C. F. Majkrzak
	Symposium: Novel Time-Resolved Probes of Dynamical Magnetism	
6194	Picosecond pulsed-field probes of magnetic systems (invited)	M. R. Freeman
6199	Femtosecond Faraday rotation in spin-engineered heterostructures (invited)	J. J. Baumberg, D. D. Awschalom, N. Samarth
6205	Time-resolved scanning probe microscopy: Investigations and applications of dynamic magnetostriction (invited)	G. Nunes, Jr., M. R. Freeman
6211	Magnetic resonance detection and imaging using force microscope techniques (invited)	O. Züger, D. Rugar
6217	Measurement of thermal switching of the magnetization of single domain particles (invited)	M. Lederman, D. R. Fredkin, R. O'Barr, S. Schultz, M. Ozaki
	Hard Magnets III: Substitutional Alloys and Novel Materials	
6223	Magnetic phase diagram of $(Tb_{1-x}Gd_x)Fe_{11}Ti$ alloys	L. C. C. M. Nagamine, H. R. Rechenberg, P. A. Algarabel, M. R. Ibarra
6226	Magnetic phase diagram of $Nd(Fe,Mo)_{12}$ alloys	Y. Z. Wang, B. P. Hu, X. L. Rao, G. C. Liu, L. Song, L. Yin, W. Y. Lai
6229	Magnetic anisotropies in $RFe_{10-x}Co_yMo_2$ compounds (R=Dy, Er)	Roy Tucker, Xie Xu, S. A. Shaheen
6232	Magnetic properties of $Nd(Fe,Ti)_{12}$ and $Nd(Fe,Ti)_{12}N_x$ films of perpendicular texture	D. Wang, D. J. Sellmyer, I. Panagiotopoulos, D. Niarchos
6235	^{57}Fe Mössbauer studies of $Nd(Fe_{12-x}Mo_x)$ and $Nd(Fe_{12-x}Mo_x)N_{0.9}$ (x=1.25 and 1.50)	Qi-Nian Qi, Bo-Ping Hu, J. M. D. Coey
6238	Magnetic properties of $(Er,R)_2Fe_{17}N_y$ compounds (R=Y,Gd)	J. L. Wang, W. G. Lin, N. Tang, W. Z. Li, Y. H. Gao, F. M. Yang
6241	Magnetic properties of $Er_2Fe_{17-x}Al_xN_y$ compounds	F. M. Yang, N. Tang, J. L. Wang, X. P. Zhong, R. W. Zhao, W. G. Lin
6244	Electrical and magnetic studies of (Cu/Zn)-bonded $Sm_2Fe_{17}M_xN_y$ magnets (M=B or C)	Y. D. Yao, P. C. Kuo, W. C. Chang, C. J. Liu

6688 Magnetic and crystallographic properties of molecular beam epitaxially grown Fe_3O_4/NiO superlattices and Fe_3O_4 films — J. J. Krebs, D. M. Lind, E. Lochner, K. A. Shaw, W. Portwine, S. D. Berry

6691 Studies of the Verwey transition in Fe_3O_4/NiO superlattices by SQUID magnetometry and neutron diffraction techniques (abstract) — S. D. Berry, J. A. Borchers, R. W. Erwin, D. M. Lind, K. A. Shaw, E. Lochner

6692 Magnetic structure determination for Fe_3O_4/NiO superlattices by neutron diffraction techniques (abstract) — J. A. Borchers, R. W. Erwin, J. F. Ankner, S. D. Berry, D. M. Lind, E. Lochner, K. A. Shaw

Symposium: Perpendicular Transport in Layered Structures

6693 Perpendicular magnetoresistance in magnetic multilayers: Theoretical model and discussion (invited) — Albert Fert, Thierry Valet, Jozef Barnas

6699 How to isolate effects of spin-flip scattering on giant magnetoresistance in magnetic multilayers (invited) — J. Bass, Q. Yang, S. F. Lee, P. Holody, R. Loloee, P. A. Schroeder, W. P. Pratt, Jr.

6704 Scattering theory of perpendicular transport in metallic multilayers (invited) — Gerrit E. W. Bauer, Arne Brataas, Kees M. Schep, Paul J. Kelly

6709 Perpendicular giant magnetoresistance of microstructures in Fe/Cr and Co/Cu multilayers (invited) — M. A. M. Gijs, J. B. Giesbers, M. T. Johnson, J. B. F. aan de Stegge, H. H. J. M. Janssen, S. K. J. Lenczowski, R. J. M. van de Veerdonk, A. J. M. de Jonge

6714 Spin polarization of gold films via transported (invited) — Mark Johnson

High T_c Superconductivity: Experiment and Theory

6720 Transport and magnetic properties of polycrystalline $Sm_{2-x}Ce_xCuO_{4-y}$ — R. F. Jardim, C. H. Westphal, C. H. Cohenca, L. Ben-Dor, M. B. Maple

6723 Relationship between weak ferromagnetism, superconductivity, and lattice parameter in the $A_{2-x-y}B_xCe_yCuO_4$ (A,B = La, Pr, Nd, Sm, Eu, Gd, Y) compounds — T. Schultz, R. Smith, A. Fondado, C. Maley, T. Beacom, P. Tinklenberg, J. Gross, C. Saylor, S. Oseroff, Z. Fisk, S.-W. Cheong, T. E. Jones

6726 Alkali metals impurities influence on the magnetic and electrical properties of YBCO — I. Nedkov, A. Veneva

(Continued)

6729	Kinematical pairing and magnetism in layered systems	Valery A. Ivanov, Michail Ye. Zhuravlev, Pavel B. Z'ubin
6731	Ground-state properties and excitations of an integrable one-dimensional model with δ-function interaction involving several bands	P. Schlottmann
6734	Two-band model for Kondo insulators: Thermodynamic and scaling properties	M. A. Continentino, G. M. Japiassu, A. Troper
6737	Local magnetic moments and intermediate valence state of cerium impurities in ferromagnetic rare-earth metals	C. E. Leal, A. Troper
6740	Thermoelectric power studies of a $Nd_{1.82-x}Sr_xCe_{0.18}CuO_y$ superconducting system (abstract)	Okram G. Singh, B. D. Padalia, Om Prakash, V. N. Moorthy, Anant V. Narlikar
6740	The magnetic and superconducting properties of $Pb_2Sr_2(R/Ca)Cu_3O_8$, R=Pr, Ce, and Cm (abstract)	J. Simon Xue, C. W. Williams, L. Soderholm
6741	^{57}Fe and ^{119}Sn Mössbauer studies on $La_{1.25}Nd_{0.6}Sr_{0.15}CuO_4$: Evidence for local magnetic ordering below $\simeq$32 K (abstract)	M. Breuer, B. Büchner, H. Micklitz, E. Baggio-Saitovitch, I. Souza Azevedo, R. B. Scorzelli, M. M. Abd-Elmeguid
6741	Peculiarities of inelastic neutron scattering on magnons in high-T_c materials of stoichiometrical composition Nd_2CuO_4, La_2CuO_4, and $YBa_2Cu_3O_6$ (abstract)	Yu. Pashkevich, M. Larionov
6742	The sign reversal of the acoustoelectric effect in anisotropic superconductors (abstract)	A. V. Goltsev
6743	Four-spin exchange in Bi_2CuO_4 (abstract)	G. Petrakovskii, V. Val'kov, K. Sablina, B. Fedoseev, A. Furrer, B. Roessli, P. Fischer
6744	Antiferromagnetic spin correlation suppression and superconducting characteristics improvement in $YBa_2Cu_3O_{6+\delta}$ films under light illumination (abstract)	V. Eremenko, V. Fomin, I. Kachur, V. Piryatinskaya, O. Prikhod'ko
6744	ac susceptibility of $Pb_xBi_{2-x}Sr_2Ca_2Cu_3O_{10}$ high T_c superconductors sintered for different durations (abstract)	S. C. Mathur, D. C. Dube, Urvija Sinha, P. K. N. Raghavan
6745	Spin magnetic moment of conduction quasiparticle (abstract)	Vladimir L. Safonov
6745	Restoration of the continuous phase transition in the vortex state due to the lattice translational symmetry: Large-N limit (abstract)	Boris N. Shalaev, Sergey A. Ktitorov
6746	Damping of spin waves in a square-lattice quantum antiferromagnet due to spin-phonon interaction (abstract)	Dirk Uwe Saenger
6746	The superconducting transition temperature of layered $S_l - J_{ij} - S_j$ superconductors (abstract)	Valery A. Cherenkov
6747	Magnetism and superconductivity in heavy-fermion compounds (abstract)	A. V. Goltsev

Magneto-optic and Other Magnetic Properties

6748	Magnetic properties of an isolated ferromagnetic bond embedded in Heisenberg antiferromagnets	S. T. Ting, S. Haas, J. E. Crow
6751	Spin diffusion in classical Heisenberg magnets with uniform, alternating, and random exchange	Niraj Srivastava, Jian-Min Liu, V. S. Viswanath, Gerhard Müller
6754	Theoretical study of magnetostriction in FeTaN thin films	James C. Cates, Chester Alexander, Jr.
6757	Dependence of the magnetic properties $Gd_{2-x}Ce_xCuO_4$, $0 \leq x \leq 0.15$, on their particle size	J. Mahía, C. Vázquez-Vázquez, J. Mira, M. A. López-Quintela, J. Rivas, T. E. Jones, S. B. Oseroff
6760	Magnetic properties of materials in the $CaO-P_2O_5-Fe_2O_3$ system	Binod Kumar, Christina H. Chen
6763	Magnetic properties of $Y_{3-x-y}Pr_xLu_yFe_5O_{12}$ garnet films	A. Azevedo, C. Cinbis, M. H. Kryder
6766	Magnetic properties of amorphous Cr–Fe alloys prepared by thermal evaporation and mechanical milling	S. K. Xia, E. Baggio-Saitovitch, C. Larica, B. V. B. Sarkissian, S. F. Cunha, J. L. Tholence

(Continued)

6769 Magnetostriction in RE-Co amorphous alloy films (abstract) — S. Uchiyama, S. Yoshino, H. Takahashi, K. Tomi-ita, T. Mori, A. Itakura, S. Iwata, S. Tsunashima

6769 A model for the Barkhausen noise power as a function of applied field and stress (abstract) — M. J. Sablik

Recording Head and System Modeling and Phenomena

6770 The effects of closure domains on flux conduction in thin film recording head — Zhenzhou Guo, Edward Della Torre

6773 Effect of recorded transition shape on spatial noise distributions and correlations — T. C. Arnoldussen, J. G. Zhu

6776 Mean interaction field in magnetic recording media — Ikuya Tagawa, Akihiko Takeo, Yoshihisa Nakamura

6779 Micromagnetic studies of medium noise mechanisms — Xiaodong Che, H. Neal Bertram

6782 Improving ferrite MIG head read-back distortions caused by domain walls and granularity (abstract) — B. E. Argyle, R. Schäfer, P. L. Trouilloud, M. E. Re, A. P. Praino, S. Takayama, D. Dingley

Magneto-optics

6783 MO polar Kerr studies of Co rich molecular beam epitaxy grown Au/Co multilayers — S. Višňovský, M. Nývlt, V. Prosser, R. Atkinson, W. R. Hendren, I. W. Salter, M. J. Walker

6786 Magneto-optical properties and magnetization processes in superlattices — Ron Atkinson, Nikolai F. Kubrakov, Sergey N. Utochkin, Anatoley K. Zvezdin

6789 The magnetic and magneto-optical properties of Co, Cr, Mn, and Ni substituted barium ferrite films — R. Carey, P. A. Gago Sandoval, D. M. Newman, B. W. J. Thomas

6792 Anisotropy of the magnetic and magnetooptic properties of HoIG:Al single crystals (low and high magnetic field) — J. Ostoréro, M. Guillot

6795 Measurement of the Faraday effect of garnet film in alternating magnetic fields — Jia Ouyang, Ying Zhang, Huahui He

6798 An investigation on the magneto-optic and magnetic properties of Tb:YIG — Jie Hui Yang, You Xu, Guo Ying Zhang

6801 Magneto-optical properties of $(BiGdY)_3Fe_5O_{12}$ for optical magnetic field sensors — O. Kamada, H. Minemoto, N. Itoh

6804 Magneto-optical properties of Al and In-substituted CeYIG epitaxial films grown by sputtering (abstract) — M. Gomi, M. Abe

6804 Enhancement of the magneto-optical quality of YIG films in a structure containing a thin metal film (abstract) — A. D. Boardman, A. I. Voronko, P. M. Vetoshko, V. B. Volkovoy, A. Yu. Toporov

6805 Magnetic Davydov splitting in 2D AFM $(CH_2)_2(NH_3)_2MnCl_4$ (abstract) — V. Eremenko, I. Kachur, V. Piryatinskaya, V. Shapiro

Symposium: User Facilities in Magnetism

6806 Magnetic neutron scattering (invited) — J. W. Lynn

6811 Soft x-ray synchrotron radiation facilities for the study of magnetic materials (invited) (abstract) — Brian Tonner, W. O'Brien, M. A. Green, H. Höchst, R. Reininger

6812 High magnetic field research: Overview of facilities and science and technology opportunities (invited) (abstract) — J. E. Crow, H. J. Schneider-Muntau, D. M. Parkin, N. Sullivan

Magnetic Structure

6813 $LiNiO_2$: Quantum liquid or concentrated spin glass? — M. Rosenberg, P. Stelmaszyk, V. Klein, S. Kemmler-Sack, G. Filoti

6816 Disappearance of three-dimensional magnetic ordering in Gd_2CuO_4 — T. Chattopadhyay, P. J. Brown, B. Roessli

(Continued)

6819	Spin-Peierls transition in $CuGeO_3$: Electron paramagnetic resonance study	S. Oseroff, S-W. Cheong, A. Fondado, B. Aktas, Z. Fisk
6822	Observations of magnetization reversal and magnetic clusters in copper ferrite films	M. M. Ibrahim, M. S. Seehra, G. Srinivasan
6825	The structure and spin dynamics of lanthanide-bearing silicate glasses	A. J. G. Ellison, C.-K. Loong, J. Wagner
6828	Magnetization and ferromagnetic resonance studies on amorphous films of Fe_2O_3-Bi_2O_3-Li_2O	J. Chen, S. Cheney, G. Srinivasan
6831	Hysteresis and magnetic aftereffect in amorphous CoZrDy films: Trends and variations versus Dy content	G. Suran, K. Roky
6834	First-principles calculation of orbital moment distribution in amorphous Fe	Xue-Fu Zhong, W. Y. Ching
6837	A magnetocalorimetric study of spin fluctuations in amorphous Fe_xZr_{100-x}	A. LeR. Dawson, D. H. Ryan
6840	Magnetic properties of colloidal silica: Potassium silicate gel/iron nanocomposites	R. D. Shull, H. M. Kerch, J. J. Ritter

Magneto-optic Recording

6843	Origin of high coercive force in rare-earth–transmission-metal thin film	D. Roy Callaby, Robert D. Lorentz, Shigeki Yatsuya
6846	Study of the effect of defect sizes and their distribution on the coercivity of magnetic media	James A. Jatau, Edward Della Torre
6849	Reversal mechanisms in Tb/Fe multilayers	K. O'Grady, T. Thomson, S. J. Greaves, G. Bayreuther
6852	Write/erase cyclability of TbFeCo for mark edge recording	Hiroyuki Awano, Masahiro Ojima, Katsusuke Shimazaki, Satoru Ohnuki, Norio Ohta
6855	Recording characteristics of Kr-sputtered Tb/FeCo multilayer magneto-optical disks	Hiro Karube, Kunihiko Matsumura, Masafumi Nakada, Osamu Okada
6858	Double compensation point media for direct overwrite	T. K. Hatwar, D. J. Genova, R. H. Victora
6861	Design and performance of magneto-optic enhanced Co/Pt-based trilayers having zero Kerr ellipticity	R. Atkinson, P. J. Grundy, C. M. Hanratty, R. J. Pollard, I. W. Salter
6864	Effect of substrate roughness on microstructure, uniaxial anisotropy, and coercivity of Co/Pt multilayer thin films	Chung-Hee Chang, Mark H. Kryder
6867	Depth distribution of birefringence in magneto-optical recording disk substrates	Raymond-Noel Kono, Myung S. Jhon, Thomas E. Karis
6870	Growth and subsequent relaxation of the anisotropic structure of amorphous Tb-Fe (abstract)	F. Hellman, M. C Robson, M. T. Messer
6871	Macroscopic ferrimagnets as magneto-optic media (abstract)	Richard J. Gambino, Ralph R. Ruf, Nestor Bojarczuk

Magnetic Imaging and Measuring Techniques

6872	High-resolution magneto-optic measurements with a Sagnac interferometer (invited)	A. Kapitulnik, J. S. Dodge, M. M. Fejer
6878	dc magnetic force microscopy imaging of thin-film recording head	Paul Rice, John Moreland, Andrzej Wadas
6881	Proposed antiferromagnetically coupled dual-layer magnetic force microscope tips	John O. Oti, Paul Rice, Stephen E. Russek
6884	Anisotropy and magnetostriction measurement by interferometry	Peter S. Harllee III, George H. Bellesis, David N. Lambeth
6887	New complex permeability measurement device for thin magnetic films	S. Hayano, I. Marinova, Y. Saito
6890	Element specific magnetic microscopy with x rays (invited) (abstract)	B. Hermsmeier, J. Stöhr, Y. Wu, M. Samant, G. Harp, S. Koranda, D. Dunham, B. P. Tonner

(Continued)

6890	High spatial resolution spin-polarized scanning electron microscopy (abstract)	H. Matsuyama, K. Koike, F. Tomiyama, H. Aoi, Y. Shiroishi, A. Ishikawa
6891	An analysis of magnetization patterns measured using a magnetic force scanning tunneling microscope (abstract)	E. R. Burke, R. D. Gomez, I. D. Mayergoyz
6892	Magnetic force microscopy of single crystal magnetite (Fe_3O_4) (abstract)	R. Proksch, S. Foss, C. Orme, S. Sahu, B. Moskowitz
6893	Interpretation of magnetic force microscopic images (abstract)	Atsushi Kikukawa, Hiroyuki Awano, Sumio Hosaka, Yukio Honda, Ryo Imura

Giant Magnetoresistence in Granular Materials

6894	Determination of para- and ferromagnetic components of magnetization and magnetoresistance of granular Co/Ag films (invited)	Mary Beth Stearns, Yuanda Cheng
6900	Giant magnetoresistance and microstructural characteristics of epitaxial Fe-Ag and Co-Ag granular thin films	N. Thangaraj, C. Echer, Kannan M. Krishnan, R. F. C. Farrow, R. F. Marks, S. S. P. Parkin
6903	Giant magnetoresistance and its dependence on processing conditions in magnetic granular alloys	Jian-Qing Wang, Edward Price, Gang Xiao
6906	Theory of magnetotransport in inhomogeneous magnetic structures	Horacio E. Camblong, Shufeng Zhang, Peter M. Levy
6909	Giant magnetoresistance of dilute Cu(Co) granular films	R. J. Gambino, T. R. McGuire, J. M. E. Harper, Cyril Cabral, Jr.
6912	Dependence of giant magnetoresistance on film thickness in heterogeneous Co-Ag alloys	J. R. Mitchell, A. E. Berkowitz
6915	Modulation-induced giant magnetoresistance in a spinodally decomposed Cu-Ni-Fe alloy	S. Jin, L. H. Chen, T. H. Tiefel, M. Eibschutz, R. Ramesh
6918	Magnetoresistance in a granular Fe–Mg system	Kevin Pettit, E. Kita, K. Araga, A. Tasaki, M. B. Salamon
6921	Giant magnetoresistance and induced exchange anisotropy in mechanically alloyed $Co_{30}Ag_{70}$	K. Ounadjela, A. Herr, R. Poinsot, J. M. D. Coey, A. Fagan, C. R. Staddon, D. Daniel, J. F. Gregg, S. M. Thompson, K. O'Grady, S. Grieves
6924	Correlation of x-ray diffraction and Mössbauer effect measurements with magnetic properties of heat-treated $Cu_{80}Co_{15}Fe_5$ ribbons	V. G. Harris, M. Rubinstein, B. N. Das, N. C. Koon
6927	Giant magnetoresistance in $Ag_{1-x}Ni_{x-y}Fe_y$ heterogeneous alloy films	M. L. Watson, V. G. Lewis, K. O'Grady
6930	Giant and anisotropic magnetoresistance in single layer $Ni_{66}Fe_{16}Co_{18}$–Ag films	A. Waknis, J. A. Barnard, M. R. Parker
6933	Giant magnetoresistance in heterogeneous $(CoFe)_XAg_{1-x}$ films (abstract)	R. S. Beach, D. Rao, M. J. Carey, F. T. Parker, A. E. Berkowitz

Soft Magnetic Materials and Applications II

6934	The effects of film geometry on the properties of FeTaN films	Gan Qiu, J. A. Barnard
6937	Relationship between ac and dc magnetic properties of a Co-based amorphous alloy	S. H. Lim, Y. S. Choi, T. H. Noh, I. K. Kang
6940	Effects of nanocrystallization upon the soft magnetic properties of Co-based amorphous alloys	P. Quintana, E. Amano, R. Valenzuela, J. T. S. Irvine
6943	Magnetic properties behaviors in $Fe_{88}Zr_7B_4Cu_1$ nanocrystalline alloy prepared by different postanneal cooling rates	K. Y. Kim, J. S. Lee, T. H. Noh, I. K. Kang, T. Kang
6946	Soft-magnetic properties of amorphous tapes after dynamic current annealing	M. A. Escobar, J. C. Perron, R. Barrué, A. R. Yavari
6949	Magnetic behavior of the amorphous wires covered by glass	Horia Chiriac, Gheorghe Pop, Firuta Barariu, Manuel Vázquez

AUTHOR INDEX

A publication of the American Institute of Physics, 500 Sunnyside Blvd., Woodbury, NY 11797-2999

Information for Contributors

Send manuscripts to the *Journal of Applied Physics,* Argonne National Laboratory, P.O. Box 8296, Argonne, Ill. 60439-8296.

For general format and style consult recent issues of the journal and the 1990 Fourth Edition of the *AIP Style Manual,* published by the American Institute of Physics. It may be obtained for $10.00 (payment must be enclosed) from the American Institute of Physics, c/o AIDC, 64 Depot Road, Colchester, VT 05446, 800-488-2665.

Two types of manuscripts are acceptable: **full-length** and **Communications.** The latter are short contributions not exceeding in length nine double-spaced typewritten pages or three printed pages including allowances for illustrations, references, and tables. Abstracts are required for manuscripts of both types.

The **Manuscript**, including the abstract, references, and captions, should be neatly typed in English, double-spaced, on one side of good letter-size 21.6×28-cm (8×11-in.) white paper with ample margins. It should be carefully proofread by the author. Unclear or excessive handwritten insertions are not acceptable. Number all pages in single sequence beginning with the title and abstract page. Authors should submit three clear copies of the manuscript including original India ink drawings or high contrast, glossy prints, and if necessary for the reviewer's use, a second set of equal quality.

The **Title** should be concise but informative enough to facilitate information retrieval. The **Abstract** should be self-contained (contain no footnotes). It should be adequate as an index (giving all subjects, major and minor, about which new information is given), and as a summary (giving the conclusions and all results of general interest in the article). It should be about 5% of the length of the article, but less than 500 words for full-length articles and correspondingly shorter for *Communications.* It must appear on its own sheets separate from the text.

"Part I," or simply "I," will not be included as part of the title of an article unless Part II has already been submitted for publication in this Journal. Part III, IV,..., etc., are likewise unacceptable unless the prior parts have already been accepted or have appeared in this Journal, and are properly identified in the references.

Author's names should preferably be written in a standard form for all publications to facilitate indexing and avoid ambiguities.

Equations should be neatly typed or written in ink, punctuated and aligned to bring out their structure, and numbered on the right. Mathematical operation signs indicating continuity of the expressions should be placed at the left of the second and succeeding lines. Use × rather than a centered dot, except for scalar products of vectors. The solidus (/) should be used instead of built-up fractions in running text, and in display wherever clarity would not be jeopardized. Use "exp" for complicated exponents.

Notation must be legible, clear, compact, and consistent with standard usage. All unusual or handwritten symbols whose identity may not be obvious must be identified in the margin the first time they appear, and at all subsequent times when confusion might arise. Superscripts are normally set directly over subscripts; authors should note where readability of the meaning requires a special order. If there is any possibility of confusion, indicate superscripts by a black pencil ∨ underneath the superscript and subscripts by a black pencil ∧ over the subscript.

References and footnotes are treated alike. They must be numbered consecutively in order of first appearance in the text and should be given in a separate double-spaced list at the end of the text material. Reference should be made to the full list of authors rather than to first author followed by an abbreviation such as *et al.* References within tables should be designated by lower-case Roman letter superscripts and given at the end of the table. For the proper form, see the *AIP Style Manual* and recent issues of this journal. The number of a grant or contract is meaningless to our readers and should be omitted unless its inclusion is required by the agency that supports the research.

Separate **Tables** (with Roman numerals in the order of their appearance) should be used for all but the simplest tabular material; they should have captions that make the tables intelligible without references to the text. The structure should be clear, with simple column headings giving all units. Unaltered computer output and notation are generally unacceptable. Long tables should, if possible, be submitted in a form ready for direct photoreproduction. Information on the preparation of camera-ready tables appears in the back of J. Appl. Phys., Vol. 73, No. 2, 15 January 1993.

Figures should not be larger than and preferably approximately the same size as the typewritten page so that they can be contained in ordinary mailing envelopes. Smaller figures are less likely to be lost if pasted on paper of this size. Figures should be planned for the 8.5-cm ($3\frac{3}{8}$-in.) column width of the journal. In some cases where the figures contain a great deal of detail, $1\frac{1}{2}$ or 2 columns may be used, at the copy editor's discretion. The lettering and plotted points on the figures should be large and clear enough so that they will be legible after reduction (their final size should be no less than 2 mm). Figures should be identified on the back, by their number, the name of the first author, and the journal. The numbering should be in the order in which they are referred to in the text. Each figure must have its own caption; list captions on a separate sheet. Graphs should have properly labeled axes with correctly abbreviated units (see *AIP Style Manual*). The form $R\times10^3\ \Omega$, for example, is ambiguous and undesirable; use either $R(10^3\ \Omega)$ or $10^{-3}\ R\ (\Omega)$.

Maximum black-white contrast is necessary. We require original India-ink drawings or good clear glossy prints. Avoid small open symbols that tend to fill in upon reduction, small dots and decimal points, and lines that are not thick enough to withstand reduction. Avoid photographs of apparatus by providing schematic line diagrams instead, and replace oscillograph photographs by black-ink tracings wherever possible. For complete instructions see the *AIP Style Manual.*

Correspondence: The Editor strongly prefers to correspond directly with the author rather than through the reports division or through executives of the author's laboratory. Manuscripts returned to authors for revision should be returned to the Editor within three months. A manuscript returned later than this will generally be regarded as newly submitted and will receive a new receipt date.

Authors whose manuscripts have been accepted for publication will receive a letter informing them of the issue for which it is *tentatively* scheduled. *All subsequent correspondence* about the paper should be addressed to Editorial Supervisor, Journal of Applied Physics, American Institute of Physics, 500 Sunnyside Blvd., Woodbury, NY 11797. Please *do not address* correspondence about proof, reprints, return of art work, publication charges, etc., to the Editor. To do so simply delays the appropriate action and reply.

General information regarding publication charges, copyrights, and similar material may be found on the inside front cover of each issue.

Use this checklist to avoid the most common mechanical errors in submitted manuscripts.

1. The manuscript must be double-spaced *throughout.*
2. Number *all* pages in sequence.
3. Type *title* and *abstract* on a separate first page.
4. Type list of *references* (including footnotes), list of *figure captions,* and *tables* on pages separate from each other and from the main text.
5. Type *references* in the style used by AIP journals.
6. Provide marginal notes to clarify symbols and expressions for the compositor.
7. The original figures must be line drawings in India ink or high-contrast, glossy prints not larger than 21.6×28 cm.
8. Submit (a) three clear copies with clear copies of figures and (b) the original figures.

Magnetic phase diagram of $(Tb_{1-x}Gd_x)Fe_{11}Ti$ alloys

P. A. Algarabel and M. R. Ibarra
DFMC and ICMA, Universidad de Zaragoza, Plaza de San Francisco s/n, 50009 Zaragoza, Spain

The spin reorientation transition (SRT) in $(Tb_{1-x}Gd_x)Fe_{11}Ti$ alloys has been studied by using susceptibility, angular-dependent magnetization, and Mössbauer measurements. Alloys with $x<0.4$ are shown to undergo an axial-to-planar SRT on cooling, while alloys with $x\geq 0.4$ remain axial down to 4.2 K. $TbFe_{11}Ti$ has an easy-axis magnetization at room temperature. A theoretical magnetic phase diagram for the $(Tb_{1-x}Gd_x)Fe_{11}Ti$ system has been calculated, showing reasonable agreement with experiment.

I. INTRODUCTION

Rare earth-transition metal compounds with the $ThMn_{12}$ structure exhibit a variety of spin reorientation (SR) phenomena arising from competition between comparable and opposite anisotropy energies of the RE and TM sublattices.[1] The former can be calculated with a single-ion model for the RE crystalline electric field (CEF) interaction and a mean-field model for the RE–TM exchange interaction. Coey and co-workers[2] have determined a complete set of CEF coefficients (i.e., B_2^0, B_4^0, B_4^4, B_6^0, and B_6^4) from an analysis of single-crystal magnetization data for $DyFe_{11}Ti$. The magnetic phase diagram of other $(RE)Fe_{11}Ti$ compounds can be calculated by appropriate scaling of these coefficients for the corresponding $(RE)^{3+}$ ions, using standard atomic parameters. Agreement with experimental data is generally good, except for $TbFe_{11}Ti$. For this compound, a first-order SR is predicted[2] to occur at 130 K, which is much lower than experimentally observed transition temperatures. A SR has indeed been reported to occur at 450 K by Hu *et al.*,[1,3] at 325 K by Boltich *et al.*,[4] at 285 K by Zhang *et al.*,[5] at 339 K by Kou *et al.*,[6] and at 250 K by Andreev *et al.*[7] The significant discrepancies among these data are to be noted. On the other hand, there is general agreement that the transition is of the easy axis-easy plane-type for descending temperatures. A second, planar-to-conical transition has been reported[1] to occur at ≈220 K, but was not confirmed in later experiments.

In this paper we report a study of the spin reorientation in $TbFe_{11}Ti$, using three experimental techniques: Low-field ac susceptibility, angular-dependent magnetization, and Mössbauer spectroscopy. In addition, Gd-substituted alloys were also studied, in order to investigate the effect of reducing the average RE anisotropy in a controlled manner.

II. EXPERIMENT

$(Tb_{1-x}Gd_x)Fe_{11}Ti$ samples with $x=0$, 0.2, 0.3, 0.4, and 0.6 were prepared by arc melting near-stoichiometric amounts of pure metals under argon, and annealed at 850 °C for ten days. The $ThMn_{12}$ structure was checked by x-ray diffraction. A small amount of α-Fe was present in some samples, but $TiFe_2$ was not detected.

The susceptibility of powdered samples was measured with a modified mutual inductance Hartshorn bridge operating at 15 Hz. Magnetization measurements were performed on magnetically aligned powders by means of an extraction magnetometer. Magnetic alignment was achieved by fixing the alloy powders in epoxy resin at ≈70 °C in a field of 5 kOe. In magnetic polar plot experiments, the oriented sample was rotated in a constant field of 5 kOe provided by an electromagnet, and both parallel ($M_\parallel$) and perpendicular ($M_\perp$) components of magnetization with respect to the applied magnetic field were measured as a function of the rotation angle.[8] Magnetization curves with fixed sample and variable applied field (0–20 kOe) were also measured. All above-mentioned experiments could be done in the 4.2–300 K temperature range.

Mössbauer spectra were measured with a constant-acceleration spectrometer in the 78–300 K range, using a $Rh(^{57}Co)$ source.

III. RESULTS AND DISCUSSION

A. $TbFe_{11}Ti$

The ternary compound is of sufficient interest to warrant a separate discussion. The first question to be addressed is whether $TbFe_{11}Ti$ is axial or planar at room temperature: As mentioned in Sec. I, opposite answers are given in Refs. 5 and 6. In the present work, it can be safely assumed that the alloy was easy axis at the powder alignment temperature of ≈345 K. The magnetization curves, measured at room temperature with H_{ext} both parallel and perpendicular to the alignment direction, revealed substantial anisotropy, giving us a first evidence that the magnetization remained axial at 296 K.

We next consider Mössbauer spectra. The intensities of the absorption lines in an ^{57}Fe magnetically split six-line spectrum are in the ratio $3:a:1:1:a:3$, where

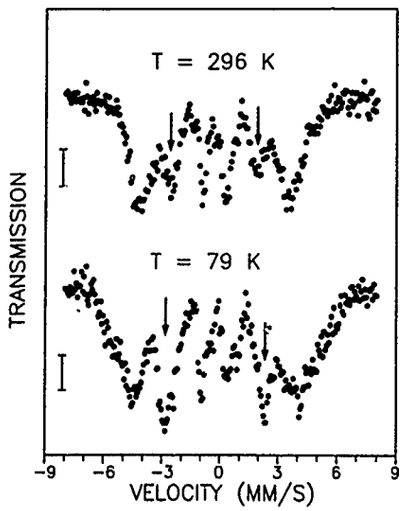

FIG. 1. Mössbauer spectra of aligned $TbFe_{11}Ti$ powder, with gamma-ray beam parallel to magnetic alignment direction. Vertical bars indicate 0.2% absorption. $\Delta m=0$ lines are indicated by arrows.

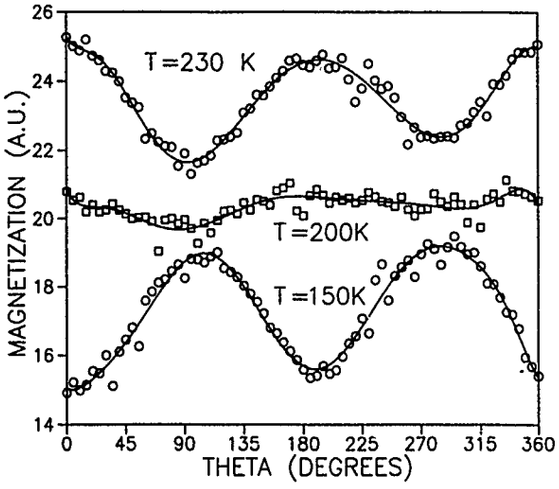

FIG. 2. Parallel magnetization component of aligned $TbFe_{11}Ti$ powder vs rotation angle with respect to the applied field ($H=5$ kOe). Continuous curves are visual guides.

$$a=\frac{4\langle\sin^2\theta\rangle}{1+\langle\cos^2\theta\rangle} \tag{1}$$

and θ is the angle between the hyperfine field and the gamma-ray propagation direction.[9] Thus the relative intensities of the second and fifth lines ($\Delta m=0$ lines) provide information on the local magnetization direction.

The magnetically aligned $TbFe_{11}Ti$ sample was cut perpendicularly to the alignment axis in thin slices, which were assembled to form a flat absorber and mounted perpendicularly to the gamma radiation beam. For this geometry, the $\Delta m=0$ spectral lines are expected to be weak (totally absent for a perfectly aligned powder). Figure 1 shows spectra measured at 296 and 79 K. Owing to the poor counting statistics caused by the small sample area, a quantitative fit could not be made. Nevertheless, a marked increase of the $\Delta m=0$ lines intensity on cooling can be clearly seen. This result suggests a spin reorientation toward the absorber plane (i.e., away from the c axis) to occur between 296 and 79 K. The nonvanishing intensity of the $\Delta m=0$ lines at room temperature is due to imperfect alignment of the crystallites in our sample, and should not be taken as evidence for e.g., a conical spin structure.

Reorientation transitions are made most visible in angular dependent magnetization experiments. When a magnetically aligned sample is rotated with respect to the applied field direction, the magnetization parallel component $M_\parallel$ is a maximum (minimum) if the easy direction is parallel (perpendicular) to the field. Some $M_\parallel$ vs θ plots for $TbFe_{11}Ti$ are shown in Fig. 2, where $\theta=0°$ or 180° denotes the alignment direction. The positions of the maxima did not change in the 296 K$>T>$200 K range, while they are shifted by 90° below this range. At $T=200$ K the $M_\parallel$ vs θ curve is nearly flat, indicating the anisotropy energy goes through zero close to this temperature, which characterizes a spin reorientation.

The canting angle α of the magnetization with respect to the c axis can be determined from the shape of the $M_\parallel$ vs θ pattern. Our data did not reveal an easy magnetization direction with α intermediate between 0° and 90° at any temperature. The SR in $TbFe_{11}Ti$ is thus confirmed to be an axial-to-planar or first-order transition. This result contrasts, e.g., with the $T=200$ K transition in $DyFe_{11}Ti$, which is of axial-to-conical-type, with α smoothly increasing on cooling.[10]

The ac susceptibility vs T curve, shown in Fig. 3, exhibits a fairly broad peak at $T=260$ K. It is reasonable to associate this anomaly with a spin reorientation. This result agrees very well with those obtained by Andreev *et al.*[7] for a $TbFe_{11}Ti$ single crystal, from both ac susceptibility and low-field (200 Oe) angular-dependent magnetization measurements. It is noteworthy that the χ vs T curve shows no anomaly in the temperature range ($T\sim200$ K) where a SR

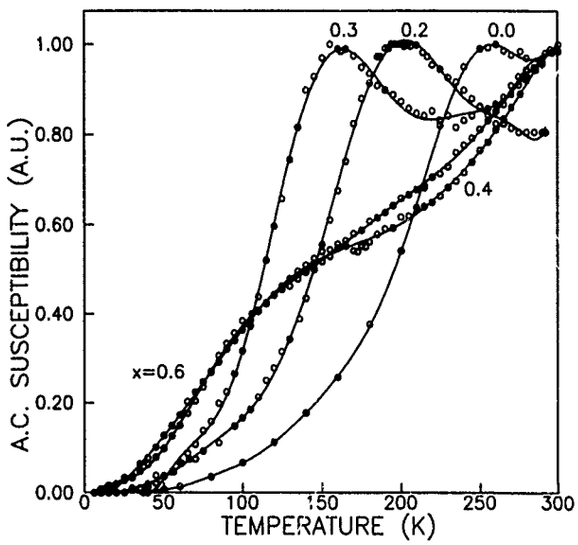

FIG. 3. Low-field susceptibility of $(Tb_{1-x}Gd_x)Fe_{11}Ti$ vs temperature (data were arbitrarily normalized for display).

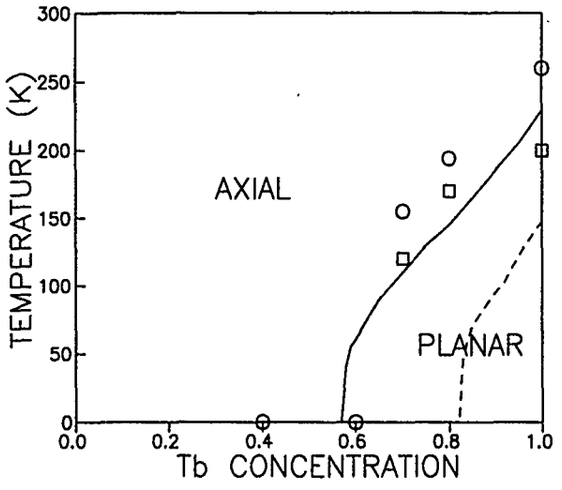

FIG. 4. Spin reorientation temperatures of $(Tb_{1-x}Gd_x)Fe_{11}Ti$ vs $(1-x)$, determined from susceptibility (○) and angular dependent magnetization (□) measurements. Curves are axial/planar boundaries, calculated with CEF coefficients from Ref. 2 (- - -) and with new values, cf. Table I (—).

was determined from polar plots. The striking difference between the T_{SR} values determined by the two methods can result from the static magnetic field applied during the magnetization measurements. Indeed, the sensitivity of T_{SR} to external fields has been experimentally verified for this material by Kou *et al.*,[6] and interpreted on grounds of the anisotropy smallness near the transition temperature. Thus the axial spin orientation will acquire additional stability from an external field, depressing the SR temperature.

We should like to comment on the dispersion of T_{SR} data found in the literature for the $TbFe_{11}Ti$ alloy. The isostructural $(RE)Fe_{12-x}V_x$ alloys are known to exhibit a broad x range, and it has been shown[11] that the V concentration has a strong influence on their magnetic properties. This effect is particularly dramatic for $TbFe_{12-x}V_x$, where the Tb sublattice anisotropy changes sign as a function of x.[11] Although no comparable solubility range has been reported for the Ti alloys, small stoichiometry variations cannot be ruled out, which could be responsible for the apparent irreproducibility of $TbFe_{11}Ti$ properties.

B. $(Tb_{1-x}Gd_x)Fe_{11}Ti$

Partial substitution of Gd^{3+} S-state ions for Tb^{3+} is expected to dilute the RE sublattice planar anisotropy and hence to lower the SR temperature. Our results confirm this prediction, both from susceptibility (see Fig. 3) and angular magnetization measurements. Measured SR temperatures are displayed as a function of x in Fig. 4. No transition was observed for $x \geq 0.4$.

We have calculated the theoretical magnetic phase diagram for this system with the formalism described in Ref. 12. Crystal-field and exchange-field parameters were taken from Ref. 2, with CEF coefficients scaled from Dy^{3+} to Tb^{3+}

TABLE I. Tb^{3+} crystal-field coefficients used in magnetic phase diagram calculations (K).

CEF coefficient	Scaled from Dy^{3+} data (Ref. 2)	This work
B_2^0	2.67×10^{-1}	2.85×10^{-1}
B_4^0	-2.49×10^{-3}	-1.10×10^{-3}
B_4^4	2.37×10^{-2}	3.17×10^{-2}
B_6^0	-1.97×10^{-5}	-1.97×10^{-5}
B_6^4	-4.93×10^{-6}	-4.93×10^{-6}

through the equation $B_n^m = \theta_n \langle r^n \rangle A_n^m$, where θ_n is the Stevens coefficient and A_n^m is assumed to be independent of the RE. These coefficients are given in Table I. The Fe sublattice anisotropy $K_{Fe}(T)$ was taken to be that of $YFe_{11}Ti$,[1] and no external field was considered. Free energy minimization yielded the canting angle α, which was found to be either 0° or 90°, i.e., no conical structure was predicted at any temperature or concentration. It was found that a minimum Tb concentration is required to stabilize an easy-plane magnetization at $T=0$ K. The calculated SR temperatures were, however, far too low, as shown by the dashed line in Fig. 4. Agreement with experiment can be improved with small changes in the B_n^m: the solid curve in Fig. 4 has been calculated with the new coefficients given in Table I. Calculations showed little sensitivity to the 6th-order coefficients, so these were left unchanged. It is noteworthy that the largest change required was on B_4^0 and B_4^4. This fact confirms the relative importance of the fourth-order CEF terms for the magnetic behavior of 1–12 compounds.

Magnetic phase diagram of $Nd(Fe,Mo)_{12}$ alloys

Y. Z. Wang, B. P. Hu, X. L. Rao, and G. C. Liu
San Huan Research Laboratory, Chinese Academy of Sciences, P.O. Box 603, Beijing 100080, China

L. Song, L. Yin, and W. Y. Lai
Institute of Physics, Chinese Academy of Sciences, P.O. Box 603, Beijing 100080, China

The magnetic phase diagram of the alloy series $NdFe_{12-x}Mo_x$ ($x=1.0\sim2.5$) is obtained. Below the Curie temperature, the ferromagnetic phase is divided into three regions: Uniaxial, canted 1, and canted 2. At a temperature of T_{sr1} (below 200 K) a spin reorientation transition (SRT) was observed for all the samples, and at T_{sr2} (above 200 K) another SRT was found for samples with Mo concentration $1.5<x<1.75$. At room temperature the easy direction of magnetization (EDM) of $NdFe_{12-x}Mo_x$ changes from the c axis to a canted structure with increasing Mo concentration, with a critical composition of $x=1.56$. At low temperatures (below 100 K) all $NdFe_{12-x}Mo_x$ compounds exhibit a canted moment structure.

I. INTRODUCTION

Among nitrided compounds having the $ThMn_{12}$ structure, the Nd–Fe–Mo system is the most attractive one for the study of permanent magnet materials. Recent experimental results showed that the intrinsic magnetic properties of $RFe_{12-x}Mo_xN_y$ gets better with lower Mo concentration.[1,2] For example the Curie temperature, the room temperature saturation magnetization $\mu_0 M_s$ and anisotropy field of the $NdFe_{12-x}Mo_xN_y$ nitride with $x=1.0$ is 654 K, 120 $JT^{-1}kg^{-1}$, and 9.5 T, respectively,[1] which makes the $NdFe_{12-x}Mo_xN_y$ nitride be a very good candidate for permanent magnet application.[3–5] However the nature of the magnetocrystalline anisotropy of the parent alloy $NdFe_{12-x}Mo_x$ is not yet quite clear, therefore we investigated the magnetic structure of this series in detail and obtained its magnetic phase diagram.

II. EXPERIMENT

The $NdFe_{12-x}Mo_x$ alloys with $x=1.0$, 1.25, 1.5, 1.56, 1.62, 1.68, 1.75, 2.0, and 2.5 were prepared by arc melting the elements with purity better than 99.5% under purified argon gas and annealing in vacuum at a temperature range of 1050 °–1150 °C for several hours. The quality of the compounds was checked by both powder x-ray diffraction (XRD) with Co-K_α or Cu-K_α radiation and by thermomagnetic analysis (TMA) methods. The spin reorientation transition was determined by TMA in the temperature range from 77 K to the Curie temperature using a vibrating sample magnetometer (VSM) in an applied field of 40 mT and also by ac susceptibility, χ_{ac}, measurements with an ac field of 0.1 mT and a frequency of 314 Hz in the temperature range of 4.2–300 K.

The nature of the magnetocrystalline anisotropy and its temperature dependence were studied by using x-ray diffraction at room temperature and using an extracting sample magnetometer in the temperature range of 4.2–300 K on magnetically aligned powders bonded using epoxy resin.

III. RESULTS AND DISCUSSION

Typical x-ray diffraction patterns for $NdFe_{12-x}Mo_x$ are given in Fig. 1. All annealed alloys are single phase with the $ThMn_{12}$ structure except $x=1$, which has a little α-Fe impurity.

The temperature dependencies of the ac susceptibility $\chi_{ac}(T)$ of different samples are shown in Fig. 2. It can be seen clearly that there are cusps on the $\chi_{ac}(T)$ curves which indicate that the spin reorientation transitions occur in all of the samples. This phenomenon is often observed in R–Fe compounds, for example, $Nd_2Fe_{14}B$,[6] $Tm_2Fe_{17}C_x$,[7] and $DyFe_{11}Ti$[8] among others. In the alloys with Mo concentration $1.5<x<1.75$, two spin reorientation temperatures were observed: One is below and the other is above 200 K. The thermomagnetic analysis traces $M(T)$ at low field are shown in Fig. 3. The magnetic phase transition temperatures for different samples, Curie temperatures T_C, spin reorientation

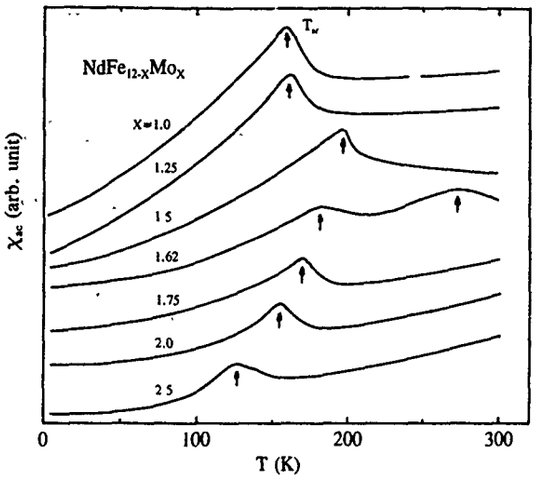

FIG. 2. Temperature dependence of the ac susceptibility $\chi_{ac}(T)$ in several $NdFe_{12-x}Mo_x$ compounds.

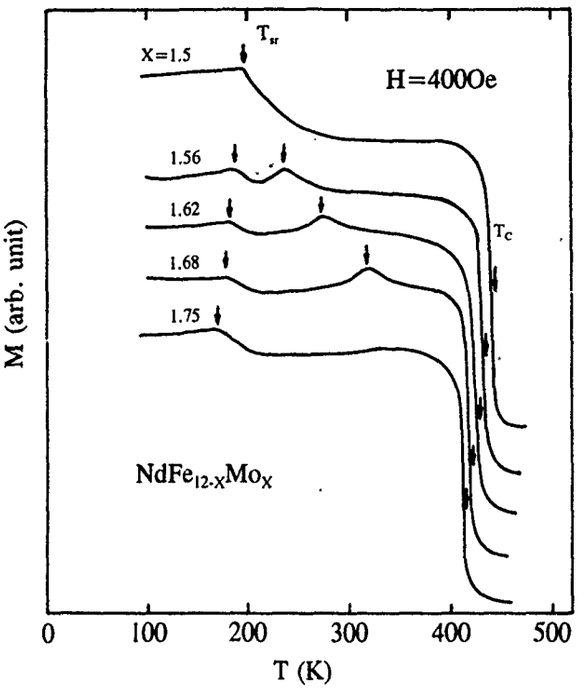

FIG. 3. Thermomagnetic analysis curves of several $NdFe_{12-x}Mo_x$ compounds in a magnetic field of 400 Oe.

temperatures T_{sr1} and T_{sr2}, are listed in Table I and plotted in Fig. 4. The Curie temperature T_C increases linearly with decreasing Mo concentration, while the variations in the spin reorientation temperature T_{sr} are complex. For $x \leqslant 1.5$, T_{sr} increases slowly with Mo concentration. At $x=1.5$ T_{sr} starts to split into two branches: One increases rapidly and the other decreases slowly. They divide the ferromagnetic state into three regions.

In order to distinguish the type of magnetocrystalline anisotropy in regions A and B in Fig. 4, we performed x-ray diffraction experiments on aligned powder samples at room temperature for all alloys. Figure 5 shows x-ray diffraction patterns of two typical compositions with $x=1.5$ and 2.0, which are located in the regions A and B, respectively. The pattern of the sample with $x=1.5$ has one dominant reflection, namely the (002) line. This result shows that the alignment direction of the sample with $x=1.5$ is parallel to the c axis, in other words, the sample with $x=1.5$ possesses uniaxial anisotropy. The x-ray diffraction patterns of other aligned powder samples located in region A are similar to that of $x=1.5$, therefore the magnetocrystalline anisotropy of all alloys in region A is uniaxial. For the sample with $x=2.0$, the x-ray diffraction pattern of the aligned powder sample is different. The pattern is similar to that of non-aligned samples (see Fig. 1). The intensity of the (400) line increases lightly and the intensities of (002), (202), and (222) obviously decreases. This pattern cannot be attributed to the uniaxial nor the easy-plane anisotropy, therefore the alloy with $x=2.0$ has a canted moment structure. Similar x-ray patterns of all the other samples in region B show that they have the same canted type of magnetocrystalline anisotropy. The above results were confirmed by the magnetization measurements on aligned powder samples.

Figure 6 shows magnetization curves of the aligned powder sample with Mo concentration of $x=1.62$ in directions parallel and perpendicular to the alignment direction at 4.2, 200 and 300 K, representing the three different ferromagnetic states in the corresponding regions C, B, and A, respectively. The magnetization curves at 300 K represent a typical uniaxial anisotropy characteristic, while the magnetization curves at low temperature reflect the characteristic of the canted moment structure.[8] At 200 K, the magnetization in the hard direction $M_\perp(0)$ has a considerable value of about 9% of the saturation magnetization M_s at zero field. The easy magnetization curve appears to be hardly saturated with a large susceptibility value of $\chi_{hf}=9.87\times10^{-5}$ emu g^{-1} Oe^{-1} at high filed up to 5 T due to the deviation of the easy magnetization direction from the c axis. When the temperature goes down to 4.2 K, the canted behavior appeared in magnetization curves is clearer than 200 K. Values of $M_\perp(0)$ and χ_{hf} increase obviously, $M_\perp(0)/M_s=24\%$ and $\chi_{hf}=34.4\times10^{-5}$ emu g^{-1} Oe^{-1}, respectively. Such canted behavior can be explained by the balance between the

anisotropy of the Fe sublattice and the Nd sublattice at different temperatures.[8]

The magnetic phase diagram of $NdFe_{12-x}Mo_x$ is shown in Fig. 4. The magnetic anisotropy of this alloy series is complicated. Very recently studies of the magnetocrystalline anisotropy of $YFe_{12-x}Mo_x$ ($1.0 \leq x \leq 2.5$) indicate that the easy c-axis anisotropy field of the Fe sublattice increases

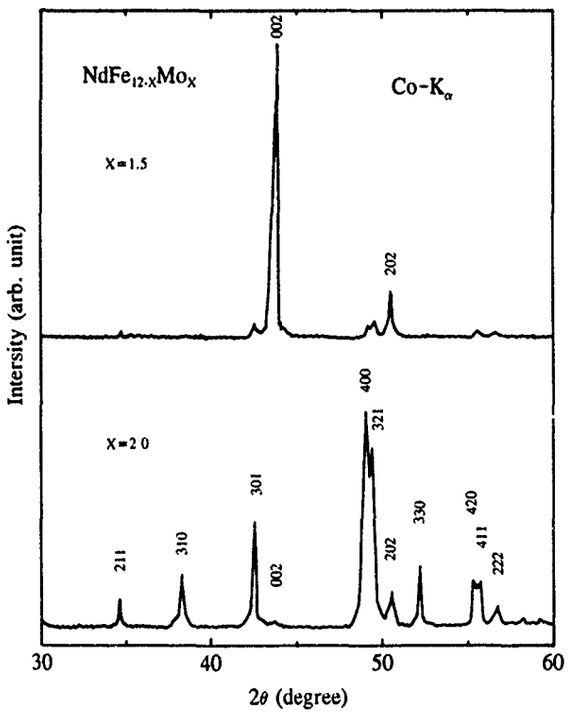

FIG. 5. X-ray diffraction patterns of magnetically aligned powder for $NdFe_{12-x}Mo_x$ with $x=1.5$ and 2.0. The plane of the incident and reflected x-ray is parallel to the alignment direction.

rapidly with the decrease of Mo concentration when $x<1.6$ and changes slowly for $x>1.6$.[10] This turning point of the anisotropy field of $YFe_{12-x}Mo_x$ is close to the triphase point of the $NdFe_{12-x}Mo_x$. Of $NdFe_{12-x}Mo_x$ with low Mo concentration, the easy c-axis anisotropy field of the Fe sublattice is strong enough to overcome the easy-plane anisotropy of the Nd sublattice so that $NdFe_{12-x}Mo_x$ exhibits uniaxial anisotropy. With high Mo concentration, the easy-plane anisotropy of the Nd-sublattice dominates the whole magnetic ordering temperature range. The complexity of the magnetocrystalline anisotropy of $NdFe_{12-x}Mo_x$ may also be affected by the variation of the crystal-field interaction with Mo concentration.

Magnetic anisotropies in $RFe_{10-x}Co_xMo_2$ compounds (R=Dy, Er)

Roy Tucker, Xie Xu, and S. A. Shaheen
Department of Physics and Center for Materials Research and Technology (MARTECH), Florida State University, Tallahassee, Florida 32306

The effects of Co substitution on magnetic anisotropy and spin reorientation phenomena have been investigated in the $DyFe_{10-x}Co_xMo_2$ and $ErFe_{10-x}Co_xMo_2$ (x=0 to 10) series in the temperature range from 4.2 to 300 K. X-ray diffraction patterns on aligned samples indicated that the easy direction of magnetization (EDM) of the $DyFe_{10-x}Co_xMo_2$ series is along the c axis at room temperature for all values of x. The spin reorientations were observed for all samples in the $DyFe_{10-x}Co_xMo_2$ series except for x=10, and the spin reorientation temperature, T_{sr}, decreases with the increase of Co content x. The magnetic phase diagram of $DyFe_{10-x}Co_xMo_2$ has been constructed. These results, together with the results from the $YFe_{10-x}Co_xMo_2$ series, may lead to the conclusion that the anisotropy of Dy sublattice changes from planar to axial in the $DyFe_{10-x}Co_xMo_2$ series with the increase of Co content. The EDM in the $ErFe_{10-x}Co_xMo_2$ series was found to be nonaxial for $2 \leqslant x \leqslant 6$ for all temperatures below T_c. For $x<2$ and $x>6$ the $ErFe_{10-x}Co_xMo_2$ compounds exhibit an axial EDM at room temperature, and spin reorientations occur at about 210 K for x=8 and at 140 K for x=10. Since Er and Dy have opposite sign of second-order Stevens factor, the above results of two systems are consistent.

I. INTRODUCTION

Recently the search for new permanent magnet materials has been focused on the ternary compounds $RFe_{12-x}M_x$ (R =rare earth, M=Ti, V, Cr, Si, Mo; x=1 or 2),[1-3] which crystallize in the tetragonal $ThMn_{12}$ structure. In this structure, the R atoms occupy the crystallographic $2a$ site and the $3d$ atoms occupy the $8i$, $8j$, $8f$ sites. Due to its low site symmetry, the Fe sublattice exhibits a strong uniaxial anisotropy. According to the second-order approximation of the point charge model, the short R-R distance along the c axis enables rare earths of a positive second-order Stevens factor ($\alpha>0$) [e.g., Sm, Er, Tm, Yb] to exhibit an axial anisotropy while rare earths with $\alpha<0$ [e.g., Nd, Tb, Dy, Ho] exhibit a nonaxial anisotropy.

Several authors have reported that the substitution of Co for Fe in the $R(Fe,Co)_{11}Ti$[4,5] and $R(Fe,Co)_{10}V_2$ (Ref. 6) systems favors a planar anisotropy, and the easy direction of magnetization (EDM) at room temperature in these alloys appears to change from axial to cone to planar with increasing Co concentration. However, our recent studies of the $RCo_{10}Mo_2$ compounds[7] showed that the $YCo_{10}Mo_2$ and $GdCo_{10}Mo_2$ compounds exhibit an axial anisotropy from 0 K to Curie temperature. Since Y is nonmagnetic and Gd has no orbital moment, the anisotropy comes from the Co sublattice only. This means that the Co sublattice favors a uniaxial anisotropy in the $RCo_{10}Mo_2$ compounds series. We also found that at room temperature the EDM in the $RCo_{10}Mo_2$ series is along the c axis for R=Nd, Pr, and Dy, and it is nonaxial for R=Sm and Er. These results strongly indicate that in contrast to the situation in $RFe_{12-x}TM_x$, the R sublattices with negative second-order Stevens factor ($\alpha<0$) favor a uniaxial anisotropy, whereas those with $\alpha>0$ favor a planar anisotropy. Ohashi *et al.* reported a similar behavior in the $RCo_{11}Ti$ compounds series.[8]

It is interesting to observe that while the $3d$ sublattice anisotropy remains axial in both $RFe_{10}Mo_2$ and $RCo_{10}Mo_2$ series, the R sublattice anisotropy undergoes a dramatic change. In order to understand this contrasting anisotropy behavior and to examine the effect of Co substitution on magnetic anisotropy and spin reorientations, systematic studies of the $RFe_{10-x}Co_xMo_2$ compounds have been made.[9] In this paper we report the spin-reorientation behavior of the $RFe_{10-x}Co_xMo_2$ (R=Dy and Er, x=0 to 10) compounds determined by the ac susceptibility method and thermomagnetic analysis. The magnetization data on these systems are also included.

II. EXPERIMENT

$RFe_{10-x}Co_xMo_2$ alloys (R=Dy and Er, and x=0, 2, 4, 6, 8, 10) were prepared by arc melting appropriate amounts of Fe, Co, Mo, and Dy or Er under a purified argon atmosphere. As-cast samples were vacuum annealed at 1000 °C for a week. All samples are almost single phase, as determined by both x-ray powder diffraction and thermomagnetic analysis. Aligned samples for magnetic anisotropy studies were prepared by mixing fine powders in an epoxy at room temperature in the presence of a magnetic field (1 T). The room temperature EDM was deduced from the x-ray diffraction patterns of aligned samples.

A quantum design SQUID magnetometer with external field up to 5.5 T was used for the measurements of the saturation magnetization (σ_s) and anisotropy field (H_A). The value of H_A was determined by measuring the easy and hard direction of magnetization on aligned samples at room temperature. The Curie temperatures were measured using a Faraday magnetometer. Both the ac susceptibility and low field dc magnetization measurements as a function of temperature in the range from 4.2 to 300 K are used to detect possible spin reorientations.

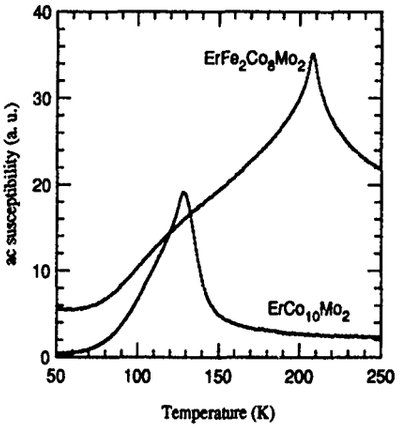

FIG. 2. Temperature dependence of the ac magnetic susceptibility of $ErFe_2Co_8Mo_2$ and $ErCo_{10}Mo_2$.

III. RESULTS AND DISCUSSIONS

The results obtained for the $DyFe_{10-x}Co_xMo_2$ series are listed in Table I. X-ray diffraction patterns on aligned samples indicated that the EDM in the $DyFe_{10-x}Co_xMo_2$ series is along the c axis at room temperature for all values of x. Figure 1 shows the magnetic phase diagram for the $DyFe_{10-x}Co_xMo_2$ series. The occurrence of a maximum in the Curie temperature, which has been observed in the $YFe_{10-x}Co_xMo_2$ and $NdFe_{10-x}Co_xMo_2$ series[9,10] appears to be a common feature of the $RFe_{10-x}Co_xMo_2$ compounds.

The spin reorientations, described as a change of the EDM from one crystallographic direction to another with varying temperature, were observed in the ac susceptibility measurements for all samples in the $DyFe_{10-x}Co_xMo_2$ series, except for $x=10$. With the increase of Co content x, the T_{sr} decreases almost linearly at an average rate of ~13 K per substituted Co atom. These results, combined with the results of the $YFe_{10-x}Co_xMo_2$ series,[10] support the conclusion that the anisotropy of Dy sublattice changes gradually from planar (in $DyFe_{10}Mo_2$) to axial (in $DyCo_{10}Mo_2$) in the $DyFe_{10-x}Co_xMo_2$ series with the increase of Co content.

The situation in the $ErFe_{10-x}Co_xMo_2$ series is somewhat more complex than that in the $DyFe_{10-x}Co_xMo_2$ series. X-ray diffraction patterns on aligned samples indicated that the EDM of the $ErFe_{10-x}Co_xMo_2$ series is nonaxial for $2 \leq x \leq 6$. For $x>6$ the $ErFe_{10-x}Co_xMo_2$ compounds exhibit an axial EDM at room temperature, and spin reorientations occur at about 210 K for $x=8$ and at 130 K for $x=10$, as shown in Fig. 2.

The magnetic anisotropy in $RFe_{10-x}Co_xMo_2$ compounds arises from two contributions: $4f$ sublattice and $3d$ sublattice anisotropies. When both R and $3d$ sublattice anisotropies favor an axial or planar arrangement of spins, then the EDM is obviously along the c axis or basal plane, respectively. However, when the R sublattice and $3d$ sublattice favor different EDM's, then the situation is complex, and the EDM of the compound is determined by the resultant of the competing sublattice anisotropies. As observed in the $YFe_{10-x}Co_xMo_2$ series,[10] the $3d$ sublattice anisotropy undergoes a change from axial at $x=0$ to planar at $4 \leq x \leq 5$ and

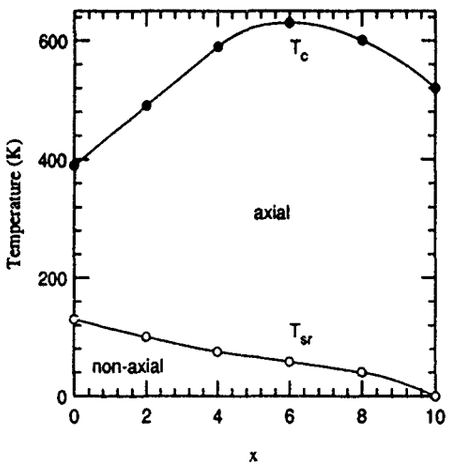

FIG 1. Magnetic phase diagram for $DyFe_{10-x}Co_xMo_2$.

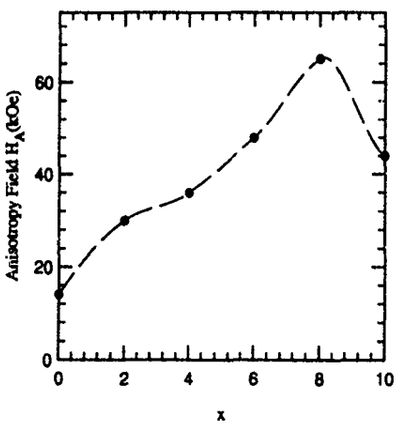

FIG. 3. The dependence of the anisotropy field H_A on Co composition x in the $DyFe_{10-x}Co_xMo_2$ series.

back to axial at higher x values. Furthermore, the R sublattice anisotropy also undergoes a dramatic change in the $RFe_{10-x}Co_xMo_2$ series, and the resultant behavior is quite complex. However, it is easy to make comparisons for the terminal compounds ($x=0$ and 10) where the $3d$ anisotropy favors axial EDM for both compound series (R=Dy and Er). Since Dy and Er have opposite signs of second order Stevens' factor, the magnetic anisotropy behavior of terminal compounds and the observations of spin reorientations are expected.

The field dependence of magnetization (up to 55 kOe) was measured along the easy and hard direction of magnetization on aligned samples at 300 K. The anisotropy field at 300 K for $DyFe_{10-x}Co_xMo_2$ is listed in Table I and plotted in Fig. 3 as a function of Co content x. As seen in Fig. 3, the anisotropy field in the $DyFe_{10-x}Co_xMo_2$ system reaches a maximum value of 6~7 T at $x=8$.

$Nd(Fe,Ti)_{12}$ and $Nd(Fe,Ti)_{12}N_x$ films textured with c axis perpendicular to the film plane were synthesized by sputtering. For the $Nd(Fe,Ti)_{12}$ films a spin reorientation took place at about 170 K. For the $Nd(Fe,Ti)_{12}N_x$ films, the anisotropy field is about 85 kOe at room temperature and 130 kOe at 5 K, corresponding to a coercivity of 2.7 and 12 kOe, respectively. Initial magnetization curves show a behavior characteristic of nucleation type of magnetization reversal mechanism. Attempts were made to fit the experimental data with Kronmüller's magnetization reversal model. The results suggest that nucleation with extended sites is responsible for the reversal.

INTRODUCTION

Higano *et al.* were probably the first to report the astonishing effect of nitriding on some rare earth-transition metal(RE-TM) compounds in 1987. They concluded that[1]: "Nitriding resulted in a lattice expansion, increase in the saturation magnetization and change in Curie temperature." Coey and co-workers reported the first detailed study[2] of various aspects of these compounds, and their results have stimulated much of the succeeding work.[3]

The synthesis of $SmFe_{12}$ films by sputtering has been reported.[4,5] But $SmFe_{12}N_x$ or $Sm(Fe,Ti)_{12}N_x$ is not a good candidate for permanent magnets because its planar magnetic anisotropy leads to a low coercivity (H_c). $Nd(Fe,Ti)_{12}N_x$ is a promising candidate for permanent-magnet applications because of its high uniaxial anisotropy field (H_k), high Curie temperature and high saturation magnetization (M_s).[6]

Previously we reported the preliminary results on the $Nd(Fe,Ti)_{12}$ and $Nd(Fe,Ti)_{12}N_x$ films.[7] A report on similar films has been given also recently by Navarathna *et al.*[8] In this paper we will discuss the magnetic properties of these sputtered films. Low temperature measurements on the $Nd(Fe,Ti)_{12}N_x$ films will be emphasized. The magnetization reversal mechanism will also be discussed with available models.

EXPERIMENTAL METHODS

$Nd(Fe,Ti)_{12}$ films were prepared in a dc magnetron sputtering system on heated Ta substrates.[5] The base pressure was better than 5×10^{-7} Torr. After the deposition, nitrogen gas was introduced into the chamber with a pressure up to about 200 Torr at various sample temperatures for various lengths of time; for example, a 400 °C anneal for one hour was typically used. All films reported on in this paper had a nominal thickness of about 1 μm.

RESULTS AND DISCUSSION

Figure 1 shows x-ray diffraction (XRD) patterns for films deposited at different substrate temperatures under an argon pressure of 1.5 mTorr. The XRD patterns are fitted nicely to the (002), (202), (222), and (004) lines of the tetragonal $ThMn_{12}$ structure. The films have the c axis preferentially aligned perpendicularly to the film plane. For a substrate temperature higher than 430 °C, the small portion of α-Fe-like phase starts to increase and the (002) texture gets worse. For a substrate temperature much lower than 340 °C the films have only XRD peaks of the α-Fe-like phase. For all the measurement shown below, the films made at a substrate temperature of 390 °C were used. The XRD pattern for the nitride film was given in Ref. 7, which is similar as the

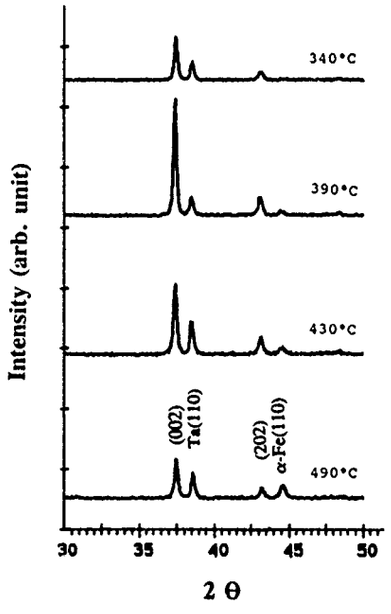

FIG. 1. XRD patterns of $Nd(Fe,Ti)_{12}$ films prepared on Ta under various substrate temperatures and at a sputtering gas pressure of 1.5 mTorr.

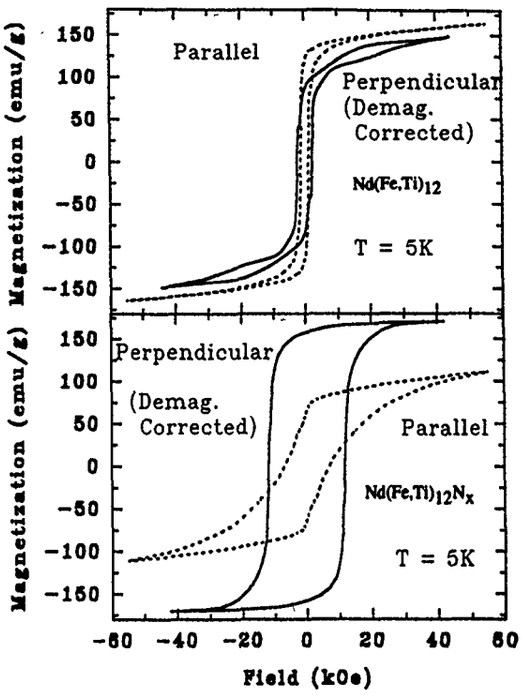

FIG. 2. Hysteresis loops of a $Nd(Fe,Ti)_{12}$ film and a $Nd(Fe,Ti)_{12}N_x$ film of about 1 μm thick measured at 5 K with a high applied field of 55 kOe.

390 °C pattern for the film before nitriding as shown in Fig. 1 with only positions shifted to lower angles.

When films are annealed *in-situ* at a temperature of 400 °C for about one hour in a nitrogen atmosphere, a unit-cell-volume expansion of 3.6% is observed. Based on the reported data[9] we estimated the nitrogen content to be about $x=0.9$. This accompanies a dramatic change in magnetic properties.

Figure 2 shows typical hysteresis loops for a $Nd(Fe,Ti)_{12}$ film and a $Nd(Fe,Ti)_{12}N_x$ film of about 1 μm thick measured at a low temperature of 5 K. For the perpendicular loops the applied field has been corrected for demagnetization. It is noted that for the $Nd(Fe,Ti)_{12}$ film the perpendicular magnetization is below the parallel magnetization, which is different from the case of room temperature measurement.[7]

Figure 3 shows the temperature dependence of the magnetization for films before and after nitriding. The procedure for this measurement was first to lower the temperature to 5 K and apply the maximum field of 55 kOe in the film plane, then decrease the field to 200 Oe, which is much lower than the coercivity, 2.7 kOe, and then measure the magnetization while increasing the temperature. A spin reorientation is observed at around 170 °C for the $Nd(Fe,Ti)_{12}$ film. For the $Nd(Fe,Ti)_{12}N_x$ film no such phenomenon is observed. This means that the spin reorientation is suppressed by nitriding.

Figure 4 shows the initial magnetization curves of a nitride film measured at 5 K from both a thermally demagnetized and a field-demagnetized state. The hysteresis loop in the first quadrant is also shown. The magnetization for the thermally demagnetized film rises rapidly to near saturation at a field well below the coercivity. For the field-

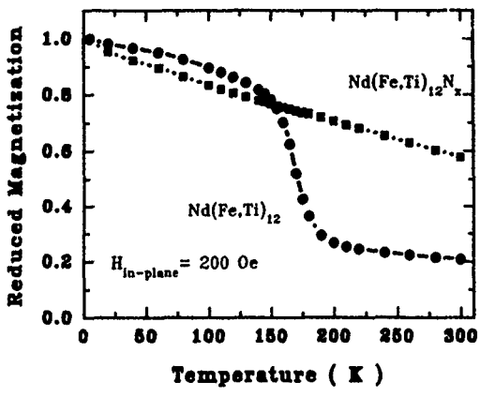

FIG. 3. Temperature dependence of magnetization for a $Nd(Fe,Ti)_{12}$ film and a $Nd(Fe,Ti)_{12}N_x$ film under a low field of 200 Oe.

demagnetized film the initial curve is much lower. These features are similar to those observed for NdFeB sintered magnets, which are believed to be strong indications of a nucleation type of magnetization-reversal mechanism.[3] Hysteresis loops were measured at different temperatures with a SQUID magnetometer. The temperature dependencies of M_s, H_k, H_c determined from the loops for a nitride film are plotted in Fig. 5. H_c decreases from 12 kOe at 5 K to 2 kOe at 350 K. At room temperature H_c is about 2.7 kOe. M_s decreases about 10% when the temperature increases from 5 K to room temperature. Kronmüller and co-workers[10] have derived a simplified formula for the coercivities due both to nucleation and pinning mechanisms by assuming that there are spatial fluctuations of the first-order anisotropy constant K_1 and the exchange constant A:

$$H_c(T)=\alpha(T)\,\frac{2K_1(T)}{M_s(T)}-N_{\text{eff}}M_s(T), \tag{1}$$

where for pinning

$$\alpha_K^{\text{pin}}(T)=a\,\frac{r_0}{\delta_B}\ \text{ when }\ r_0\ll\delta_B, \tag{2}$$

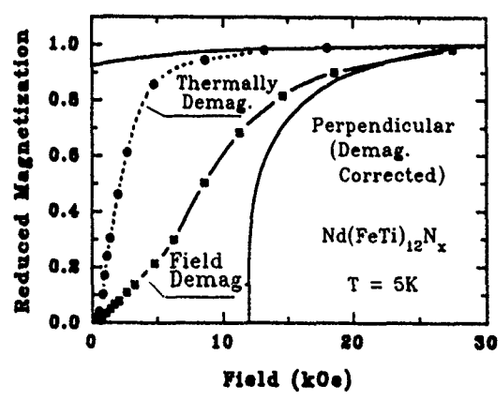

FIG. 4. Initial magnetization curve measured from a thermally demagnetized and field demagnetized state of a $Nd(Fe,Ti)_{12}N_x$ film at a low temperature of 5 K.

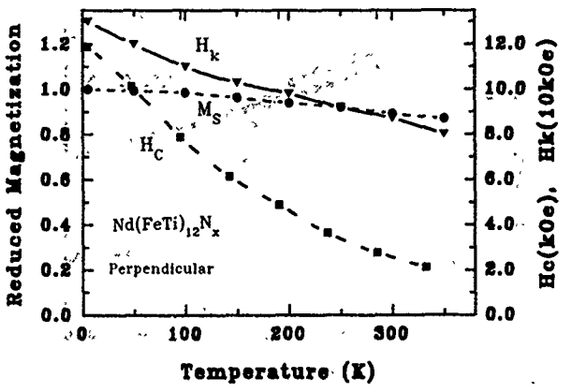

FIG. 5. Temperature dependence of the parameters M_s, H_k, H_c extrapolated from hysteresis loops for a $Nd(Fe,Ti)_{12}N_x$ film.

$$\alpha_K^{\text{pin}}(T)=b\frac{\delta_B}{r_0} \quad \text{when} \quad r_0 \gg \delta_B, \tag{3}$$

and where

$$\delta_B=\pi\sqrt{\frac{A}{K_1}} \tag{4}$$

is the domain-wall width for a uniaxial crystal and r_0 is the pinning-center size.

Equation (1) also applies to reversal by nucleation according to different sizes of the nucleation site (r_0):

$$\alpha_K^{\text{nuc}}=1-\frac{r_0^2}{\delta_B}, \quad \text{when} \quad r_0 \ll \delta_B, \tag{5}$$

$$\alpha_K^{\text{nuc}}=\frac{\delta_B}{\pi r_0}, \quad \text{when} \quad 2\pi r_0 \approx \delta_B, \tag{6}$$

$$\alpha_K^{\text{nuc}}=1-\frac{\Delta K}{K_1}, \quad \text{when} \quad 2\pi r_0 \gg \delta_B. \tag{7}$$

We assume that the exchange constant A for the main region[11] is 10^{-6} erg/cm and the domain-wall thickness δ_B is given by Eq. (4). After fitting the experimental results to the cases presented in Eqs. (2) to (7), the main results of this analysis are summarized as follows: (a) Assuming reversal by pinning with small pinning centers, the fitting according to Eq. (2) gives an r_0 value of 0.03 Å, which is unreasonably small though the H_c/M_s vs $2K/M_s^2/\delta_B$ curve shows a near linear relationship; (b) assuming reversal by pinning with large pinning centers according to Eq. (3), the experimental results are shown in Fig. 6(a). H_c/M_s does not vary linearly with $2K/M_s^2\delta_B$, so this case can be excluded; (c) for reversal by nucleation with small nucleation sites, the experimental results are fitted according to Eq. (5). The value of r_0 obtained is 150 Å, which is inconsistent with the small site assumption; (d) for reversal by nucleation with medium size nucleation sites, no linear relationship is expected since Eq. (6) and Eq. (3) have similar δ_B dependence; (e) for reversal by nucleation with extended nucleation sites, Fig. 6(b) gives

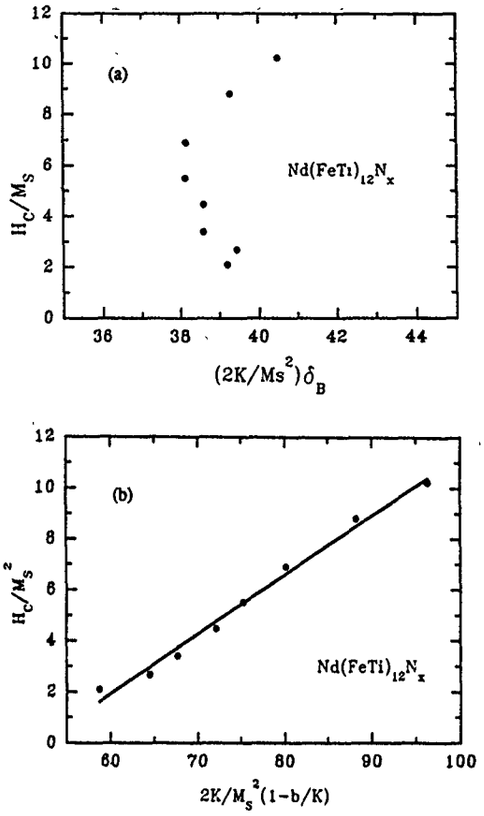

FIG. 6. (a) Experimental results for pinning with large pinning sites; (b) Experimental results and fitting results for nucleation with large sites for a $Nd(Fe,Ti)_{12}N_x$ film.

the experimental results and fitting results according to Eq. (7). There is a reasonably good linear relationship between H_c/M_s and $2K/M_s^2(1-b/K)$. The prefactor in Eq. (1) is about 0.23 and N_{eff} is about 3.8.

$Nd(Fe_{12-x}Mo_x)N_y$ (x=1.25 and 1.50, y=0.9) ^{57}Fe Mössbauer spectra of parent compounds and nitrides have been measured at 15 and 293 K. Hyperfine fields are little changed by the presence of nitrogen at 15 K, where the average value is about 25 T but at 293 K there is a change in average hyperfine field from 19 T for parent compounds to 24 T for nitrides due to the increase in Curie temperature. Spin reorientations occur in the parent compounds in the temperature range between 160–190 K but not in the nitrides, which show c-axis anisotropy throughout this range.

Recent experiments have shown that the best intrinsic magnetic properties in $R(Fe_{12-x}Mo_x)N_y$ are found for the lowest Mo concentrations.[1,2] The nitride with R=Nd is a candidate for permanent magnet development. Coercivities of up to 0.8 T are reported for mechanically alloyed $Nd_{10}(Fe_{75}Mo_{15})N_y$ (Ref. 3) and 0.64 T for milled $NdFe_{10.75}Mo_{1.25}N_{0.9}$.[4] A maximum energy product of $(BH)_{max}$=240 kJ/m^3 at room temperature has been inferred from work on thin films.[5] In order to improve the understanding of the microscopic magnetic properties, in this work, we investigated $Nd(Fe_{12-x}Mo_x)$ with x=1.25 and 1.50 and their nitrides by ^{57}Fe Mössbauer effect at the temperatures of 15 and 293 K.

The $Nd(Fe_{12-x}Mo_x)$ alloys were prepared by arc-melting elements of purity better than 99.5% with about 10% excess of Nd to compensate the loss on melting. Buttons were then annealed in vacuum at a temperature of 1050 °C for about 5 h. The homogenized ingots were pulverized into a fine powder with an average size of about 15 μm. Nitrogenation was performed by heating the alloy powder in pure N_2 at 400–450 °C for 1–3 h. The nitrogen content was evaluated from the weight difference of the samples before and after nitrogenation.

Mössbauer absorbers consisted of about 15 mg cm^{-2} of alloy powder mixed with icing sugar. Oriented absorbers were prepared by mixing alloy powder with epoxy resin and setting in an applied field of 2 T applied perpendicular to the surface of the sample. ^{57}Fe Mössbauer spectra were collected using a conventional constant acceleration spectrometer with a 20 mCi source of ^{57}Co in rhodium. The γ ray was along the alignment direction for the oriented absorbers. The velocity scale was calibrated using an α-Fe absorber at room temperature. Low temperature data were obtained using a closed-cycle two stage helium refrigerator (Air Products. model HC-2).

Figure 1 shows CuK_α x-ray diffraction patterns of $Nd(Fe_{10.75}Mo_{1.25})$ and $Nd(Fe_{10.75}Mo_{1.25})N_{0.9}$. The magnetic characteristics of the samples are summarized in Table I.

The $Nd(Fe_{12-x}Mo_x)$ and $Nd(Fe_{12-x}Mo_x)N_{0.9}$ nitrides (x =1.25 and 1.50) are single phase with a $ThMn_{12}$-type structure[4] as shown in Fig. 1. A detailed study of magnetization as a function of Mo concentration shows that at room temperature there is uniaxial anisotropy when x<1.55 in the parent compounds,[6] but the corresponding nitrides have uniaxial anisotropy for all x values.[1] X-ray diffraction patterns on our oriented absorbers indicate that they all well aligned except for $Nd(Fe_{10.50}Mo_{1.50})$ which has a low anisotropy field at room temperature.[6]

X-ray diffraction analysis has shown that in $Nd(Fe_{10}Mo_2)$, 8f and 8j sites are fully occupied by Fe atoms while 8i sites are shared by Fe and Mo atoms.[7] A recent neutron diffraction study on $Y(Fe_{11}Mo)$ showed that 20% of Mo atoms occupy 8f sites with the rest on 8i sites.[8] The N atoms in 1:12 nitrides occupy 2b sites exclusively.[8,9] In our work, we suppose the Mo atoms to be located on 8i sites only.

The distribution of Mo causes a distribution of Fe nearest neighbors for each Fe site, which results in quite broad outer lines in the Mössbauer spectrum due to a distribution of hyperfine fields. An acceptable fit of the spectra of isotro-

pic absorbers was achieved using just five components with a constrained intensity ratio of $12{:}8{:}4{:}(8-2x){:}(4-x)$, corresponding to $8f{:}8j_1{:}8j_2{:}8i_1{:}8i_2$. The outer line width of each sextet was varied independently from the middle and inner lines to help account for the distribution in hyperfine field at each site. The same isomer shifts and hyperfine fields are imposed for the subspectra of each site for the parent compounds and nitrides. For the spectra of oriented absorbers the same intensity constraint and Mössbauer parameters are used as for isotropic absorbers except that the angle ϕ_{Fe} between the γ-ray direction and hyperfine field was taken the same for all three iron sites due to ferromagnetic ordering.[10] The hyperfine fields for the Fe sites then decrease in the order $B_{hf}(8i)>B_{hf}(8j)>B_{hf}(8f)$.[10,11]

Figures 2 and 3 show the spectra of isotropic and oriented absorbers of $Nd(Fe_{12-x}Mo_x)$ and $Nd(Fe_{12-x}Mo_x)N_{0.9}$ ($x=1.25$ and 1.50) at 15 and 293 K together with the envelopes of the fits. The α-Fe content of the parent compounds is less than 1% and it is not included in fits, but there is about 3% α-Fe in the nitride spectra. The fitted hyperfine parameters of isotropic absorbers obtained are listed in Table II. The average hyperfine field of $Nd(Fe_{10.50}Mo_{1.50})$ is smaller by about 1 T than that of $Nd(Fe_{10.75}Mo_{1.25})$ at both 15 and 293 K, which indicates that the presence of Mo around Fe reduces the atomic magnetic moment of Fe, in accordance with the data in Table I. The increase of 24% in average hyperfine fields, from 19.3 to 24.0 T, at room temperature after nitrogenation stems from the large increase of Curie temperature, from about 450 K for parent compounds to 630 K for nitrides (Table I). At 15 K there is little change of the average hyperfine field after nitrogenation, only about 1.6 T (6%), which is much smaller than the increase of 13% found in the cases of $Nd(Fe_{11}Ti)N_{0.8}$ (Ref. 11) and $Nd_2Fe_{17}N_y$.[13]

Taking the relative volume expansion values of $\delta V/V = \delta \ln V = 3.07\%$ and 3.02% for $x=1.25$ and $x=1.50$ compounds, respectively. We found that $\delta IS/\delta \ln V$ on nitrogenation is 2.6 mm/s for the former and 2.0 mm/s for the latter. This is larger than that for $R_2Fe_{17}N_x$ ($\delta IS/\delta \ln V=1.7$ mm/s)[13] and close to that for $R(Fe_{11}Ti)N_x$ ($\delta IS/\delta \ln V=2.2$ mm/s)[11] which suggests that the interband electron transfer on nitrogenation in $Nd(Fe_{12-x}Mo_x)N_{0.9}$ ($x=1.25$ and 1.50) is stronger than in nitrides of the 2:17 series.

Comparing the spectra of oriented absorbers at two temperatures as shown in Fig. 3, the lines 2 and 5 of the spectra at 15 K are much stronger than those at 293 K for parent

compounds but there is no large change for nitrides. Although the fitting angles ϕ_{Fe} at room temperature are about 35° and 39° for $Nd(Fe_{12-x}Mo_x)$ and nitrides respectively because of imperfect orientation of the powder samples, the change of more than 15° for parent compounds and less than 5° for nitrides at 15 K implies that a spin reorientation transition occurs in the parent compounds at low temperature but not in the nitrides.[10] magnetization, taking account of the imperfect c-axis orientation of the absorbers. For the case where the magnetization is along c axis when the absorber is oriented at room temperature, the tilting angle θ between c axis and iron magnetization can be determined from This suggested that $Nd(Fe_{12-x}Mo_x)$ undergoes a spin reorientation away from the c axis when temperature decreases below 160 or 190 K for x=1.25 and 1.50, respectively. The nitrides have a magnetic structure with easy c axis between 15 and 293 K.[6]

Compared with the compounds $Nd(Fe_{12-x}Ti_x)$, the $Nd(Fe_{12-x}Mo_x)$ have a slightly larger magnetic moment, but a reduced hyperfine field. Easy c-axis anisotropy is more easily achieved in the nitrides of the Mo system since with titanium there is a 2:19 or 3:29 phase with c-plane anisotropy.[15]

The average hyperfine fields of nitrides $NdFe_{12-x}Mo_xN_y$ (x=1.25 and 1.50, y=0.9) are slightly larger than those of the parent compounds at 15 K and increase by 24% at room temperature. The isomer shifts increase by 0.1 mm/s mainly due to the 3% volume expansion. $\delta IS/\delta \ln V$ on nitrogenation (2.3 mm/s) is larger than that in $R_2Fe_{17}N_x$ ($\delta IS/\delta \ln V$ =1.7 mm/s). The increase of Mo content from 1.25 to 1.50 causes a decrease of average hyperfine fields of about 1 T at 15 and 293 K for both parent compounds and nitrides. Spin reorientations occur for the parent compounds but the nitrides exhibit easy c-axis anisotropy throughout the temperature range due to the crystal field created at the neodymium by the pair of nitrogen neighbors along the c axis.

Magnetic properties of $(Er,R)_2Fe_{17}N_y$ compounds (R=Y,Gd)

J. L. Wang, W. G. Lin, N. Tang, W. Z. Li, Y. H. Gao, and F. M. Yang
Magnetism Laboratory, Institute of Physics, Chinese Academy of Sciences, P. O. Box 603, Beijing 100080, People's Republic of China

Structural and magnetic properties of the interstitial $(Er_{1-x}R_x)_2Fe_{17}N_y$ compounds with R=Y and Gd, x=0, 0.1, 0.25, 0.4, 0.5, 0.6, 0.75, and 1.0, $2<y<3$, have been investigated. All the parent compounds crystallize in the Th_2Ni_{17}-type structure, except for Gd_2Fe_{17} which crystallizes in the Th_2Zn_{17}-structure. All nitrides preserve the same structure as the parents. Introduction of nitrogen results in an increase in lattice constants a and c, and the expansion of unit-cell volume is about 6%. The Curie temperature was found to increase distinctly after nitrogenation. Nitrogen absorption leads to an increase in saturation magnetization, the values of the saturation magnetization increase monotonically with increasing Y or Gd concentration. Nitrogenation increases the uniaxial anisotropy of the Er sublattice, and causes a spin reorientation. The Y and Gd concentration dependencies of the spin reorientation temperature T_{sr} exhibit maxima. The tentative spin phase diagrams are presented.

INTRODUCTION

Since Coey and Sun[1] reported a distinct improvement of the magnetic properties of the iron-rich R_2Fe_{17} compounds (R=rare earth or Y) by introducing nitrogen, the rare earth-iron nitrides of the type $R_2Fe_{17}N_y$ have attracted considerable interest, because of the excellent intrinsic magnetic properties for permanent magnet application. The structural and magnetic properties of the R_2Fe_{17} nitrides and $R_2Fe_{17}N_y$-based pseudoternary compounds have been extensively investigated. It is well known now that introduction of nitrogen in R_2Fe_{17} compounds not only results in an increase in the Curie temperature and saturation magnetization, but also leads to a marked change of magnetocrystalline anisotropy of the compounds.[2–4] Both $Y_2Fe_{17}N_y$ and $Er_2Fe_{17}N_y$ crystallize in a hexagonal Th_2Ni_{17}-type structure. For $Gd_2Fe_{17}N_y$ both hexagonal Th_2Ni_{17}- and rhombohedral Th_2Zn_{17}-type structures may coexist.[5,6] These compounds have similar Curie temperatures. However, the magnetocrystalline anisotropy of the three compounds are totally different. According to a crystal field theory of the anisotropy of the rare earth-transition metal intermetallic compounds,[7] a positive second-order Stevens coefficient α_J of Er ion combining with a negative second-order crystal field coefficient A_{20} in the R_2Fe_{17} compounds[8] results in a uniaxial anisotropy of the Er sublattice, whereas the anisotropy of the Fe sublattice is planar. The contribution to the uniaxial anisotropy which results from the Er sublattice can be enhanced by introduction of nitrogen. On the other hand, because the orbital moment of Gd is zero and Y has no magnetic moment, it can be expected that Gd or Y has no contribution to the anisotropy. Therefore, a study on the structural and magnetic properties of the $(Er_{1-x}R_x)_2Fe_{17}N_y$ series (R=Y and Gd) may be helpful for a better understanding of the magnetocrystalline anisotropy in these systems.

In the present investigation we have focused our attention on the crystal structure and magnetic properties of the $(Er_{1-x}R_x)_2Fe_{17}N_y$ series with R=Y and Gd, especially on magnetization and magnetocrystalline anisotropy. The results on the effect of Y and Gd substituted for Er in the $Er_2Fe_{17}N_y$ compound on the Curie temperature, saturation magnetization and magnetocrystalline anisotropy are presented.

EXPERIMENTAL METHODS

All $(Er_{1-x}R_x)_2Fe_{17}$ host compounds with R=Y, Gd and x=0, 0.1, 0.25, 0.4, 0.5, 0.6, 0.75, and 1.0, were prepared by arc melting starting elements with purity of 99.9%, followed by annealing in vacuum at 1423 K for 4 h. The ingots were pulverized to an average particle size of 25 μm and the powder samples obtained were heated in purified nitrogen gas under a pressure of about 1 atm at 770 K for 4 h to form the nitride compounds $(Er_{1-x}R_x)_2Fe_{17}N_y$. The value of the nitrogen content y was determined to be between 2 and 3 by weighing. X-ray diffraction was employed to determine the structure and lattice parameters of the compounds. The thermomagnetic curves were measured in a Faraday balance in the temperature region from 77 K to above the Curie temperature. The Curie temperatures T_C were derived from σ^2-T plots. Magnetization curves were measured with an extracting sample magnetometer in applied fields up to 7 T at 4.2 K. The spin reorientation temperatures T_{sr} were determined from ac-susceptibility measurements.

RESULTS AND DISCUSSION

Based on x-ray powder diffraction and thermomagnetic analysis, all the investigated $(Er_{1-x}Y_x)_2Fe_{17}N_y$ and their host compounds crystallize in the hexagonal Th_2Ni_{17}-type structure, whereas $(Er_{1-x}Gd_x)_2Fe_{17}N_y$ and their host compounds crystallize in the Th_2Ni_{17}-type structure for $x\leq 0.75$ and Th_2Zn_{17}-type structure for $x>0.75$ which suggests that the large size of Gd atoms makes the hexagonal Th_2Ni_{17}-type structure unstable. In all compounds a small amount of α-Fe was detected. The typical x-ray diffraction patterns for $(Er_{0.75}Gd_{0.25})_2Fe_{17}N_y$, $Gd_2Fe_{17}N_y$ and their host compounds are shown in Fig. 1. Compared with the host, the diffraction peak positions for the nitride exhibits a clear shift toward lower angles, indicating the lattice expansion upon nitrogenation. The lattice constants a and c of the nitrides, like those of their host compounds, change very little with x. The average values of a and c of the nitrides are 8.642 Å(8.462

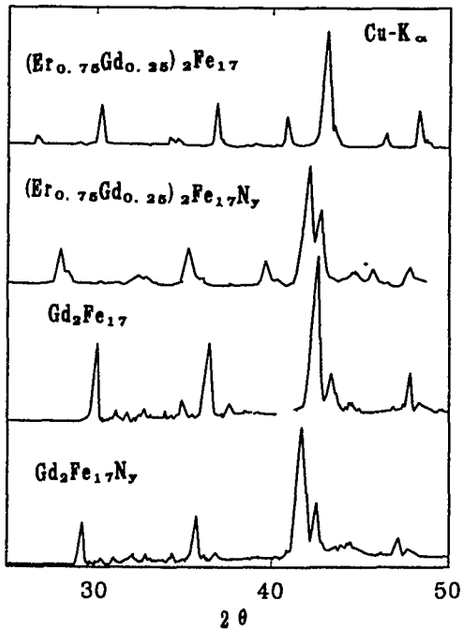

FIG. 1. X-ray diffraction patterns of $(Er_{0.75}Gd_{0.25})_2Fe_{17}$, $(Er_{0.75}Y_{0.25})_2Fe_{17}N_y$, Gd_2Fe_{17}, and $Gd_2Fe_{17}N_y$ compounds.

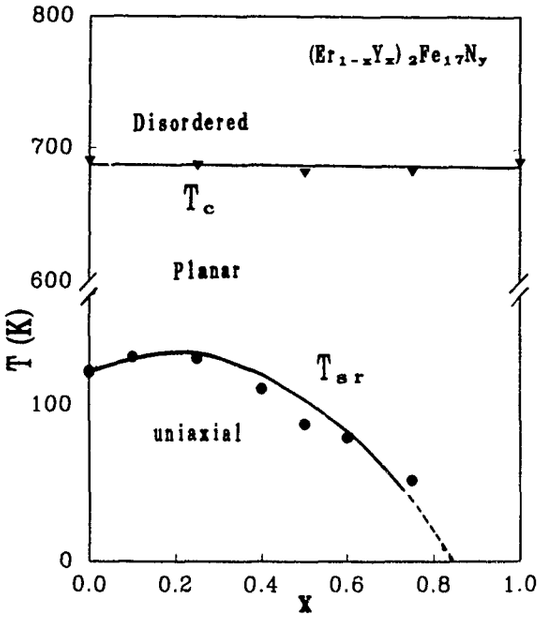

FIG. 3. Spin phase diagram of the $(Er_{1-x}Y_x)_2Fe_{17}N_y$ compounds.

Å) and 8.458 Å(8.307 Å) for $(Er_{1-x}Y_x)_2Fe_{17}N_y$ and 8.661 Å(8.473 Å) and 8.539 Å(8.332 Å) for $(Er_{1-x}Gd_x)_2Fe_{17}N_y$ compounds, respectively. The data between parentheses pertain to the compounds before nitriding. After nitrogenation the average unit-cell volume expansion $\Delta V/V$ amounts to 6.0% for both series.

Figure 2 shows the temperature dependence of ac susceptibility χ measured at temperatures between 4.2 K and room temperature, for several compositions of $(Er_{1-x}Y_x)_2Fe_{17}N_y$. Indications for spin reorientations were found in the form of maxima or jumps in the χ (T) curves. Based on the values of the spin reorientation temperature T_{sr} deduced from ac susceptibility data, the tentative spin phase diagrams are shown in Fig. 3 for $(Er_{1-x}Y_x)_2Fe_{17}N_y$ and in Fig. 4 for $(Er_{1-x}Gd_x)_2Fe_{17}N_y$ compounds. It is well known now that in the Er_2Fe_{17} compound the magnetization of Er sublattice exhibits uniaxial anisotropy, whereas the magnetization of Fe sublattice has easy plane anisotropy. Because the

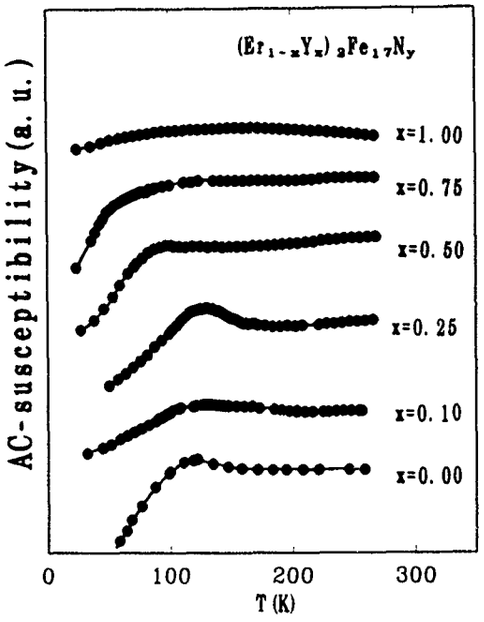

FIG. 2. Temperature dependence of the ac susceptibility (in arbitrary units) for $(Er_{1-x}Y_x)_2Fe_{17}N_y$ compounds.

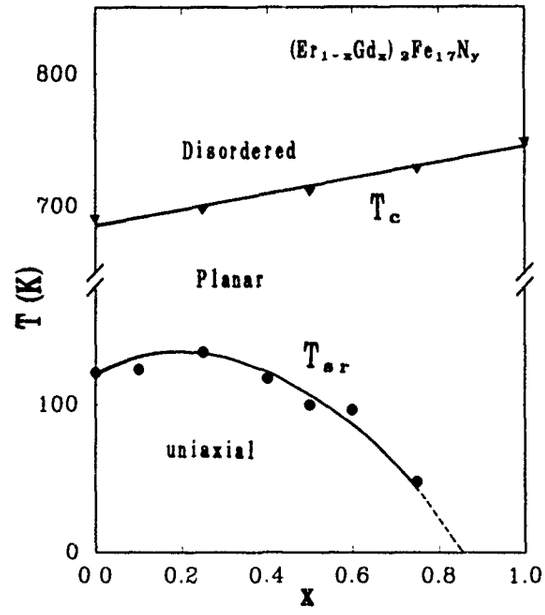

FIG. 4. Spin phase diagram of the $(Er_{1-x}Gd_x)_2Fe_{17}N_y$ compounds.

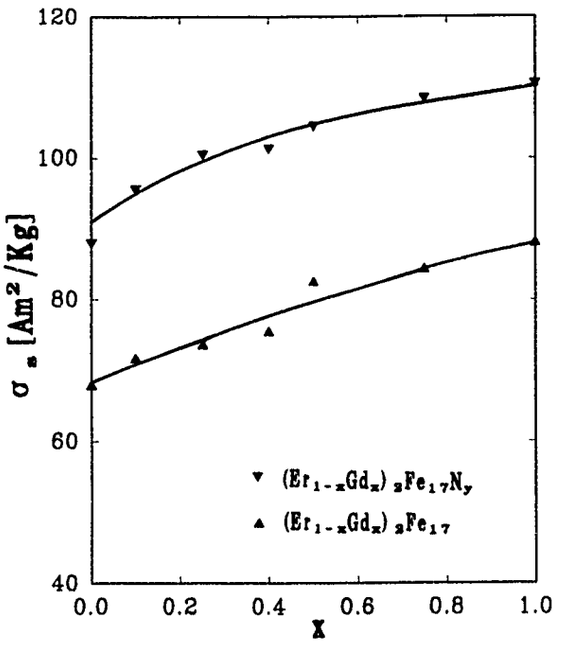

FIG. 5. Concentration dependence of the 4.2 K saturation magnetization of the $(Er_{1-x}Gd_x)_2Fe_{17}N_y$ compounds.

latter is much larger than the former, the net anisotropy of Er_2Fe_{17} compound is planar in the whole magnetically ordered temperature region. Introduction of nitrogen leads to an increase in the uniaxial anisotropy of the Er sublattice and a spin reorientation from easy plane to easy axis observed at 120 K on cooling. It can be seen from Fig. 3 and Fig. 4 that the T_{sr} value increases a little with Y or Gd concentration for small x, going through a broad maximum at $x=0.25$ for both $(Er_{1-x}Y_x)_2Fe_{17}N_y$ and $(Er_{1-x}Gd_x)_2Fe_{17}N_y$ compounds, then decreases monotonically with increasing x and reaches zero at $x\approx0.9$ for both $(Er_{1-x}Y_x)_2Fe_{17}N_y$ and $(Er_{1-x}Gd_x)_2Fe_{17}N_y$ compounds. Therefore, tentatively, we suggest, as indicated in Fig. 3 and Fig. 4, that the increase of the uniaxial anisotropy with x for a small x may be associated with the preferential substitution of Y and Gd for Er. In the hexagonal Th_2Ni_{17} structure there are two crystallographically nonequivalent rare earth sites, $2b$ and $2d$. In the Tm_2Fe_{17} compounds, A_{20} is negative at $2b$ sites and positive at $2d$ sites, so the Tm with a positive α_J exhibits uniaxial anisotropy at $2b$ sites and planar anisotropy at $2d$ sites.[9] It can be reasonably assumed that such a situation is applicable for the investigated $(Er,R)_2Fe_{17}N_y$ compounds. The preferential substitution of Y and Gd atoms for Er atoms on certain sites at which Er exhibits a planar anisotropy may lead to an increase in the uniaxial anisotropy of the resultant Er sublattice. For larger x the substitution of Y or Gd for Er leads to a decrease of Er atom number at $2b$ sites which causes a decrease of uniaxial anisotropy.

The Curie temperatures of the $(Er_{1-x}Y_x)_2Fe_{17}N_y$ and $(Er_{1-x}Gd_x)_2Fe_{17}N_y$ compounds are also shown in Fig. 3 and Fig. 4, respectively. The T_c value of the $Er_2Fe_{17}N_y$ is as much as 340 K higher than that of the host. The T_c of $(Er_{1-x}Gd_x)_2Fe_{17}N_y$ compounds increases with x, whereas T_c of $(Er_{1-x}Y_x)_2Fe_{17}N_y$ compounds shows no change as x increases. A strong increase of the Curie temperature upon nitrogenation may partly be explained in terms of the lattice expansion of the nitrides which leads to an increase in the average nearest neighbor Fe–Fe distance and, therefore, to an increase of the positive Fe–Fe exchange interaction. The values for the saturation magnetization σ_s were derived by extrapolating the high field part of the magnetization curves measured at 4.2 K to $B=0$. The σ_s values have been corrected for the contribution of the α-Fe impurity phase to the magnetization, which could be deduced from the high temperature magnetization measurements. Figure 5 shows the saturation magnetization σ_s as a function of x for $(Er_{1-x}Gd_x)_2Fe_{17}N_y$ compounds. The σ_s values of the host compounds are also presented in Fig. 5 for comparison. Introduction of nitrogen leads to an increase in saturation magnetization. The σ_s values in both the $(Er_{1-x}Y_x)_2Fe_{17}N_y$ and $(Er_{1-x}Gd_x)_2Fe_{17}N_y$ compounds increase monotonically with x. However, the σ_s value increases much faster in the former than in the latter, because the moment of the heavy rare earth element exhibits an antiferromagnetic coupling with the Fe moment, the Gd moment is smaller than the Er moment, and the Y has no magnetic moment.

Structural and magnetic properties of the $Er_2Fe_{17-x}Al_xN_y$ compounds ($0 \leq x \leq 3$) have been investigated. All nitrides and parent compounds crystallize in the Th_2Ni_{17} structure. Al substituted for Fe leads to an increase in lattice constants a and c. Introduction of nitrogen results in a further increase of lattice constants, but the magnitude of this increase is smaller for increasing x. As Al content increases, the Curie temperature of the parent compound increases, whereas the Curie temperature of the nitride decreases. The substitution of Al for Fe results in a decrease of Fe moment in both nitrides and parent compounds. Introduction of nitrogen leads to an increase in the uniaxial anisotropy of the Er sublattice and a spin reorientation. A tentative spin phase diagram has been constructed.

INTRODUCTION

Recently the interstitial rare earth-iron nitrides $R_2Fe_{17}N_y$ have attracted much attention because of the outstanding intrinsic hard-magnetic properties as potential high-performance permanent magnets.[1] The structural and magnetic properties of these compounds have been extensively investigated.[2–5] It is well known now that the magnetic moment and Curie temperature of R_2Fe_{17} compounds are strongly increased by the introduction of interstitial nitrogen. Furthermore, the absorption of nitrogen also strongly changes the magnetocrystalline anisotropy of the compounds. The introduction of nitrogen leads to the appearance of uniaxial anisotropy in the $Sm_2Fe_{17}N_y$ compounds in the whole magnetic ordering temperature region. Although Er, like Sm, possesses positive second-order Stevens coefficient α_J, the easy magnetization direction of Er_2Fe_{17} compound is on the basal plane in whole temperature region up to Curie temperature. Introduction of nitrogen in the Er_2Fe_{17} compound leads to an increase of uniaxial anisotropy and a spin reorientation from the easy plane to the easy axis on cooling.[6]

It has been found[7] that the substitution of Al for Fe leads to an increase in the uniaxial anisotropy of Sm sublattice in $Sm_2Fe_{17-x}Al_x$ compounds. On the other hand, Al is also considered as an important element in improvement of magnetic performance of the permanent magnetic materials. For example, the outstanding values of magnetic hardness can be achieved at cryogenic temperature, both in powder and bulk materials of $SmCo_5$, by substitution of Al for Co.[8] As mentioned above, both substituting a third element (such as Al) for Fe and introducing the interstitial atoms (such as N, C) lead to a remarkable enhancement of the Curie temperature and the uniaxial anisotropy in the R_2Fe_{17} series with R having a positive α_J. Here, in an attempt to maximize these enhancements, we studied the $Er_2Fe_{17-x}Al_xN_y$ series to investigate the effect of the substitution of Al for Fe on the structure and magnetic properties of the interstitial $R_2Fe_{17}N_y$ nitrides. In this contribution such an effect has been determined and the results are presented.

EXPERIMENT

$Er_2Fe_{17-x}Al_x$ compounds with $x=0$, 0.1, 0.2, 0.5, 0.75, 1.0, 2.0, and 3.0 were prepared by arc melting the constituent elements of at least 99.9% purity. The samples were homogenized by annealing in vacuum at 1370 K for 10 h. The $Er_2Fe_{17-x}Al_xN_y$ nitrides were prepared by heat treating the pulverized parent compounds in purified nitrogen gas at a pressure of one atmosphere at 773 K for different times, depending on the Al content in the parent compounds, to achieve a sufficient nitrogenation. The nitrogen content in each nitride was determined by weighting.

X-ray diffraction with Cu-$K\alpha$ radiation was used to check the crystal structure and to determine the lattice constants. Thermomagnetic analysis (TMA) was performed in the temperature range from 77 K to above the Curie temperature in a magnetic field of 0.8 T by means of a Faraday balance. The Curie temperatures were derived from σ^2-T plots. The field dependencies of magnetization of samples consisting of powders which were free to be oriented by an applied magnetic field were measured at 4.2 K by means of an extracting sample magnetometer using a field up to 7 T produced by a superconducting magnet. The values of saturation magnetization were derived by extrapolating the high-field value to $B=0$. The spin reorientation temperatures T_{sr} were determined from ac-susceptibility measurements.

RESULTS AND DISCUSSION

X-ray powder diffraction patterns and TMA show that all investigated ternaries and their nitrides are single phase except for a small amount of α-Fe in a few samples. All $Er_2Fe_{17-x}Al_x$ compounds and corresponding nitrides crystallize in the hexagonal Th_2Ni_{17}-type structure. The values of lattice constants a, c are given in Table I. Figure 1 shows the lattice constants a and c as a function of Al content for both nitrides and parent compounds. The substitution of Al for Fe results in a linear increase of lattice constants a and c in the parent compounds. This may be associated with the larger radius of the Al atom compared with that of the Fe atom. The introduction of nitrogen in $Er_2Fe_{17-x}Al_x$ leads to a further increase of lattice constants, whereas the amplitude of this increase decreases monotonically with increasing Al content, furthermore, the lattice constants a and c of the nitrides are almost independent of Al content, which suggests that the substitution of Al for Fe prevents the absorption of nitrogen. The values of nitrogen content y introduced in nitrides are

	(8.544)	(8.377)	(412)		(1.83)	

listed in Table I. The nitrogen content y in $Er_2Fe_{17-x}Al_xN_y$ decreases monotonically with increasing Al content. According to the neutron diffraction and Mössbauer effect studies of $Nd_2Fe_{17-x}Al_x$,[9] the Al fractional occupancy on the 18 f sites in the $Nd_2Fe_{17-x}Al_x$ increases uniformly with increasing the Al content. The occupancy of the larger Al atoms on the 18 f sites results in a decrease of 9e spacial volume and may prevent the introduction of nitrogen atoms.

The average iron magnetic moment μ_{Fe} was calculated on the basis of the saturation magnetization σ_s measured at 4.2 K. The σ_s values have been corrected for the contribution of the α-Fe impurity phase to the magnetization, which could

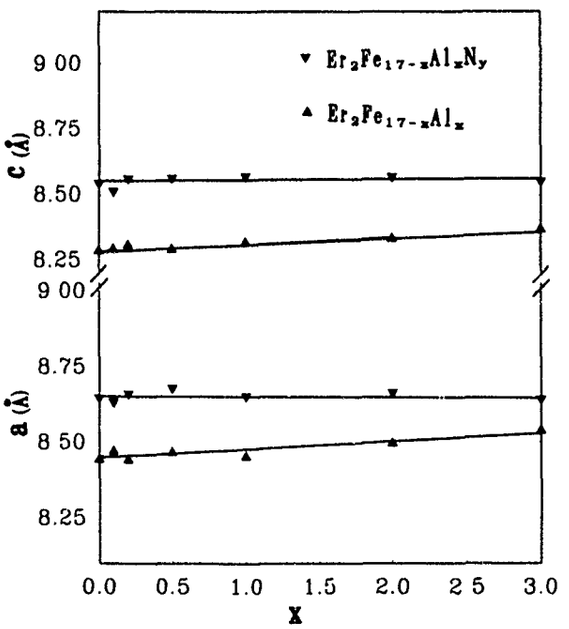

FIG. 1. Al content dependence of the lattice constants a and c of the $Er_2Fe_{17-x}Al_xN_y$ and $Er_2Fe_{17-x}Al_x$ compounds.

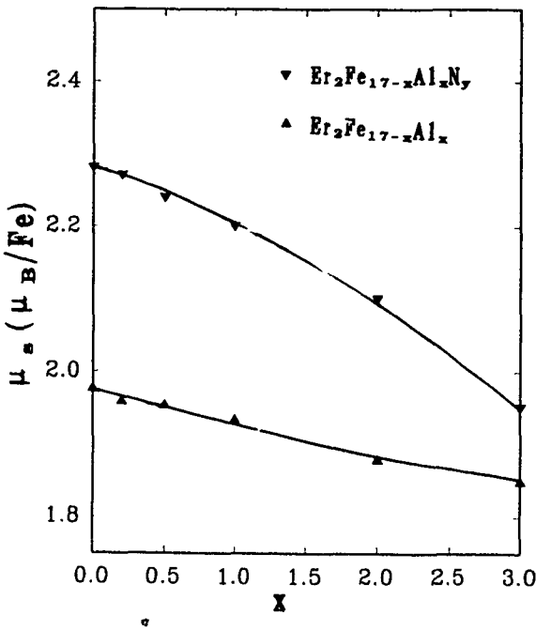

FIG. 2. The average iron magnetic moment μ_{Fe} vs the Al concentration for $Er_2Fe_{17-x}Al_xN_y$ and $Er_2Fe_{17-x}Al_x$ compounds.

be deduced from the high temperature magnetization measurements. μ_{Fe} values as a function of Al content are shown in Fig. 2. In the evaluation of the magnetic moment per iron ion it was assumed that the moment of Er ion is independent of the Al content and the value is same as that of the free Er ion. It can be seen that either in the parent compounds or in the nitrides the average Fe ion moment decreases monotonically with increasing Al content. In the case of the parent compounds, the Fe moment decreases from 1.98 μ_B for $x=0$ to 1.83 μ_B for $x=3$. This indicates a quenching of the Fe moment by the substitution of Al, which is similar to various analogous systems based on Al, rare earth and magnetic transition metals.[10] Plusa *et al.*[11] explained the decrease of the average Fe moment with Al concentration in $Y_2(Fe_{1-x}Al_x)_{17}$ pseudobinary compounds by assuming that all the aluminum valence electrons populate the 3d band of the Y_2Fe_{17} compound and that one spin subband is completely full. Introduction of nitrogen leads to an increase in the average iron moment, but the amplitude of the increase upon nitrogenation decreases monotonically with increasing Al content, which may be associated with the decrease of the nitrogen content with increasing Al content. The values of Curie temperature T_C for both nitrides and parent compounds are also listed in Table I. T_C of the parent compounds increases with x, which may be related to the increase of lattice constants, corresponding to an increase of the positive Fe–Fe exchange coupling. Introduction of nitrogen leads to a further increase in T_c, but T_c of the nitrides decreases monotonically with increasing x. Because the lattice constants of the nitrides are nearly independent of Al content, the decrease of T_c of nitrides with Al content should be associated with the decrease of Fe moment and the decrease of the nitrogen content.

Figure 3 shows the temperature dependence of ac susceptibility χ, measured at temperatures between 4.2 K and

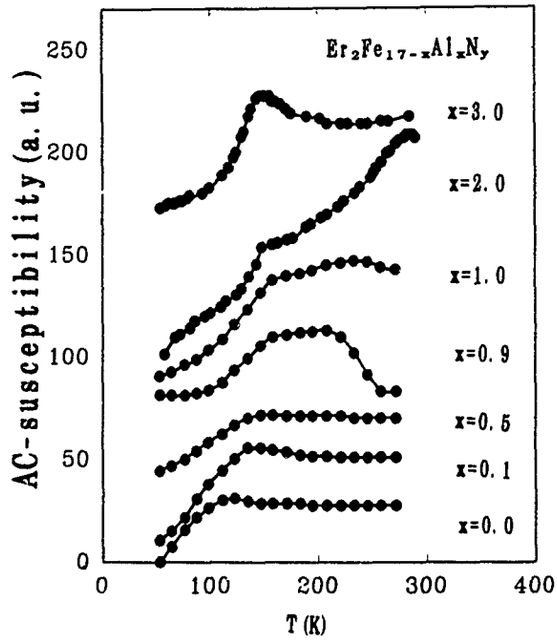

FIG. 3. Temperature dependence of the ac susceptibility (in arbitrary units) for $Er_2Fe_{17-x}Al_xN_y$ compounds.

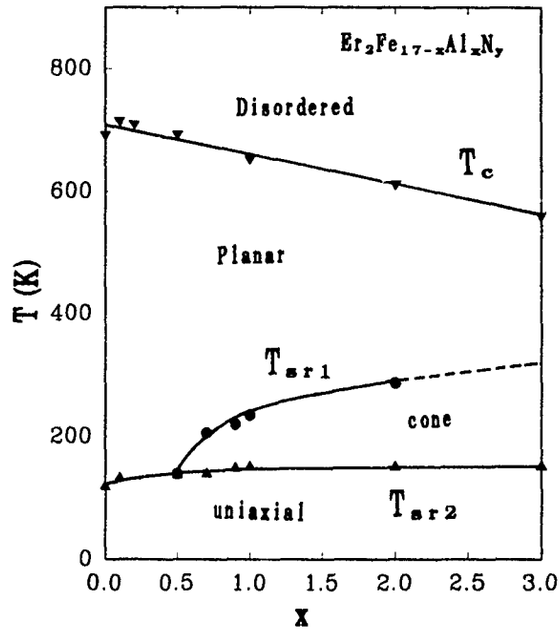

FIG 4. The tentative spin phase diagram of the $Er_2Fe_{17-x}Al_xN_y$ compounds.

room temperature, for several compositions. Indications for spin reorientation were found in the form of maxima or jumps in the χ (T) curves. Based on the values of the spin reorientation temperatures T_{sr} deduced from ac susceptibility data, a tentative spin phase diagram for the nitride is shown in Fig. 4. Introduction of nitrogen leads to an increase in the uniaxial anisotropy of the Er sublattice and a spin reorientation at 120 K. The spin reorientation temperature T_{sr} increases with increasing Al content. For the nitrides with $x>0.5$, two spin reorientations can be observed at T_{sr1} and T_{sr2}, respectively, which suggests that with decreasing temperature the magnetization of the nitrides starts to depart from the c plane at T_{sr1} and coincides with the c axis at T_{sr2}. For the temperature between T_{sr1} and T_{sr2} an easy cone can be expected. Li and Cadogan[12] investigated the carbon content dependence of the crystal field coefficients for $Sm_2Fe_{17}C_{3-x}$ compounds and found that both A_{20} and A_{60} become more negative with increasing carbon content whereas A_{40} becomes more positive. It can be reasonably assumed that such a content dependence of the crystal field coefficients is applicable for $Er_2Fe_{17}N_y$ compounds. The appearance of an easy cone in the nitrides with $x>0.5$ may be due to the fact that the decrease of nitrogen content with increasing Al content resulted in a shift of A_{20} toward less negative and a negative K_1 value (including the negative contribution of the Fe sublattice). In addition, a positive A_{40} gives a positive K_2 which leads, in certain x region, to the condition for easy cone, $\sin^2\theta=-K_1/2K_2$, to be satisfied.

Samples of (Cu/Zn)-bonded and unbonded $Sm_2Fe_{17}M_xN_y$ with M=B or C (x=0, 0.25, and 0.5; y<3) were fabricated. All the samples, besides those with B, show single Curie temperature T_C and with Sm_2Fe_{17}-type crystal structure; however, multiphase structure and double T_C were observed in all the samples with B. For all the heating runs the electrical resistivity roughly above 600 K increases abruptly for all Zn-bonded samples; and decreases abruptly for all Cu-bonded samples. After these high temperature runs, the residual electrical resistivity increases for all Zn-bonded samples, and decreases for all Cu-bonded samples. The effects of Cu segregation and Zn reaction with samples are identified by the EPMA analyses.

Interstitial nitrides $Sm_2Fe_{17}N_y$ magnets discovered by Coey *et al.*[1] have been extensively studied during the past few years, e.g., Refs. 1–9. It was found that the effect of nitrogen on the structure is to expand the unit cell without changing the symmetry of the 2:17 parent compound. $Sm_2Fe_{17}N_y$ compound possesses high Curie temperature, a strong uniaxial anisotropy field, and a high saturation magnetization, which are comparable or superior to those of $Nd_2Fe_{14}B$. However, $Sm_2Fe_{17}N_y$ is metastable and decomposes to SmN and α-Fe at high temperatures roughly above 650 °C.[10] In general, low-temperature-melting metals such as Zn, Sn, and In or organic resins such as epoxy are used to form $Sm_2Fe_{17}N_y$ bonded magnets.[11–15]

Samples for this study were prepared from commercially available high purity Sm(99.9%), Fe(99.99%), C, B, and nitrogen gas. The Sm_2Fe_{17} ingots were prepared by arc melting technique, followed by an anneal in vacuum at 1270 K for two days. For samples containing C or B, the C and B were added during the arc-melting process. These ingots were crushed and milled to powders with the average particle size of 10 μm. The temperature for nitrogenation is in the range from 700 to 800 K. In order to avoid a possible phase transition during cooling the quartz tubes were water quenched afterwards. For bonded samples, the milled samples were blended with 25 wt % of Zn or Cu powders (−325 mesh), and pressed into pellets with a pressure of 4 tons/cm^2 in a magnetic field of 1 T. Pellets were then heat treated in N_2 for 2 h at temperatures of 620–720 K for Zn-bonded samples, and of 620–800 K for Cu-bonded samples. All the samples were characterized by powder x-ray diffraction, scanning electron microscopy (SEM) with electron probe microanalysis (EPMA) and differential scanning calorimeter (DSC), etc.

The electrical resistivity and magnetization of these samples were measured as functions of temperatures between 4 and 1200 K. For the magnetization studies, both vibration sample magnetometer (VSM) and superconducting quantum interference device (SQUID) were used to determine the magnetization.

Powder x-ray diffraction analyses show that the Sm_2Fe_{17} phase with the Th_2Zn_{17} crystal structure exists in our samples; however, a small amount of α-Fe is always presented in most of our samples. Multiphase structure was observed in the samples with B. As an example, the powder x-ray diffraction patterns observed for Sm_2Fe_{17}, $Sm_2Fe_{17}C_{0.5}$, $Sm_2Fe_{17}B_{0.5}$, and $Sm_2Fe_{17}N_{2.6}$ samples are shown in Fig. 1 (a) to 1 (d), respectively. It is clearly that the 2 : 17 phase peaks in (b) and (d) are shifted to lower angles in comparison with (a) for Sm_2Fe_{17}; their lattice parameters a and b were roughly calculated from the powder x-ray diffraction pattern to be a=8.58, 8.63, 8.71 Å, and b=12.41, 12.45, 12.61 Å, for Sm_2Fe_{17}, $Sm_2Fe_{17}C_{0.5}$, and $Sm_2Fe_{17}N_y$, respectively. Curve (b) in Fig. 1 shows multiphase structure in $Sm_2Fe_{17}B_{0.5}$.

The temperature dependence of the magnetization M at 8 kG of the samples had been studied between 4 and 1100 K. The value of the magnetization at 4 K are roughly between 100 and 120 emu/g for all the unbounded samples, and between 80 and 100 emu/g for all (Zn/Cu)-bonded samples. Typically, four kinds of behaviors have been observed; as an example, Fig. 2 presents the normalized magnetization M/M_0 as functions of temperature for (a) Sm_2Fe_{17}, (b) $Sm_2Fe_{17}C_{0.5}$, (c) $Sm_2Fe_{17}B_{0.5}$, and (d) $Sm_2Fe_{17}N_{2.6}$. M_0 is the magnetization at 4 K and 8 kG for each sample. Clearly, the magnetization roughly above 900 K increase slowly and then drop abruptly around 1040 K with increasing temperature. This suggests that α-Fe is precipitated roughly above 900 K. Besides the Curie temperature T_c of α-Fe around 1040 K, the curves show single T_c around 390 K for Sm_2Fe_{17}, around 540 K for $Sm_2Fe_{17}C_{0.5}$, and around 780 K for $Sm_2Fe_{17}N_{2.6}$. However, double T_c around 400 and 600 K had

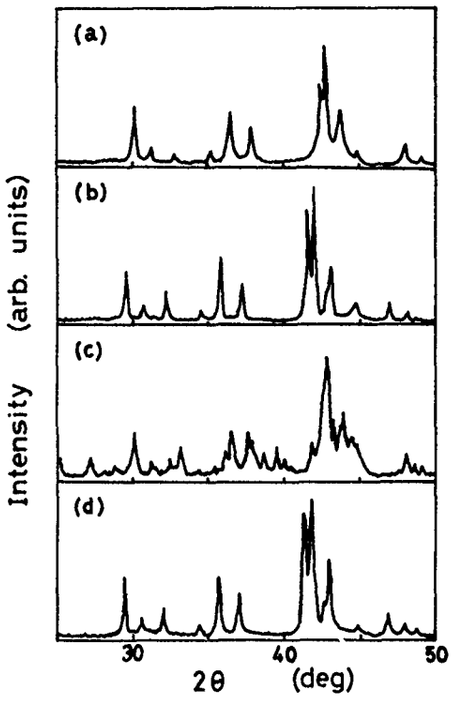

FIG. 1. The powder x-ray diffraction patterns for (a) Sm_2Fe_{17}, (b) $Sm_2Fe_{17}C_{0.5}$, (c) $Sm_2Fe_{17}B_{0.5}$, and (d) $Sm_2Fe_{17}N_{2.6}$ samples.

observed for all the $Sm_2Fe_{17}B_x$ samples. From the x-ray diffraction pattern, the electrical resistivity, and the magnetization studies, we conclude that besides the α-Fe phase, at least two major mixture phases with T_c around 400 and 600 K, are coexisted in the $Sm_2Fe_{17}B_x$ magnets. We guess that they may be the Sm_2Fe_{17} and $Sm_2Fe_{14}B$ phases.

The electrical resistivity ρ of the bulk $Sm_2Fe_{17}M_x$ (M=C or B; x=0, 0.25, and 0.5) samples has been studied with increasing and decreasing temperatures between 4 and 1200 K. Each resistivity curve approaches to a constant residual resistivity near 4 K; and its value decreases after the high temperature run. This indicates that the scattering centers for the conduction electrons are decreased after high temperature runs; and also suggests that α-Fe and other ordered phases

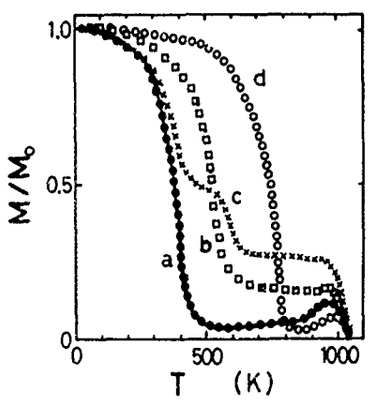

FIG. 2. The normalized magnetization as a function of temperature for (a) Sm_2Fe_{17}, (b) $Sm_2Fe_{17}C_{0.5}$, (c) $Sm_2Fe_{17}B_{0.5}$, and (d) $Sm_2Fe_{17}N_{2.6}$ samples.

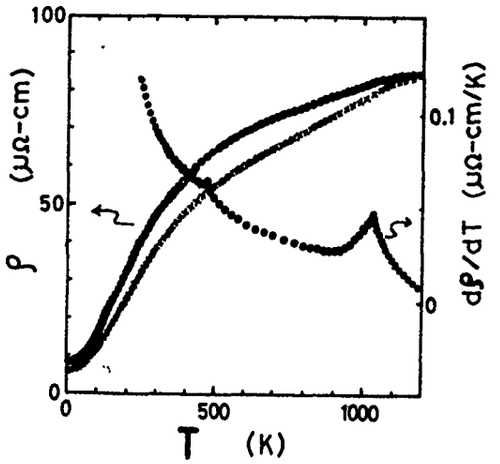

FIG. 3. The electrical resistivity and its derivative $d\rho/dT$ of the $Sm_2Fe_{17}C_{0.25}$ sample as functions of T between 4 and 1200 K. (O: heating run, ×: cooling run, and ●: $d\rho$/dT for heating run.)

may be precipitated after the high temperature runs. Typically, Fig. 3 presents the electrical resistivity data of $Sm_2Fe_{17}C_{0.25}$ sample. The open circle and cross are associated with heating and cooling runs, respectively. The derivative of the electrical resistivity with respect to temperature for the heating run is plotted by dots in Fig. 3. T_c determined from the peak of $d\rho/dT$ are 480 K for $Sm_2Fe_{17}C_{0.25}$ phase and 1040 K for α-Fe phase.

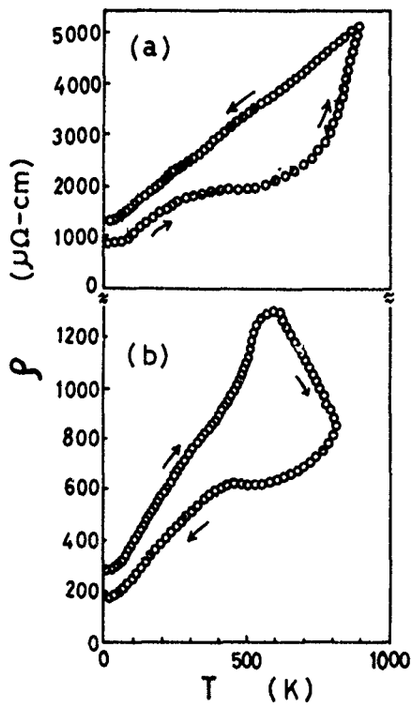

FIG. 4. The electrical resistivity as a function of T between 4 and 1000 K for (a) Zn-bonded $Sm_2Fe_{17}N_{2.0}$, and (b) Cu-bonded $Sm_2Fe_{17}C_{0.25}N_{2.6}$ (The sequence of the heating and cooling runs is indicated by arrows.)

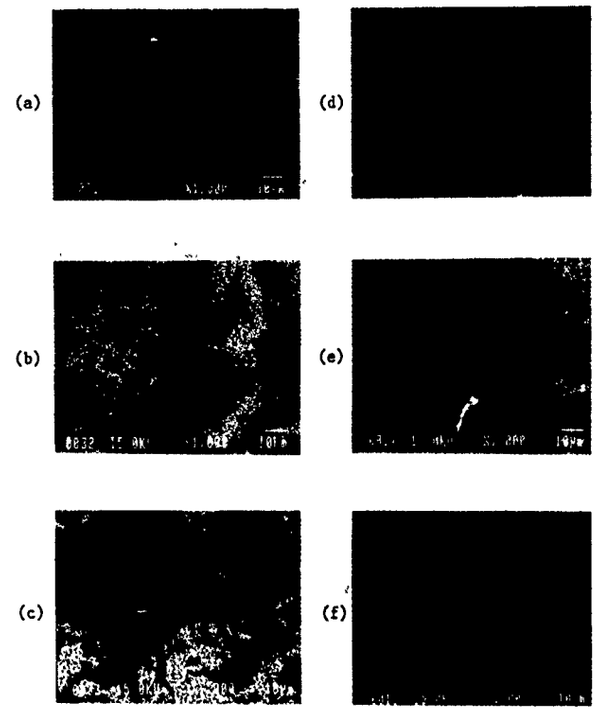

FIG. 5. (a) The SEM micrograph of the Cu-bonded $Sm_2Fe_{17}C_{0.25}N_{2.6}$ after the high temperature resistivity measurement. (b) The EPMA picture of (a) for Fe-rich distribution. (c) The EPMA picture of (a) for Cu-rich distribution. (d) The SEM micrograph of the Zn-bonded $Sm_2Fe_{17}N_{2.0}$ after the high temperature resistivity measurement. (e) The EPMA picture of (d) for Fe-rich distribution. (f) The EPMA picture of (d) for Zn-rich distribution.

The coercivity H_c of the Zn-bonded samples can be improved to 6–14 kOe after annealing them between 620 and 720 K in N_2 for 2 h. However, H_c of the Cu-bonded samples was only reached 1–3 kOe after annealing them between 620 and 800 K in N_2 for 2 h. Generally speaking, from the DSC investigations below 700 K for all the (Zn/Cu)-bonded samples, we found that an exotherm peak between 600 and 700 K for all the bonded samples, and an endothermic peak between 400 and 450 K for Cu-bonded samples only. The exotherm peak has been explained to be the onset temperature of the nitrogen absorption into Sm_2Fe_{17}.[16] It is not clear at present about the corresponding changes correlated to the exdothermic peak for all the Cu-bonded samples. However, it seems to relate the slope increase of the resistivity near 450 K with increasing temperature for all the Cu-bonded samples as shown in Fig. 4.

In general, the temperature dependence of the magnetization at 8 kG for all the (Zn/Cu)-bonded $Sm_2Fe_{17}M_xN_y$ samples behaves quite similarly to the curve d in Fig. 2 with T_c around 780 K. However, this two bonded groups show completely different behaviors for the temperature dependence of ρ with increasing and decreasing temperatures between 4 and 1000 K. The typical behaviors are that (1) for all Zn-bonded samples, the heating run ρ increases abruptly roughly above 600 K, and the value of ρ for the cooling run is always higher than that of heating run; (2) for all Cu-bonded samples, the heating run ρ decreases abruptly roughly above 600 K, and the value of cooling run ρ is always lower than that of the heating run. In Fig. 4, as an example, curve a shows the ρ of Zn-bonded $Sm_2Fe_{17}N_{2.0}$ samples, and curve b shows the ρ of Cu-bonded $Sm_2Fe_{17}C_{0.25}N_{2.6}$ samples. The sequence of the heating and cooling runs is indicated by arrows in the figures.

From the EPMA investigations of the SEM micrographs of the (Zn/Cu)-bonded samples, we found that in the Cu-bonded samples after the high temperature measurements the Fe-rich and Cu-rich areas are completely distinguishable. As shown in Fig. 5, (a) is the SEM micrograph of the Cu-bonded $Sm_2Fe_{17}C_{0.25}N_{2.6}$ sample after the electrical resistivity measurements; (b) is the EPMA picture of Fig. 5(a) for the Fe-rich distribution (white regions); and (c) is the EPMA picture of Fig. 5(a) for the Cu-rich distribution (white regions). However, it is difficult to separate the Fe-rich and Zn-rich regions in Zn-bonded samples. As an example, Fig. 5(d) is the SEM micrograph of the Zn-bonded $Sm_2Fe_{17}N_{2.0}$ sample after the electrical resistivity measurements; (e) is the EPMA picture of Fig. 5(d) for the Fe-rich distribution (white regions); and (f) is the EPMA picture of Fig. 5(d) for the Zn-rich distribution (white regions).

Finally, for Cu-bonded samples, the main reason for the decrease of ρ after high temperature runs is due to the segregation of Cu and precipitation of Fe, so that the scattering center for conducting electrons is reduced; however, the variation of the magnetization and coercivity is small after the Cu bonding. For Zn-bonded samples, the main reason for the increase of ρ after high temperature runs is due to the chemical reactions between Zn and $Sm_2Fe_{17}M_xN_y$; and under proper annealing, the variation of magnetization is small, but the coercivity can be enhanced up to 14 kOe.

Structure and magnetic properties of interstitial compounds of the series $Dy_2Fe_{17-x}Al_xZ_y$ (Z=N or H)

J. P. Liu, D. C. Zeng, N. Tang, A. J. M. Winkelman, and F. R. de Boer
Van der Waals-Zeeman Laboratory, University of Amsterdam, 1018 XE Amsterdam, The Netherlands

K. H. J. Buschow
Philips Research Laboratories, 5600 JA Eindhoven, The Netherlands

The interstitial nitrides $Dy_2Fe_{17-x}Al_xN_y$ with $0 \leq x \leq 6$ and $0 \leq y \leq 2.7$ and hydrides $Dy_2Fe_{17-x}Al_xH_y$ with $0 \leq x \leq 4$ and $0 \leq y \leq 4.2$ have been synthesized by means of melting and by means of the gas-phase-interaction method. The effect of the interstitial atoms on the structure and the lattice parameters has been investigated. For the nitrogenated compounds, it is found that nitrogen can be introduced until a maximum volume expansion is reached. The magnetic properties of the interstitial compounds, including high-field magnetization at 4.2 K and Curie temperatures, have been measured. The Dy-Fe exchange interaction is found to decrease upon introduction of the interstitial atoms.

I. INTRODUCTION

Since the discovery by Coey and Sun[1] that the introduction of interstitial nitrogen greatly improves the magnetic properties of Y_2Fe_{17} and Sm_2Fe_{17}, much work has been done to investigate the interstitial nitrides. It has been established that nitrogenation enhances the Curie temperatures and the saturation magnetization of R_2Fe_{17} (R=rare earth) compounds. A similar effect has been observed earlier for the introduction of interstitial hydrogen in R_2Fe_{17} compounds (see, for instance, Ref. 2). However, the influence of the interstitial atoms on the R-T (T=transition metal) exchange interaction in nitrides and hydrides has not been studied in very much detail. In the present work, we have investigated the effect of interstitial nitrogen and hydrogen on the Dy-Fe coupling in $Dy_2Fe_{17-x}Al_x$ compounds.

II. EXPERIMENT

The parent compounds of the series $Dy_2Fe_{17-x}Al_x$ with x=0.0, 1.0, 2.0, 3.0, 4.0, 5.0, 6.0, and 7.0 were prepared by arc melting the starting materials with purities higher than or equal to 99.9%. After the melting, the ingots were annealed at 1000 °C for three weeks. The homogenized ingots were checked by x-ray diffraction and found to be single phase.

The nitrogenation was carried out on fine powder particles (with diameters ≤ 40 μm) in a furnace at about 500 °C with flowing nitrogen gas. The time needed to reach sufficient nitrogenation varies from compound to compound. It was found that with increasing aluminum content in the parent series, the nitrogenation becomes increasingly difficult. Hydrogenation was performed by heating powdered samples for a few hours at about 250 °C in flowing hydrogen gas. It was found that the hydrogenation can only be carried out for compounds with $x<5$. The nitrogen and hydrogen contents were determined by weighing the samples. A detailed description of the synthesis of the interstitial nitrides and hydrides will be given in Ref. 3.

All nitrogenated and hydrogenated compounds have been checked by x-ray diffraction (with Cu $K\alpha$ radiation) to confirm the formation of the interstitial phases, to determine the lattice constants, and to detect the presence of possible impurity phases.

High-field magnetization measurements up to 35 T at 4.2 K have been carried out in the Amsterdam high-field installation.[4] The samples consisted of powder particles that were free to rotate in the sample holder. The Curie temperatures were measured by means of an automatic magnetization-temperature recorder based on the Faraday method. The magnetic field applied in the measurement was 0.14 T.

III. RESULTS AND DISCUSSION

A. Expansion of the unit cells upon the introduction of interstitial nitrogen and hydrogen

Figure 1 shows as an example the diffraction patterns of the $Dy_2Fe_{17-x}Al_x$ compound with x=1 and its nitride and

[a]These data should be considered as less accurate.

hydride. It can be clearly seen that the unit-cell volume expands upon nitrogenation and hydrogenation, the expansion caused by the nitrogenation being the largest. Similar results have been obtained for the nitrides up to $x=6$ and for the hydrides up to $x=4$. In Table I, the structural data of the compounds are listed. In the calculation of the unit-cell volumes, the volumes of the compounds crystallizing in hexagonal structure have been multiplied by 1.5 to compare them with the unit-cell volumes of the compounds with rhombohedral structure.

It is interesting to note that the amount of interstitial atoms that can be introduced into the compounds decreases with increasing aluminum concentration. Above $x=6$ nitrogenation was not found to be possible and above $x=4$ hydrogenation was not possible, even after treatments for a very long time. All nitrogenated compounds have almost the same lattice parameters, appearing to reach a maximum expansion. The same phenomenon has previously been observed for other series.[5] In the case of the hydrides, this "maximum expansion" phenomenon was not observed.

As is usually observed, α-Fe precipitates in the samples during the nitrogenation, which contributes to the magnetization of the compounds. A method to correct for this impurity contribution is presented elsewhere.[6]

B. Magnetic properties of the interstitial nitrides and hydrides

The Curie temperatures of the compounds $Dy_2Fe_{17-x}Al_x$ and $Dy_2Fe_{17-x}Al_xN_y$ are listed in Table II. In the range $x\leq 3$, substitution of Fe by Al causes an increase in the Curie temperature, which has been discussed in Refs. 7 and 8. The expansion of the unit cell caused by the introduction of nitrogen is accompanied by an increase of the Curie temperature. The amount of nitrogen that can be introduced, however, decreases with increasing Al concentration, which is accompanied by a reduced increase of the Curie temperature.

In R-T compounds, the magnetic properties change from ferromagnetic to ferrimagnetic when R proceeds from the light rare earths to the heavy rare earths.[9] If the applied external field is sufficiently high, the ferrimagnetic spin structure is affected, the magnetic moments start to bend, and the magnetization increases. A simple model that describes the magnetization process of (single-crystalline) powder particles that are free to rotate in the applied field has been presented by Verhoef *et al.*[10] According to this model, the intersublattice molecular-field coefficient n_{RT} can be derived directly from the magnetic susceptibility in the region where the departure from the ferrimagnetic structure occurs:

$$n_{RT}=B/M. \tag{1}$$

The exchange constant J_{RT} (the exchange parameter appearing in a nearest-neighbor Heisenberg-type Hamiltonian) can be obtained by means of the equation

$$J_{RT}=\frac{g_R\mu_B^2 N_T}{(g_R-1)Z_{RT}}\ n_{RT}, \tag{2}$$

where g_R is the Landé factor of the R ion, N_T is the number of T atoms per formula unit, and the Z_{RT} is the number of nearest T-atom neighbors of an R atom.

As examples, in Fig. 2 the free-powder magnetization curves are presented for the hydride and the nitride with $x=4$. The J_{RT} values that could be derived for the investigated nitrides and hydrides are collected in Table II, together with the J_{RT} values for the parent compounds taken from Ref. 7. It can be seen clearly from the table that the introduction of hydrogen or nitrogen leads to a decrease of $|J_{DyFe}|$, which is the strongest for the nitrides. This decrease of the R-T coupling upon introduction of interstitial atoms has also been observed in other series.[11] The decrease may be inter-

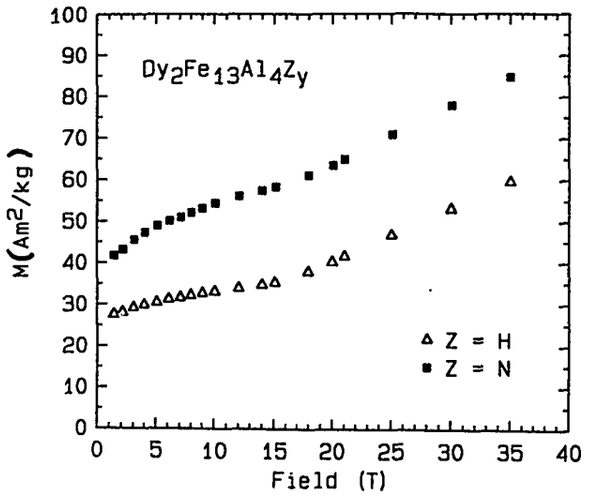

FIG. 2. Magnetic isotherms at 4.2 K of the interstitial hydride $Dy_2Fe_{13}Al_4H_{1.8}$ and nitride $Dy_2Fe_{13}Al_4N_{1.3}$.

preted to result from the increase of the unit-cell volume and the associated increase of the spatial separation of the ions. Since the $3d$-$4f$ interaction which is mediated by the hybridization of the $3d$- and $5d$-electron states is distance dependent, a decrease of $|J_{RT}|$ upon introduction of interstitial atoms seems natural.

High-coercivity Sm–Fe–Ga–C compounds with Th_2Zn_{17} structure by melt spinning

Lin-Shu Kong, Bao-gen Shen, Fang-wei Wang, Lei Cao, Hui-qun Guo, and Tai-shan Ning
State Key Laboratory of Magnetism, Institute of Physics, Chinese Academy of Sciences, P. O. Box 603, Beijing 100080, China

The magnetic hardening of the $Sm_2Fe_{14}Ga_3C_x$ was investigated by melt spinning. It was found that high coercivities can be achieved by direct quenching at the optimum substrate velocity. The coercivities of 12.6–15.0 kOe were obtained in $Sm_2Fe_{14}Ga_3C_x$ ribbons with carbon contents x from 1.0 to 2.5. The as-quenched $Sm_2Fe_{14}Ga_3C_{1.5}$ ribbons had a coercivity exceeding 13 kOe within a large range of quench rates between 18 and 30 m/s. X-ray diffraction experiments indicate that the ribbons are almost entirely comprised of the Th_2Zn_{17} phase. It is concluded that Ga not only stabilizes the hard magnetic phase but also is very effective in raising the coercivity in the $Sm_2Fe_{14}Ga_3C_x$ melt-spun ribbons.

I. INTRODUCTION

The rare-earth–iron intermetallic compounds based on the 2:17 structure have been attracting much attention as potential candidates for permanent magnet materials. It has been shown that $Sm_2Fe_{17}N_x$ and $Sm_2Fe_{17}C_x$ prepared by solid–gas reaction have excellent intrinsic magnetic properties.[1,2] Unfortunately these nitrides and carbides have a poor thermal stability and degrade when heating to temperatures above about 600 °C, which may limit their widespread applications. Our early work showed that the heavy rare-earth compounds $R_2Fe_{17}C_x$ with high C content (x close to 3.0) could be obtained by melt spinning, and that they are stable at high temperatures (above 1000 °C), while the light rare-earth compounds $R_2Fe_{17}C_x$ ($x>1.5$) are still hard to stabilize.[3–5] The magnetic hardening of $Sm_2Fe_{17}C_x$ was studied by melt-spinning techniques a few years ago, and the coercivity of 4.6 kOe for $Sm_2Fe_{17}C_{1.5}$ alloys was reported.[6]

Recently we have found that the Th_2Zn_{17} phase of Sm–Fe–C alloys with high C contents can be formed by addition of Ga.[7,8] In this paper we report the magnetic hardening of Sm–Fe–Ga–C alloys by melt spinning. A high coercivity of up to 15 kOe was achieved by direct quenching at the optimum substrate velocity.

II. EXPERIMENT

Fe and C were first melted together in an induction furnace to form Fe–C alloys which have a lower melting temperature. Then Fe, Sm, Ga, and Fe–C alloys were melted by arc melting in an argon atmosphere of high purity. An excess of 4%–10% Sm was added to compensate for the vaporization of Sm during the melting and melt-spinning steps. For homogeneity the samples were remelted for at least four times. The ingots were melt spun in a high-purify argon atmosphere using a copper quench wheel rotating at a surface velocity v_s between 0 and 47 m/s. The ribbons were about 1 mm wide and 20–30 μm thick. The phase composition and structure were investigated with a Co K_α x-ray diffractometer. The demagnetization curves were measured by an extracting sample magnetometer with fields up to 70 kOe.

III. RESULTS AND DISCUSSION

X-ray diffraction experiments indicate that $Sm_2Fe_{14}Ga_3C_x$ (x=1.0, 1.5, 2.0, and 2.5) alloys are single phase with rhombohedral Th_2Zn_{17}-type structure. As an example, the powder x-ray diffraction pattern of $Sm_2Fe_{14}Ga_3C_{1.5}$ ingot is shown in Fig. 1(a). In order to obtain a high coercivity, we prepared ribbons at various quench rates. Figure 2 shows the demagnetization curves for as-quenched $Sm_2Fe_{14}Ga_3C_{1.5}$ samples by direct melt spinning at v_s=18 and 30 m/s, respectively. The ribbons have an intrinsic coercivity H_{ci}=13.1 kOe and remanence B_r=4.64 kG for v_s=18 m/s, and H_{ci}=15.0 kOe and B_r=4.57 kG for v_s=30 m/s. The coercivities of $Sm_2Fe_{14}Ga_3C_{1.5}$ ribbons as a function of quench rates are plotted in Fig. 3. It can be seen that

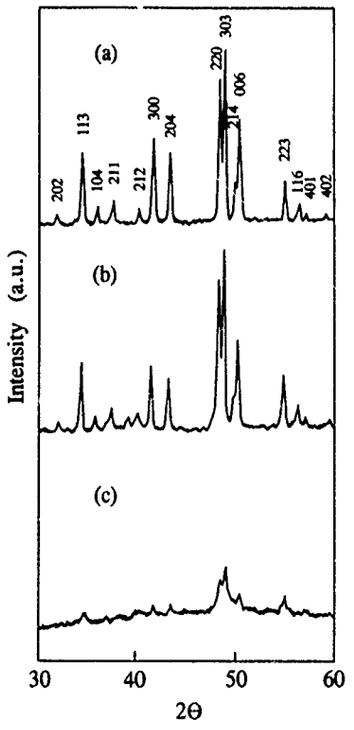

FIG. 1. X-ray diffraction patterns for $Sm_2Fe_{14}Ga_3C_{1.5}$ ingot (a), ribbons for v_s=30 m/s (b), and v_s=40 m/s (c).

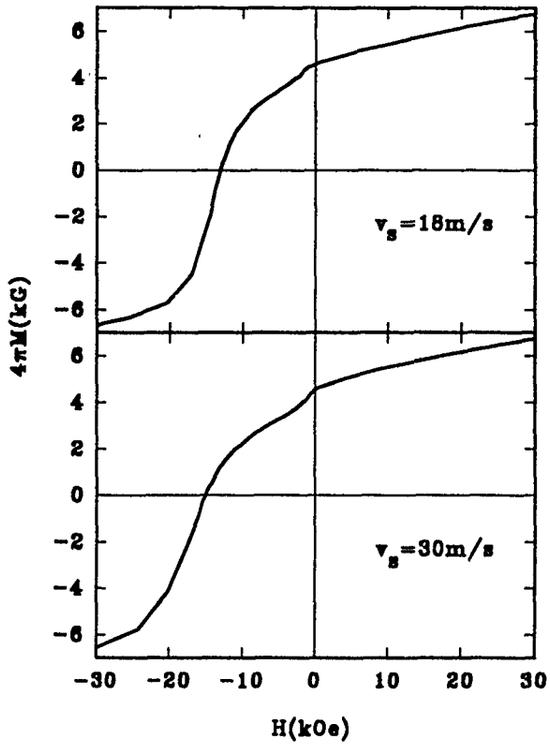

FIG. 2. Demagnetization curves for $Sm_2Fe_{14}Ga_3C_{1.5}$ ribbons.

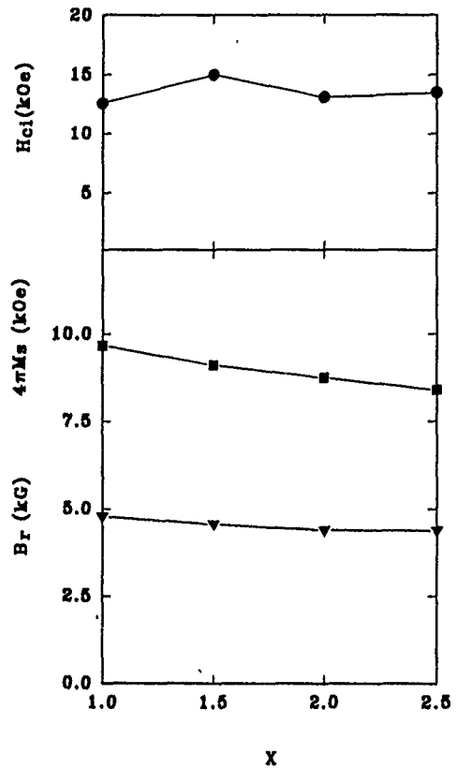

FIG. 4. Intrinsic coercivities H_{ci}, remanences B_r, and saturation magnetizations $4\pi M_s$ as a function of carbon content x for $Sm_2Fe_{14}Ga_3C_x$.

coercivities exceed 13 kOe within a large range of quench rates between 18 and 30 m/s and are reduced when the quench rate is either slower or faster than optimum, falling to less than 100 Oe at 40 m/s. The optimum quench rate in $Sm_2Fe_{14}Ga_3C_{1.5}$ is higher than that of $Nd_2Fe_{14}B$ (near 19 m/s).[9]

The x-ray powder diffraction patterns of the as-quenched $Sm_2Fe_{14}Ga_3C$ ribbons are also included in Fig. 1. All diffraction peaks in the pattern for $v_s=30$ m/s can be indexed to the Th_2Zn_{17}-type structure, indicating that the ribbons are almost entirely comprised of hard magnetic phase.

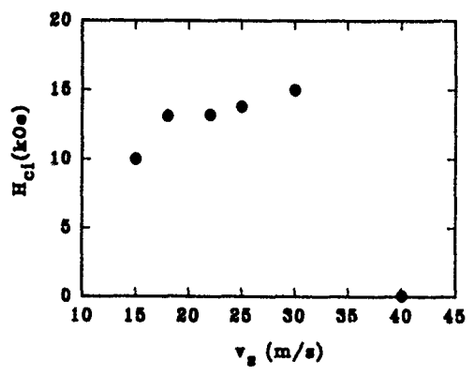

FIG. 3. Intrinsic coercivities H_{ci} as a function of quench rates v_s for $Sm_2Fe_{14}Ga_3C_{1.5}$. The data for $v_s=40$ m/s were measured in a field of up to 8 kOe.

Early studies of the $Sm_2Fe_{17}C_x$ alloys showed the reasonable strength of magnetic hardening could be attained only for high-carbon compounds.[6] However, the relatively high carbon concentration results in the formation of α-Fe and other soft magnetic phases, which prevent obtaining a higher coercivity. Because the magnetizations in the grains comprised of these soft phases are easily reversed under an external small opposite magnetic field, they induce then a cascade of demagnetization processes within adjacent grains.

The situation changes in $Sm_2Fe_{14}Ga_3C_{1.5}$. The addition of Ga helps stabilize the Th_2Zn_{17} structure and reduces the soft magnetic impurity phases such as α-Fe. Thus optimum coercivities above 13 kOe, which are substantially higher than the corresponding values of Ga-free compounds $Sm_2Fe_{17}C_x$, are easily obtained in $Sm_2Fe_{14}Ga_3C_{1.5}$.

As seen in Fig. 1, the $Sm_2Fe_{14}Ga_3C_{1.5}$ ribbons for $v_s=30$ m/s are still crystalline while an amorphous phase starts to form and only a small amount of the Th_2Zn_{17} phase remains in the ribbons for $v_s=40$ m/s. The line broadening of the diffraction peaks corresponding to the Th_2Zh_{17} phase is observed in Fig. 1(c), revealing a fine-grained microstructure. The formation of the amorphous phase and the very fine grains is consistent with the substantially low coercivity (Fig. 3).

Figure 4 shows the dependences of the intrinsic coercivity H_{ci}, saturation magnetization $4\pi M_s$, and remanence B_r on the carbon content x for $Sm_2Fe_{14}Ga_3C_x$. The remanences decrease slightly with increasing carbon content x. As expected in the isotropic uniaxial materials, B_r is near half of

the saturation magnetization $4\pi M_s$. The coercivity does not change much with the carbon content x. This is not surprising. It has been shown that the substitution of Ga for Fe in $Sm_2Fe_{14}Ga_3C_x$ with lower carbon contents results in a larger increase of uniaxial anisotropy than for higher-carbon compounds.[7] $Sm_2Fe_{14}Ga_3C_{1.0}$ exhibits an anisotropy field of 85 kOe close to that of $Sm_2Fe_{14}Ga_3C_{2.5}$ (90 kOe), which is responsible for the high coercivity.

The maximum coercivity of 15 kOe in $Sm_2Fe_{14}Ga_3C_x$ is comparable to that of $Nd_2Fe_{14}B$ (also about 15 kOe) initially reported by Croat *et al.*[9] and higher than that of $Sm(FeTiV)_{12}$ (about 9 kOe).[10] The remanence of $Sm_2Fe_{14}Ga_3C_x$ is somewhat low. The reason for this is that the replacement of Fe by Ga, which is nonmagnetic, leads to a considerable reduction of saturation magnetization.

In summary, it has been found that the $Sm_2Fe_{14}Ga_3C_x$ compounds can be magnetically hardened by direct quenching. Coercivities in excess of 13 kOe for $Sm_2Fe_{14}Ga_3C_{1.5}$ are achieved within a wide range of quenching rate between 18 and 30 m/s. $Sm_2Fe_{14}Ga_3C_x$ with the C content x from 1.0 to 2.5 has a similar hard magnetic property. Further effects to improve the remanence are in progress by two ways: one is the minimization of the Ga content, and the other is the stabilization of the 2:17 phase by other elemental substitution, such as Si and Al.

A novel hard magnetic material for sintering permanent magnets

Bao-gen Shen, Fang-wei Wang, Lin-shu Kong, Lei Cao, and Wen-shan Zhan
State Key Laboratory of Magnetism, Institute of Physics, Chinese Academy of Sciences, P.O. Box 603, Beijing 100080, China

We have discovered that the substitution of Ga or Si for Fe in $Sm_2Fe_{17}C_x$ helps the formation of high-carbon rare-earth iron compounds with 2:17-type structure. We have succeeded in preparing $Sm_2Fe_{15}M_2C_x$ (M=Ga, $x=0$, 1.0, 2.0, and 3.0; M=Si, $x=0$, 0.5, 1.0, and 1.5) compounds with Th_2Zn_{17}-type structure by arc melting. The carbides are single phase except for $Sm_2Fe_{15}Ga_2C_{3.0}$, which contains a few percent of α-Fe. The Curie temperature T_C of $Sm_2Fe_{15}Si_2C_x$ compounds is found to increase from 550 to 590 K, as x increases from 0 to 1.5. For $Sm_2Fe_{15}Ga_2C_x$, T_C increases with x from 565 K for $x=0$ to 635 K for $x=2.0$, and then decreases with x. Room-temperature saturation magnetization of these carbides is in excess of 100 emu/g and has a small dependence on carbon content. All compounds of $Sm_2Fe_{15}M_2C_x$ studied in this work except for $Sm_2Fe_{15}Si_2$ exhibit an easy c-axis anisotropy at room temperature and show an anisotropy field of higher than 90 kOe for $x \geq 1.0$. The present work suggests the possibility of producing high-performance 2:17-type sintering permanent magnets.

INTRODUCTION

The intermetallic compounds $Sm_2Fe_{17}N_x$ and $Sm_2Fe_{17}C_x$ with higher nitrogen or carbon concentration were found to have the excellent intrinsic magnetic properties.[1] They are promising candidate for permanent magnets. However, the major drawback of the nitrides or carbides prepared by the gas–solid reaction is their high temperature instability. The aim of our work is to search for highly stable hard magnetic materials based on these nitrides or carbides. Recently, we have discovered that the carbides $R_2Fe_{17}C_x$ with carbon concentration up to $x=3.0$ can be formed by melt spinning.[2–4] The melt-spun $R_2Fe_{17}C_x$ compounds were found to have a good high-temperature stability and retain Th_2Zn_{17}-type or Th_2Ni_{17}-type structures up to at least 1273 K. However, the carbides prepared by melt spinning are isotropic, while the high remanence and energy product can only be achieved in anisotropic materials. In order to obtain new anisotropic materials for sintering permanent magnets, we have studied the effect of the various elemental substitutions for Fe in the $R_2Fe_{17}C_x$ alloys on their formation, structure, and magnetic properties. It is found that the high-carbon $R_2Fe_{17}C_x$ compounds by the substitution of Ga, Si, Al, etc., for Fe exhibit a high thermal stability, in contrast with the carbides produced by the gas–solid reaction. We have succeeded in preparing single-phase compounds of high-carbon $R_2Fe,M_{17}C_x$ (R=Y, Nd, Sm, Gd, Tb, Dy, Ho, Er, and Tm; M=Ga, Si, and Al) with Th_2Zn_{17}-type or Th_2Ni_{17}-type structures by arc melting.[5–7] It was found that the arc-melted $Sm_2Fe_{14}Ga_3C_x$ compounds with $x \geq 1.5$ have a Curie temperature of higher than 600 K, and exhibit an easy c-axis anisotropy at room temperature and have an anisotropy field of higher than 90 kOe.[1] In this paper, the formation, structure, and magnetic properties of $Sm_2Fe_{15}M_2C_x$ (M=Ga, $x=0$–3.0; M=Si, $x=0$–1.5) compounds prepared by arc melting are reported.

EXPERIMENT

Iron and carbon were first arc melted into Fe–C alloys, and then Fe, Ga, Si, Sm, and Fe–C were melted by arc melting under high purified argon atmosphere into homogeneous buttons with the compositions $Sm_2Fe_{15}Ga_2C_x$ ($x=0$, 1.0, 2.0, and 3.0) and $Sm_2Fe_{15}Si_2C_x$ ($x=0$, 0.5, 1.0, and 1.5). Elements used were at least 99.9% pure. An excess of 4.5% Sm was added to compensate the mass loss due to the evaporation of Sm during melting. The arc-melted ingots of $Sm_2Fe_{15}Ga_2C_x$ were annealed in argon atmosphere at 1450 K for 24–66 h. X-ray diffraction measurements on powder samples were performed using Co $K\alpha$ radiation to determine the crystallographic structure. The Curie temperatures were determined from the temperature dependence of the magnetization measured by a vibrating sample magnetometer or a magnetic balance in a magnetic field of 1 kOe. The saturation magnetizations were measured by an extracting sample magnetometer in a field of 70 kOe. The aligned samples for anisotropy field measurements were prepared by mixing the powder with epoxy resin and then aligning in a magnetic field of 20 kOe. The room-temperature anisotropy field was determined from magnetization curves measured along and perpendicular to the orientation direction by using the extracting sample magnetometer with a magnetic field of up to 70 kOe.

RESULTS AND DISCUSSION

X-ray diffraction measurements indicate that the $Sm_2Fe_{17}C_x$ alloys with higher carbon concentration of $x>1.0$ have a multiphase structure with a predominant α-Fe phase. The arc-melted $Sm_2Fe_{15}Ga_2C_x$ ($0 \leq x \leq 3.0$) ingots exhibit a two-phase structure with the 2:17 type as the major phase coexisting with α-Fe. When these carbides were annealed at 1450 K for 24–66 h, they formed single-phase compounds of 2:17-type structure except for $Sm_2Fe_{15}Ga_2C_{3.0}$, which contains a few percent of α-Fe as a second phase. Figure 1 shows the x-ray diffraction patterns of the annealed $Sm_2Fe_{15}Ga_2C_x$ compounds. For $Sm_2Fe_{15}Si_2C_x$, when the carbon concentration x is lower than 1.5, the arc-melted samples are single phase with 2:17-type structure. When $x>1.5$, a multiphase structure of the samples are shown. In previous study it has been shown that the $Sm_2Fe_{17}C_x$ compounds with high carbon concentration

can be prepared by the gas–solid reaction[8] and rapid quenching[2–4] and cannot be formed by arc melting. The present studies have found that the substitution of Ga or Si for Fe has a significant effect on the stability of the crystal structure of high-carbon $Sm_2Fe_{17}C_x$ with 2:17-type structure. It is obvious that the substitution of Ga, Si, etc. for Fe in $R_2Fe_{17}C_x$ with high carbon concentration, like the substitution of Ti, V, Mo, etc., for Fe in RFe_{12}, plays an important role in the structural stability of rare-earth iron intermetallic compounds.

TABLE I. Structure and magnetic data for $Sm_2Fe_{15}M_2C_x$ (M=Ga and Si).

Compound	a (Å)	c (Å)	v (Å^3)	T_C (K)	M_s (emu/g)	H_A (kOe)	Anisotropy
$Sm_2Fe_{15}Ga_2$	8.648	12.515	810.6	565			c axis
$Sm_2Fe_{15}Ga_2C_{1.0}$	8.695	12.565	822.7	619	106.0	>90	c axis
$Sm_2Fe_{15}Ga_2C_{2.0}$	8.724	12.586	829.4	635	102.3	>90	c axis
$Sm_2Fe_{15}Ga_2C_{3.0}$	8.754	12.599	836.1	622			c axis
$Sm_2Fe_{15}Si_2$	8.530	12.423	782.8	550			plane
$Sm_2Fe_{15}Si_2C_{0.5}$	8.566	12.443	790.7	561	108.1	55	c axis
$Sm_2Fe_{15}Si_2C_{1.0}$	8.607	12.447	798.5	578	104.3	≈90	c axis
$Sm_2Fe_{15}Si_2C_{1.5}$	8.648	12.478	808.2	590	101.8	>90	c axis
Sm_2Fe_{17}	8.559	12.410	787.3	387			plane

X-ray diffraction shows that all compounds of $Sm_2Fe_{15}M_2C_x$ have rhombohedral Th_2Zn_{17}-type structure. The lattice constants a and c and unit-cell volumes v of $Sm_2Fe_{15}M_2C_x$ compounds are listed in Table I, also including the values for Sm_2Fe_{17} for comparison. It can be seen from Table I that both the lattice constants and unit-cell volumes increase monotonically with increasing carbon concentrations. For $Sm_2Fe_{15}Ga_2C_{3.0}$ and $Sm_2Fe_{15}Si_2C_{1.5}$, the unit-cell volume expansion is about 3.1% and 3.2% compared with the carbon-free unit cell, respectively. For $x=0$, the substitution of Ga for Fe leads to an increase of the unit-cell volume by 3.1%, in contrast with the Si-substituted unit cell, which shows a negative increase of the unit-cell volume by 0.6%. A similar reduction of the unit-cell volume was also observed in other $R_2(Fe,Si)_{17}$ compounds.[9]

The Curie temperature T_C and the saturation magnetization M_s of $Sm_2Fe_{15}M_2C_x$ compounds are also listed in Table I. The room-temperature M_s of these carbides is found to be in excess of 100 emu/g and has a small dependence on carbon content. T_C of $Sm_2Fe_{15}Si_2C_x$ is found to increase from 550 to 590 K, as x increases from 0 to 1.5. For $Sm_2Fe_{15}Ga_2C_x$, T_C increases from 565 K for $x=0$ to 635 K for $x=2.0$, then decreases with x. It is commonly assumed that the Fe–Fe interaction is dominant in the Fe-rich rare-earth iron intermetallic compounds. The Curie temperature

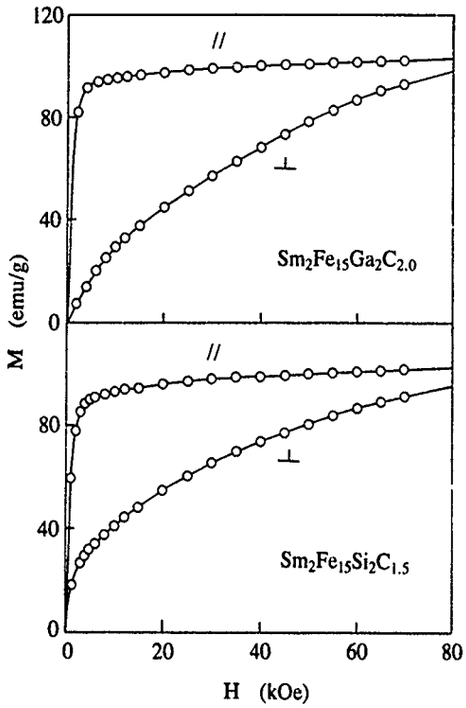

FIG. 3. The magnetization curves of the orientated $Sm_2Fe_{15}Ga_2C_{2.0}$ and $Sm_2Fe_{15}Si_2C_{1.5}$ samples measured along and perpendicular to the aligned directions.

depends strongly on the exchange interactions between Fe–Fe atoms, which is sensitive to the distance of Fe–Fe atoms. The enhancement of T_C with x in $Sm_2Fe_{15}M_2C_x$ compounds can be suggested to be mainly due to the lattice expansion induced by the introduction of carbon atoms, as with Ga- or Si-free compounds.[2–4,8]

All compounds investigated in this work exhibit an easy c-axis anisotropy at room temperature except for $Sm_2Fe_{15}Si_2$, which shows an easy plane anisotropy. This can be seen clearly from the x-ray diffraction patterns, shown in Fig. 2 as an example of magnetically aligned powder samples of $Sm_2Fe_{15}M_2C_x$. An important effect of the substitution Ga for Fe in the carbon-free compound on the magnetocrystalline anisotropy of Sm_2Fe_{17} is found. Although the Sm sublattice in the Sm_2Fe_{17} compound has an easy c-axis anisotropy, the planar anisotropy of the Fe sublattice overcomes the axial anisotropy. The role of Ga is to reduce the planar anisotropy of the Fe sublattice, resulting in a uniaxial anisotropy of the $Sm_2Fe_{15}Ga_2$ compound at room temperature. Figure 3 shows the magnetization curves of the $Sm_2Fe_{15}Ga_2C_{2.0}$ and $Sm_2Fe_{15}Si_2C_{1.5}$ samples measured along and perpendicular to the aligned directions. The room-temperature anisotropy field H_A estimated from Fig. 4 is found to be higher than 90 kOe for $x \geq 1.0$, which is about 40 kOe higher than that of $Sm_2Fe_{17}C$ (Ref. 10) and is comparable with that of $Nd_2Fe_{14}B$. Accordingly, a high-performance permanent magnet could be expected for $Sm_2(Fe,M)_{17}C_x$.

Effect of Sm substitution on structure and magnetic properties of high-carbon $Er_2Fe_{17}C_y$ compounds

Bao-gen Shen, Lei Cao, Lin-shu Kong, Tai-shan Ning, and Ming Hu
State Key Laboratory of Magnetism, Institute of Physics, Chinese Academy of Sciences, P.O. Box 603, Beijing 100080, China

The carbides $(Er_{1-x}Sm_x)_2Fe_{17}C_y$ ($0 \leq x \leq 0.8$) with a carbon concentration up to $y=3.0$ for the Er-rich region and up to $y=1.5$ for the Sm-rich region have been successfully prepared by melt spinning. They are found to crystallize in the hexagonal Th_2Ni_{17}-type or the rhombohedral Th_2Zn_{17}-type structure and to be stable at high temperature. The introduction of the interstitial carbon results in a large increase in the unit-cell volumes and Curie temperatures. The room-temperature saturation magnetization is found to increase with increasing carbon or samarium concentrations. X-ray diffraction studies of magnetically aligned powder show that the samples with $x<0.2$ or $y \leq 0.5$ exhibit easy plane anisotropy while the samples with $x \geq 0.2$ and $y \geq 1.0$ exhibit easy c-axis anisotropy at room temperature. For $(Er_{0.2}Sm_{0.8})_2Fe_{17}C_{1.5}$, the room-temperature anisotropy field is found to be 8 T, which is comparable to that of $Nd_2Fe_{14}B$.

INTRODUCTION

Introducing interstitial nitrogen or carbon atoms into R_2Fe_{17} intermetallic compounds results in a significant improvement of the magnetic properties of these compounds. The carbides $R_2Fe_{17}C_y$ ($y \approx 2.5$) prepared by the gas–solid reaction have unit-cell volumes about 6.5% larger and Curie temperatures 288–478 K higher than those of the R_2Fe_{17} compounds.[1] For $Sm_2Fe_{17}C_{2.5}$, the Curie temperature is 760 K and the room-temperature anisotropy field is 15 ± 0.5 T.[1] These carbides are promising new materials for applications in permanent magnets. However, their drawback is high-temperature unstability. In our previous work, we have discovered that the carbides $R_2Fe_{17}C_x$ with high carbon concentration can be prepared by melt spinning.[2–4] The melt-spun $R_2Fe_{17}C_x$ compounds were found to be stable at high temperature and retain still Th_2Zn_{17}-type or Th_2Ni_{17}-type structure up to at least 1273 K. We have successfully obtained melt-spun $R_2Fe_{17}C_y$ (R=Y, Gd, Tb, Dy, Ho, Er, and Tm; $x=0-3.0$) compounds and systematically studied their structure and magnetic properties.[2–6] In this article, we report the formation, structure, and magnetic properties of $(Er_{1-x}Sm_x)_2Fe_{17}C_y$ compounds prepared by melt spinning.

EXPERIMENT

Iron and carbon were first arc melted into Fe–C alloys, and then Er, Sm, Fe, and Fe–C alloy were melted by arc melting in an argon atmosphere of high purity into homogeneous buttons with the compositions $(Er_{1-x}Sm_x)_2Fe_{17}C_y$ ($0 \leq x \leq 0.8$, $y \leq 3.0$). For homogeneity the ingots were melted several times. The purities of the elements used were at least 99.9%. An excess of 4.5% Sm was added to compensate the mass loss due to the evaporation of Sm during melting. After arc melting, the ingots were melt spun under high-purity argon atmosphere on the surface of a rotating copper wheel. The quenching rate was varied by changing the surface velocity v_s of the copper wheel between 0 and 47 m/s. The ribbons obtained are about 1 mm wide and 20–30 μm thick.

X-ray diffraction measurements were performed on the melt-spun ribbons using Co $K\alpha$ radiation to identify the phase components and determine the crystallographic structure. The Curie temperatures were determined from the temperature dependence of the magnetization measured by a vibrating sample magnetometer in a magnetic field of 1 kOe. The room-temperature saturation magnetization was measured by an extracting sample magnetometer in a field of 70 kOe. The powder samples were oriented in an applied field of 10 kOe in an epoxy resin, in order to determine the magnetocrystalline anisotropy of the $(Er_{1-x}Sm_x)_2Fe_{17}C_y$ samples. The anisotropy field was determined from magnetization curves along and perpendicular to the orientation direction by using the extracting sample magnetometer with a magnetic field of up to 70 kOe at room temperature.

RESULTS AND DISCUSSION

X-ray diffraction indicates that arc-melted $(Er_{1-x}Sm_x)_2Fe_{17}C_y$ alloys with $y \leq 1.0$ are almost single phase with hexagonal Th_2Ni_{17}-type structure for $x \leq 0.3$ and rhombohedral Th_2Zn_{17}-type structure for $x \geq 0.5$. For $y>1.0$, the α-Fe phase appears coexisting with rare-earth carbides (RC) and the 2:17 phases. The amount of α-Fe increases rapidly with increasing carbon concentration y. However, we have found that by melt spinning, at an appropriate quenching rate, the $(Er_{1-x}Sm_x)_2Fe_{17}C_y$ samples with high carbon concentration crystallize in the 2:17-type structure. The formation of the 2:17 phase is found to depend strongly on the composition. The $(Er_{1-x}Sm_x)_2Fe_{17}C_y$ ($0 \leq x \leq 0.8$) compounds with carbon concentration up to $y=3.0$ for the Er-rich region and up to $y=1.5$ for the Sm-rich region can be obtained by melt spinning. For the Sm-rich end, a synthesis of high-carbon 2:17 compounds is difficult. The formation of the 2:17 phase is also sensitive to the quenching rate v_s. A low quenching rate cannot overcome the large amounts of α-Fe, whereas a high quenching rate leads to the formation of amorphous phase. For $(Er_{1-x}Sm_x)_2Fe_{17}C_y$ with

 0021-8979/94/75(10)/6256/3/$6.00 © 1994 American Institute of Physics

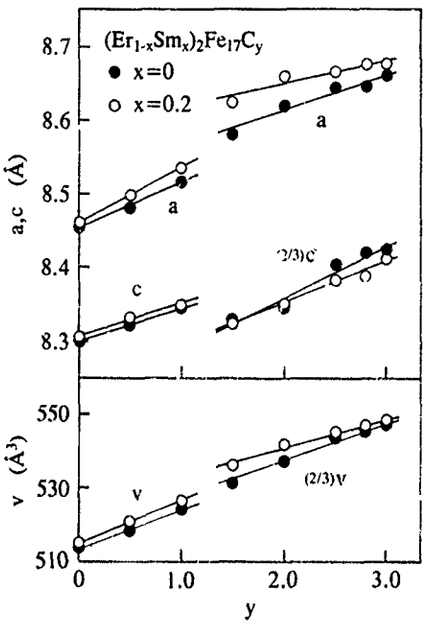

FIG. 1. The lattice parameters a and c, and the unit-cell volume v of $(Er_{1-x}Sm_x)_2Fe_{17}C_y$ with $x=0$ and 0.2 as a function of carbon concentration.

$1.5 \leqslant y \leqslant 2.8$, the optimal quenching rates to obtain the 2:17 phase are 10–20 m/s. It is interesting to note that the sample annealed at high temperature still maintains the Th_2Zn_{17}-type structure. This demonstrates the high stability of the carbides $(Er_{1-x}Sm_x)_2Fe_{17}C_y$ with high carbon concentration prepared by melt spinning, unlike the metastability of the carbides prepared by the gas–solid reaction.

It has been shown previously that the Er_2Fe_{17} compound has a hexagonal Th_2Ni_{17}-type structure, while the Sm_2Fe_{17} compound has a rhombohedral Th_2Zn_{17}-type structure. The substitution of Sm for Er leads to the structure change from Th_2Ni_{17} type to Th_2Zn_{17} type. At lower Sm concentration of $x \leqslant 0.2$, the structure change from hexagonal to rhombohedral with increasing carbon concentration x is also observed. The carbon concentration dependence of the lattice parameters and the unit-cell volumes for $(Er_{1-x}Sm_x)_2Fe_{17}C_y$ with $x=0$ and 0.2, shown in Fig. 1, shows a drastic change between 1.0 and 1.5, which results from the structure change from Th_2Ni_{17} type to Th_2Zn_{17} type.

The lattice parameters a and c, and the unit-cell volume v for $(Er_{1-x}Sm_x)_2Fe_{17}C_y$ are listed in Table I. It is found that the substitution of Sm for Er in the $Er_2Fe_{17}C_y$ gives rise to a small change of the unit-cell volumes, while the addition of the interstitial carbon results in a large increase of the unit-cell volume. It is apparent in Table I that the $Er_2Fe_{17}C_{3.0}$ compound has a unit-cell volume about 6.6% larger than that of Er_2Fe_{17}. For $(Er_{0.8}Sm_{0.2})_2Fe_{17}C_{3.0}$, the unit-cell volume expansion is about 6.5% compared with the carbon-free compound of $(Er_{0.8}Sm_{0.2})_2Fe_{17}$.

The room-temperature saturation magnetization M_s and the Curie temperature T_c for $(Er_{1-x}Sm_x)_2Fe_{17}C_y$ compounds are also summarized in Table I. The substitution of Sm for Er is found to has a relatively small effect on both M_s and T_c.

[a]Taken from Ref. 3.

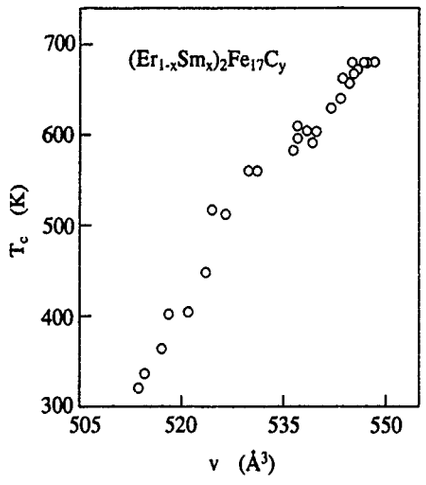

FIG. 2. The Curie temperature T_c of $(Er_{1-x}Sm_x)_2Fe_{17}C_y$ compounds as a function of unit-cell volume.

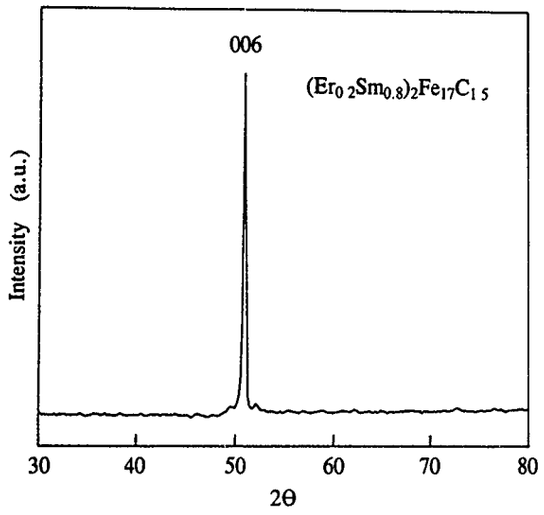

FIG. 3. X-ray diffraction patterns of magnetically aligned $(Er_{0.2}Sm_{0.8})_2Fe_{17}C_{1.5}$ powder samples.

M_s and T_c increase monotonously with increasing carbon concentration y. For $x=0.2$, the saturation magnetization of the compound with $y=2.8$ has a 43% enhancement over the carbon-free compound with $y=0$. The increase of the room-temperature M_s is due to the enhancement of the Curie temperature which shifts the thermomagnetization curve to higher temperature. The strong increase of the Curie temperature with the carbon concentration y demonstrates the increase of the Fe–Fe interaction in $(Er_{1-x}Sm_x)_2Fe_{17}C_y$ by the interstitial carbon atoms. Figure 2 shows the Curie temperature of the $(Er_{1-x}Sm_x)_2Fe_{17}C_y$ compounds as a function of the unit-cell volume. An approximately linear dependence of T_c on the unit-cell volume is observed. Previous studies have shown that the relationship between T_c and volume is almost independent of the rare-earth and the interstitial atoms.[5] From the fact that the Curie temperatures are not sensitive to the chemical composition, it seems reasonable to suggest that the enhancement of T_c in $(Er_{1-x}Sm_x)_2Fe_{17}C_y$ compounds is mainly due to the unit-cell expansion induced by the interstitial carbon atoms.

X-ray diffraction measurements on the magnetically aligned powder samples show that the $Er_2Fe_{17}C_y$ and the carbon-free compounds have an easy plane magnetocrystalline anisotropy at room temperature. An important effect of the interstitial carbon atoms on the magnetocrystalline anisotropy in the samples containing Sm is observed. The addition of the carbon content increases the Sm sublattice anisotropy, resulting in the uniaxial anisotropy of the $(Er_{1-x}Sm_x)_2Fe_{17}C_y$. It is found that the samples with $x<0.2$ or $y\leq 0.5$ exhibit an easy plane anisotropy, and the samples with $x\geq 0.2$ and $y\geq 1.0$ exhibit an easy c-axis anisotropy at room temperature. This can be seen clearly from the x-ray diffraction pattern of magnetically aligned powder sample of $(Er_{0.2}Sm_{0.8})_2Fe_{17}C_{1.5}$, as shown in Fig. 3 as an example. The anisotropy field rises as x or y increases. For $(Er_{0.2}Sm_{0.8})_2Fe_{17}C_{1.5}$, the room-temperature anisotropy field is found to be 8 T, which is comparable with that of $Nd_2Fe_{14}B$.

Structure and magnetic properties of $Gd_2Fe_{17-x}Ga_xC_2$ compounds

Bao-gen Shen, Fang-wei Wang, Lin-shu Kong, Lei Cao, Bo Zhang, and Jian-gao Zhao
State Key Laboratory of Magnetism, Institute of Physics, Chinese Academy of Sciences, P.O. Box 603, Beijing 100080, China

The single-phase compounds of $Gd_2Fe_{17-x}Ga_xC_2$ ($x=0$, 1, 2, 3, 4, 5, and 6) with rhombohedral Th_2Zn_{17}-type structure were prepared by melt spinning for $x\leq 1$ and arc melting for $x\geq 2$. Their formation, structure, and magnetic properties were studied. The substitution of Ga for Fe in $Gd_2Fe_{17}C_2$ helps the formation of the 2:17-type structure. The addition of Ga results in the increase of the lattice constants and the unit-cell volumes. The Curie temperature has a small change when $x\leq 2$, and then decreases rapidly with increasing Ga concentration. An approximately linear decrease of the saturation magnetization with x is observed when the nonmagnetic Ga atom is substituted for Fe.

INTRODUCTION

The binary rare-earth (R) iron intermetallic compounds with Th_2Zn_{17} or Th_2Ni_{17} structure have not been regarded as potential permanent magnets because their Curie temperatures are very low and none of these compounds show a uniaxial anisotropy at room temperature. A large improvement of intrinsic magnetic properties has been achieved by introducing interstitial nitrogen or carbon atoms into R_2Fe_{17} compounds.[1,2] The $Sm_2Fe_{17}N_x$ and $Sm_2Fe_{17}C_x$ compounds with higher nitrogen or carbon concentration are promising candidates for permanent magnets. However, a serious drawback of the nitrides or carbides prepared by the gas–solid reaction is their poor high-temperature stability. Recently, we have studied the effect of various elemental substitutions for Fe on the formation, structure, and magnetic properties in the $R_2Fe_{17}C_x$ alloys. We have found that the high-carbon $R_2Fe_{17}C_x$ compounds with Ga, Si, or Al, etc., substituted for Fe exhibit a high thermal stability.[3–5] This is in contrast with the carbides produced by the gas–solid reaction which decompose into the equilibrium phases rare-earth carbides (RC) and α-Fe upon heating to 600–700 °C. The carbides containing Ga, Si, or Al, etc. can be formed by arc melting. We have reported some studied results of high-carbon $R_2(Fe,M)_{17}C_x$ (R=Y, Nd, Sm, Gd, Tb, Dy, Ho, Er, and Tm; M=Ga and Si; $x\leq 2.5$) compounds with Th_2Zn_{17}-type or Th_2Ni_{17}-type structures.[3–5] In this article, the formation, structure, and magnetic properties of $Gd_2Fe_{17-x}Ga_xC_2$ ($0\leq x\leq 6$) compounds prepared by arc melting or melt spinning are reported.

EXPERIMENT

The $Gd_2Fe_{17-x}Ga_xC_2$ alloys with $x=0$, 1, 2, 3, 4, 5, and 6 were prepared by arc melting in an argon atmosphere of high purity using raw materials of Gd, Fe, Ga, and Fe–C alloy of 99.9% purity. The ingots were melted several times to ensure homogeneity. The ingots with $x=0$ and 1 were then melt spun in argon atmosphere on the outside of a single copper wheel rotating with a surface speed of about 15 m/s, resulting in the formation of the single-phase compounds of the 2:17-type structure. For $2\leq x\leq 6$, the heat treatment of the arc-melted ingots was performed in a steel tube in a highly purified argon atmosphere at 1273 K for 12 h. X-ray diffraction measurements on powder samples were performed using Co $K\alpha$ radiation to identify the single phase and determine the crystallographic structure. The Curie temperature was determined from the temperature dependence of ac susceptibility in a field of less than 1 Oe. The saturation magnetization at 1.5 K was measured by an extracting sample magnetometer in a field of 70 kOe.

RESULTS AND DISCUSSION

Figure 1 shows x-ray diffraction patterns of arc-melted and heat-treated $Gd_2Fe_{17-x}Ga_xC_2$ samples with $0\leq x\leq 6$. It can be seen clearly from Fig. 1 that the gallium-free sample exhibits a multiphase structure with RC, the 2:17 phase, and a predominant α-Fe phase. The substitution of Ga for Fe in these materials is found to have a significant effect on the crystal structure. The addition of Ga results in a remarkable decrease of the diffraction peaks of α-Fe. For $x=1$, the arc-melted sample is found to consist only of the rhombohedral Th_2Zn_{17} and α-Fe phases. When the Ga concentration x is richer than 1, the samples prepared by arc melting are almost single phase with rhombohedral Th_2Zn_{17}-type structure. No significant diffraction from impurity phases is observed. The role of Ga in the high-carbon $R_2Fe_{17-x}Ga_xC_2$ helps the formation of rare-earth iron compounds of the 2:17 type. A similar effect has been observed in other 2:17-type rare-earth iron compounds.[3–5]

The lattice constants a and c and the unit-cell volumes v obtained from the x-ray diffraction patterns of the melt-spun samples with $x=0$ and 1 and arc-melted and heat-treated samples with $2\leq x\leq 6$ are shown in Fig. 2 as a function of Ga concentration. The substitution of larger Ga for Fe in the $Gd_2Fe_{17}C_2$ leads to an expansion of the unit cell. An approximately linear increase of the unit-cell volume with x is observed. The expansion of the unit-cell results from the effect of both Ga and C additions. The $Gd_2Fe_{17}C_2$ compound has a unit-cell volume about 4.9% larger than that of Gd_2Fe_{17}. For $Gd_2Fe_{11}Ga_6C_2$, the unit-cell volume expansion is about 3.4% compared with the gallium-free compound.

The present results of x-ray diffraction do not provide enough evidence to determine the occupancy site of the Ga atoms. However, neutron diffraction studies for $Ho_2Fe_{17-x}Ga_xC_2$ compounds have demonstrated[6] that the Ga

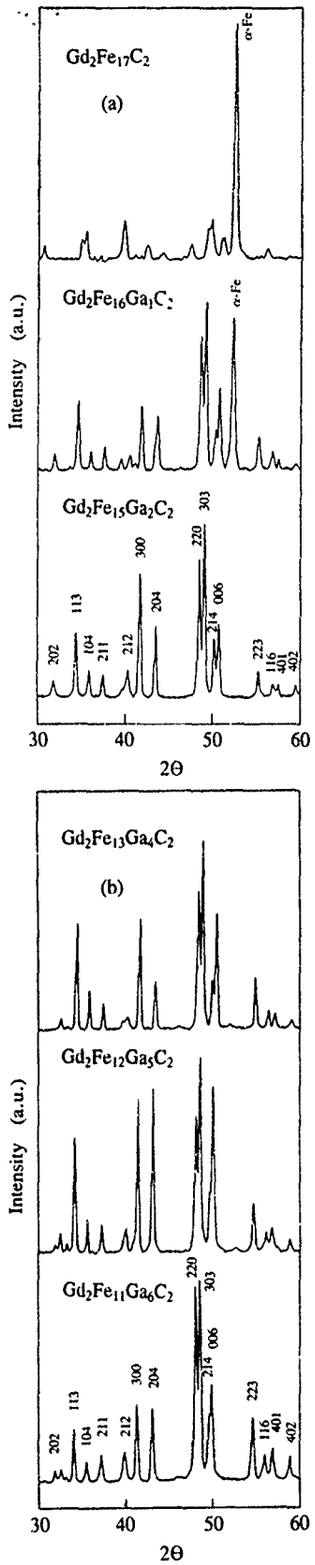

FIG. 1. X-ray diffraction patterns of arc-melted and heat-treated $Gd_2Fe_{17-x}Ga_xC_2$ samples with (a) $x=0$, 1, and 2, (b) $x=4$, 5, and 6.

atoms preferentially occupy $18h$ sites, when $x<4$. For $x>4$, the Ga atoms occupy $18h$ and $6c$ sites. In these carbides containing Ga the carbon atoms still occupy the $9e$ interstitial sites.

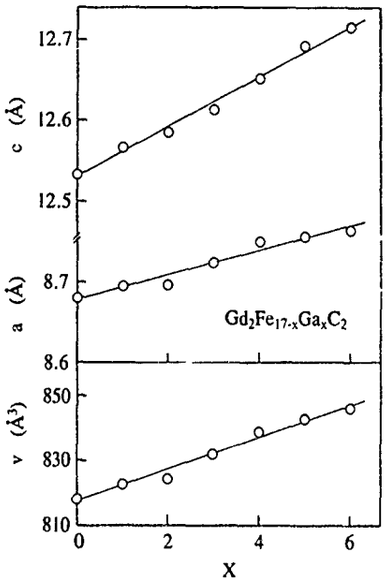

FIG. 2. The lattice constants a and c and the unit-cell volumes v of $Gd_2Fe_{17-x}Ga_xC_2$ compounds as a function of Ga concentration.

The Ga-concentration dependence of the Curie temperatures T_C of $Gd_2Fe_{17-x}Ga_xC_2$ compounds is shown in Fig. 3. The T_C is found to decrease slowly until about $x=2$ and then drop at a more rapid rate with increasing Ga concentration. It is commonly assumed that the Curie temperature of rare-earth iron compounds is determined by the Fe–Fe, R–Fe, and R–R interactions. In general, the Fe–Fe interaction is dominant, and the R–R interaction is negligible. The difference of T_C among the different rare-earth compounds indicates the influence of R–Fe interaction. It has been shown previously that the low values of the Curie temperatures of the R_2Fe_{17} compounds result from the relatively small Fe–Fe distance. The increase in Curie temperature of the nitrides or

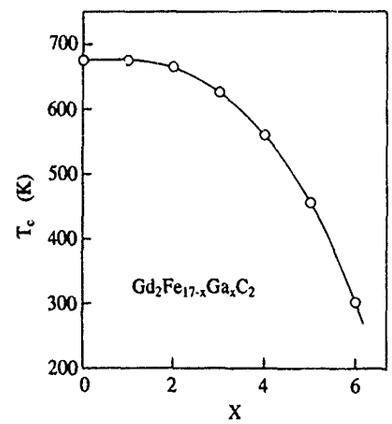

FIG. 3. The Curie temperature T_C of $Gd_2Fe_{17-x}Ga_xC_2$ compounds as a function of Ga concentration.

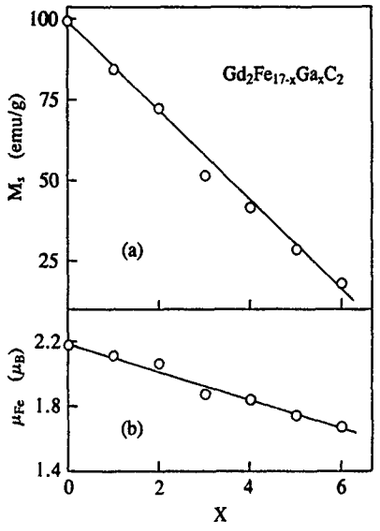

FIG. 4. (a) The saturation magnetization M_s at 1.5 K and (b) the Fe magnetic moment μ_{Fe} of $Gd_2Fe_{17-x}Ga_xC_2$ compounds as a function of Ga concentration.

carbides is mainly due to the increase of the Fe–Fe interaction which results from the increasing interatomic distance produced by the interstitial nitrogen or carbon. For $Gd_2Fe_{17-x}Ga_xC_2$ compounds with $x=0$, T_C is 200 K higher than that of Gd_2Fe_{17}.[1] However, the decrease of Curie temperature with increasing x in $Gd_2Fe_{17-x}Ga_xC_2$ is observed, although the substitution of Ga for Fe results in a monotonic increase of the unit cell. This indicates that the substitution of nonmagnetic Ga in the rare-earth iron carbides with higher carbon concentration would decrease the Fe–Fe interaction and the number of Fe–Fe atom pairs, resulting in the drop in T_C.

The saturation magnetization M_s of $Gd_2Fe_{17-x}Ga_xC_2$ compounds at 1.5 K is shown in Fig. 4(a) as a function of Ga concentration x. The M_s of the samples is found to decrease linearly with increasing x, with an approximately rate of -12 (emu/g)/at. % Ga. The antiparallel coupling between the rare-earth spin moment and the Fe moment for heavy rare-earth compounds leads to ferrimagnetism. Accordingly, the saturation moment μ_s of $Gd_2Fe_{17-x}Ga_xC_2$ compounds can be expressed by the equation

$$\mu_s=(17-x)\mu_{Fe}-2\mu_{Gd}, \tag{1}$$

where μ_{Fe} and μ_{Gd} are the Fe and Gd magnetic moments, respectively. The μ_{Gd} can be assumed to be $7\mu_B$. Thus the Fe magnetic moment μ_{Fe} can be obtained according to Eq. (1), as shown in Fig. 4(b). It can be seen from Fig. 4(b) that μ_{Fe} of $Gd_2Fe_{17-x}Ga_xC_2$ compounds decreases linearly from $2.17\mu_B$ for $x=0$ to $1.67\mu_B$ for $x=6$ as a result of the dilution of Fe by nonmagnetic Ga atoms.

Effect of cobalt substitution on magnetic properties of R_2Fe_{17} silicides (R=Y, Gd, Tb, Er, and Tm)

F. Pourarian, R. T. Obermyer,[a] and S. G. Sankar
Carnegie Mellon Research Institute, Carnegie Mellon University, Advanced Material Corporation, Pittsburgh, Pennsylvania 15213

Magnetic characteristics and unit-cell dimensions of the (off-stoichiometric) R_2Fe_{17}-type alloys based on $R_2Fe_{14-x}Co_xSi_2$, where R=Gd, Tb, Er, Tm, and Y and $x=4$ were determined. Partial substitution of Fe by Co slightly increases the saturation magnetization of the alloys and produces an average increase in the Curie temperature (T_c) of 55 K per Co atom. The enhancement of the Curie temperature with the addition of cobalt is attributed to the strengthening of the average $3d$-$3d$ exchange interaction. For Er- and Tm-containing compounds, replacement of Fe by Co has a remarkable effect in shifting the observed spin reorientation temperature toward higher temperatures. These results are discussed in terms of the influence of the interaction of the $4f$ electrons of the rare-earth ions with the $3d$ electrons of the transition-metal ions, which modifies the overall anisotropy of the alloys.

I. INTRODUCTION

It is well established that binary R_2Fe_{17} compounds have basal plane anisotropy, which arises from a combination of the contribution from the $3d$ Fe and $4f$ rare-earth sublattice magnetizations.[1] Recently it was found that incorporation of Si atoms in the lattice of R_2Fe_{17} significantly enhanced the magnetic ordering temperature T_c (Refs. 2 and 3) and produced spin reorientation transition regions in the Er_2Fe_{17} alloy system.[2] The spin reorientation temperature T_{sr} observed in $Er_2Fe_{14}Si_2$ and in Tm-based compounds is believed to be due to a change of magnetocrystalline anisotropy from an easy axis to a basal plane with increasing temperature.[3] The region of uniaxial anisotropy as determined from the spin reorientation transition is crucial for production of high-performance permanent magnet materials. The addition of Si in the lattice was also found to have a remarkable influence in reducing the unit-cell volume of 2:17 compounds. This behavior is related to a particular Si site occupation in the lattice.[4] In the latter reference the observation showed that the position of Si in the off-stoichiometric lattice is interestingly different from that of the stoichiometric one. This may suggest a particular influence of the Si atoms on the local anisotropy of the sublattices.

The objective of the present work is to study the effect of partial substitution of Fe by Co on the magnetic properties of off-stoichiometric R–Fe silicides. The physical and magnetic properties of the latter off-stoichiometric system was investigated before.[2] Results of lattice dimensions, saturation magnetization, Curie temperatures for all the studied alloys, and the spin reorientation temperatures for Er and Tm compounds are reported in detail.

II. EXPERIMENT

The starting materials were prepared by induction melting of the constituent metals in a water-cooled copper boat under a flowing argon atmosphere. As-cast ingots were heat treated at 900 °C for 2 days and then rapidly cooled to room temperature. Powder x-ray diffraction with Cu $K\alpha$ radiation was employed to determine phase purity and lattice dimensions. The magnetic measurements were carried out at 295 and 20 K using a vibrating sample magnetometer in external fields up to 16 kOe. The saturation magnetization M_s was determined by measuring the magnetization of random and aligned powders of sizes <38 μm. The spin reorientation temperature T_{sr} was obtained from the temperature dependence of the magnetization in the temperature range 10–1100 K with a field of 0.5 kOe on both rough chunk and aligned powders. Curie temperatures T_c were also determined by plotting M^2 vs T and extrapolating the steep part of the curve to $M^2=0$.

III. RESULTS AND DISCUSSION

A. Lattice parameters

Results of x-ray diffraction on $R_2Fe_{10}Co_4Si_2$ revealed the formation of single-phase materials which have the characteristics of hexagonal crystal structure type Th_2Ni_{17} when R=Y, Tb, Er, and Tm and of rhombohedral type Th_2Zn_{17} when R=Gd. Table I shows results of lattice parameters compared to those of $R_2Fe_{14}Si_2$ compounds. Introduction of cobalt in the lattice (up to $x=4$) resulted in a decrease of unit-cell volume. This is expected due to the smaller size of

$Y_2Fe_{10}Co_4Si_2$	703	123	148

the cobalt atom compared to that of iron. This reduction of lattice dimensions is also related to the preferential site occupation of cobalt in the lattice which was revealed to be the transition metal sites d and h in the rhombohedral type and the f sites in the hexagonal type.[5]

B. Magnetic properties

Saturation magnetization at 20 K and room temperature and magnetic ordering temperature T_c data for $R_2Fe_{10}Co_4Si_2$ are presented in Table II. It should be noted that partial replacement of Fe by Co produces an average increase of the Curie temperature of 55 K per Co atom. The enhancement of T_c in these alloys was observed earlier when Fe is partially replaced by Si atoms.[2] This effect and the decrease observed in the interatomic distances of $R_2Fe_{10}Co_4Si_2$ lattice can be attributed to the modification of short Fe–Fe distances by Co atoms[6] and concomitantly to the particular Si site occupation, which all contribute to the strengthening of the average $3d$-$3d$ exchange interaction. Results of saturation moments for $x=4$ indicate an expected net increase relative to $R_2Fe_{14}Si_2$. The average $3d$ transition moments range between $1.9\mu_B$ and $2.0\mu_B$.

Measurements of temperature-dependent magnetization of rough chunk samples and aligned powders for Er- and Tm-based alloys are illustrated in Figs. 1–3. Er_2Fe_{17} exhibits no magnetic transition down to 4.2 K. In contrast, the Tm_2Fe_{17} alloy shows a remarkable spin reorientation transition at 72 K at which the easy direction of magnetization

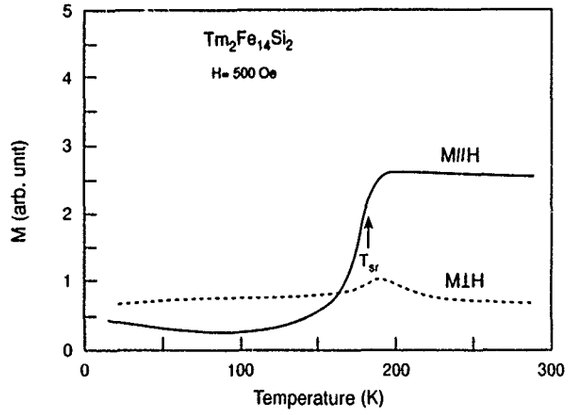

FIG. 1. Temperature dependence of the magnetization of the $Tm_2Fe_{14}Si_2$ sample with field parallel $H\|M$ and perpendicular $H\perp M$ to the alignment The arrow indicates the spin reorientation temperature T_{sr} at 180 K.

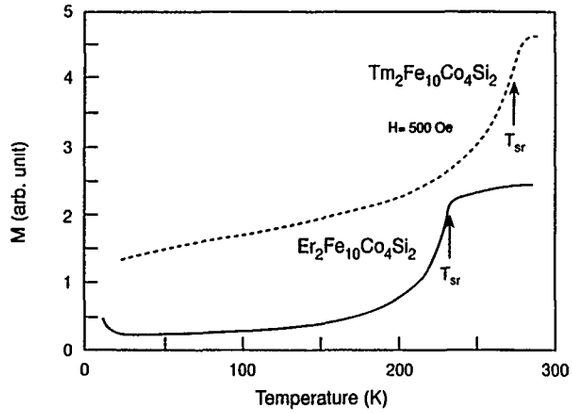

FIG. 2. Temperature dependence of the magnetization of rough chunk samples of $Er_2Fe_{10}Co_4Si_2$ and $Tm_2Fe_{10}Co_4Si_2$. The arrows indicate the spin reorientation temperatures 230 and 270 K.

TABLE III. Spin reorientation (T_{sr}) and easy direction magnetization (EDM) of $R_2Fe_{10}Co_4Si_2$ (R=Er,Tm) compounds.

Composition	T_{sr} (K)	EDM RT	EDM 20 K
Er_2Fe_{17}	...	plane	plane
$Er_2Fe_{14}Si_2$	35(100)[a]	plane	c axis
$Er_2Fe_{10}Co_4Si_2$	230	plane	c axis
Tm_2Fe_{17}	72	plane	c axis
$Tm_2Fe_{14}Si_2$	180	plane	c axis
$Tm_2Fe_{10}Co_4Si_2$	270	plane	c axis

[a] T_{sr2}=100 K taken from Ref. 2.

(EDM) changes from easy plane to a hard c axis.[3] Addition of Si atoms ($x>0.5$) in the lattice of the former alloy triggers a spin reorientation transition (T_{sr}) at low temperatures. In both cases the substitution of Fe by Co leads to an additional shift in T_{sr} toward higher temperatures. In fact, this behavior can be understood in these compounds, because Er and Tm, which are characterized by a positive second-order Stevens coefficient ($\alpha>0$), together with the Co atom seek axial anisotropy. This is in contrast to the Fe moments which align in the basal plane. Therefore the axial anisotropy dominates over a wider temperature region with Co substitution. Results of T_{sr} and proposed EDM for Er- and Tm-based compounds are given in Table III. For $Er_2Fe_{10}Si_2$ the two transitions observed at $T_{sr1}=35$ K and $T_{sr2}=100$ K are believed to be related to the crystal structure forms rhombohedral and hexagonal type.[2] In $Er_2Fe_{10}Co_4Si_2$ cobalt influences the lattice and stabilizes only the hexagonal structure with a remarkable increase in the T_{sr2} value. Results indicate that both Si and Co site occupations have a strong effect on the local anisotropy of Er (or Tm) $4f$ ions and induce a larger negative second-order crystal field parameter A_0^2. The latter behavior resembles that generated in interstitial carbon in $Tm_2Fe_{17}C_x$.[7]

A contribution to the knowledge of phase equilibria and the magnetic properties of the Nd–Fe–B–X systems (X=Al,Co,V)

Anders Micski and Björn Uhrenius
Swedish Institute for Metals Research, Drottning Kristinas väg 48, 114 28 Stockholm, Sweden

A technique based on diffusion couples for the determination of the compositions of different phases present in the Fe–Nd–B and Fe–Nd–B–Al systems was used. By this technique the composition of the liquid in equilibrium with the solid phases could be determined. Since all elements are encapsulated in an iron capsule, the study of oxidation-sensitive elements like neodymium was easily made. By using this technique, new information on the composition of the liquid phase in equilibrium with solid phases in the Fe–Nd–B system as well as the Fe–Nd–B–Al system was determined at two temperatures. This information was used to improve the representation of the liquidus surfaces of the systems. The effects of Al, V, and/or Co additions on the coercivity and energy product of sintered Fe–Nd–B magnets are also presented.

INTRODUCTION

Permanent magnets based on the Fe–Nd–B system are among the strongest available today. The excellent magnetic properties are attributed to the $Nd_2Fe_{14}B$ phase (ϕ). These magnets, however, suffer from two major drawbacks as compared to, e.g., magnets based on Sm–Co, namely, (i) poor corrosion resistance and (ii) a rapid decline in coercivity ($_jH_c$) and magnetization above relatively low temperatures (≈150 °C). A major field of research is to improve these properties, which may be achieved by adding different elements to the Fe–Nd–B system, e.g., Co, V, or Al.[1–5] Co is added to improve the Curie temperature of the material and also to improve the thermal stability of the coercivity. The coercivity at room temperature, however, is reduced by Co addition. Tenaud *et al.*[5] found that this detrimental effect could be compensated by additions of V. Al is believed to improve the wetting between the Nd-rich intergranular phase and ϕ, thus increasing the fraction of Nd-filled grain boundaries and therefore the coercivity.

When new elements are added to the Fe–Nd–B system, new phases may appear in the material. These elements may also enter the different phases already present in the material, e.g., the $Nd_2Fe_{14}B$ phase and/or the Nd-rich intergranular phase. These changes of the microstructure are of great importance for the magnetic properties of the material and may result in an improvement of the magnetic properties. To understand the influence of the different alloying elements on the microstructure, the appropriate phase diagram has to be known. The method most often used for the investigation of phase equilibria is based on differential thermal analysis (DTA), standard metallography, and electron probe microanalysis (EPMA).[6–8] The composition of the different precipitated phases and the temperatures of the phase transformations can be determined with this technique. However, it is difficult to determine the composition of the liquid phase as well as the equilibrium composition of the solid phases present at the different temperatures. Such information is vital for the understanding of the development of the microstructure during liquid-phase sintering.

In the present study, results obtained using a complementary method involving diffusion couples are presented. Some results obtained after magnetic measurements of Nd–Fe–B–X magnets, where X=Al, V, and/or Co, are also presented.

EXPERIMENTAL DETAILS

The diffusion-couple technique involved enclosing the elements Nd, B, and X (where X stands for any alloying element used) or alloys of the elements in an iron capsule and heat treating at the appropriate temperatures. During heat treatment the equilibrium phases between the Nd–B mixture and iron were formed. After quenching, the composition of the different phases at temperature were frozen in and were determined by EPMA. This technique made it rather easy to heat treat alloys based on oxidation-sensitive elements, like neodymium, since all elements were encapsulated in a protective capsule of iron.

Raw materials used were an iron tube (99.9% iron, wall thickness 10 mm). This was filled with neodymium (99.9%) and FeB powder (99.3%) of a Nd/B ratio which would produce the equilibrium structures of interest. The iron tube was sealed with an iron rod, which was welded to place. Heat treatments were performed at 1000 and 1100 °C in argon gas for ten or seven days, respectively, after which the specimens were quenched. After cutting the specimens, the microstructure was studied using metallographic techniques. The compositions of the different microstructural constituents was analyzed using a microprobe (JEOL 6400 equipped with a Tracor system 2). Four alloys with different B:Nd:Fe ratios were used as standards. These were made from rapidly quenched melt-spun ribbons produced at a cooling rate of about 10^5 K/s to ensure a homogeneous material without segregations. These standards were chemically analyzed with respect to their B, Fe, and Nd content.

The effects of Al, Co, and V additions on the magnetic properties of a Fe–Nd–B magnet with the composition $Nd_{20}Fe_{74}B_6$ was also studied. The magnets were produced from induction-melted alloys. The cast alloys were hydrogen decrepitated, milled, dried, aligned in an open coil pulse magnetizer, cold isostatically pressed at 200 MPa, and sintered in vacuum at 1080 °C for 1 h. The effect of a post-sinter heat treatment at 650 °C for 1 h in vacuum on the magnetic properties was studied. The magnetic properties

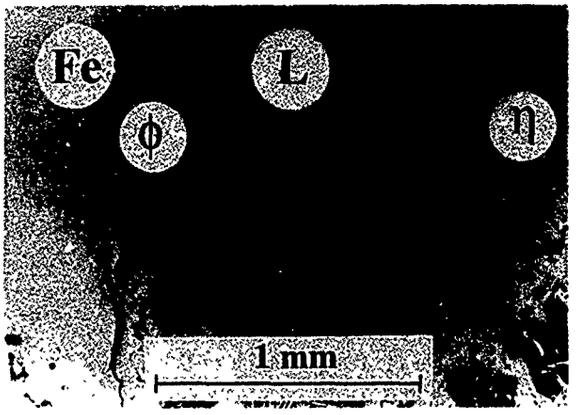

FIG. 1. Light optical micrograph of a cross section through a diffusion couple in the Fe–Nd–B system in an as-polished condition. The different phases present after heat treatment at 1000 °C for 10 days are seen. The multiphase region marked L was a homogeneous liquid phase at the heat-treatment temperature.

were measured in a superconducting quantum-interference device magnetometer at 273 K.

RESULTS

Phase relations

A picture of the part of the phase diagram along a line connecting the iron-rich corner with the Nd/B alloy could be obtained by a careful analysis of the microstructure. A typical appearance of a cross section through a diffusion couple is seen in Fig. 1. This specimen was heat treated at 1000 °C for 10 days before quenching. The iron tube is seen to the far left and has partly reacted with Nd and B at temperature. The different phases present in the microstructure are as follows: $Nd_2Fe_{14}B(\phi)$ is seen in contact (i.e., in equilibrium) with the iron to the left. Outside the ϕ phase there is a region, which at the heat treatment temperature, consisted of liquid in equilibrium with ϕ and $Nd_{1.1}Fe_4B_4(\eta)$, the latter phase seen to the far right. During quenching, the liquid phase decomposed to primarily precipitated needles of ϕ and an eutectic structure consisting of ϕ, η, and other intermetallic phases. The composition of the liquid phase was determined by scanning over large areas of this composite structure. An average of about 10 measurements was evaluated where each measurement was made on an area the size of about 10^4 μm^2.

In Fig. 2(a), a tentative liquidus projection of the Fe–Nd–B system according to Matsuura *et al.*[8] is shown. The positions of the three ternary phases ϕ, η, and $Nd_2FeB_3(\rho)$ are also marked. The results obtained in the present study on the Fe–Nd–B system were used to construct the diagram shown in Fig. 2(b). It was assumed that the eutectic compositions E_1 and E_2 are known from the literature.[8] The positions of the transition composition U_{13} has tentatively been shifted to a position closer to the Fe–Nd axis, while the transition composition U_{12} is assumed to be known. The liquidus projection E_1E_2 has been drawn closer to the Fe–Nd axis as compared to Fig. 2(a) at lower temperatures, indicating a less boron-rich liquid. The composition of the

phase containing Al in equilibrium with ϕ and η at 1000 and 1100 °C, respectively. The composition of the liquid correspond well with the composition in the Fe–Nd–B system and is slightly shifted closer to the Nd corner. The composition of this liquid is given in Table I. In the quaternary Fe–Nd–B–Al system, the ϕ phase was found to contain aluminium, replacing iron, which is in agreement with previous work.[2] The composition of this phase at 1000 °C was determined both in equilibrium with pure iron and in equilibrium with the liquid. The composition can be described by the formula $Nd_2Fe_{14-x}Al_xB$, where $x=1.2$ in the equilibrium with the liquid, and $x=0.7$ in the equilibrium with Fe. The slightly lower Nd content obtained for this phase in the quaternary system, see Table I, as compared to the ϕ phase in the Fe–Nd–B system, might be due to the uncertainty in the EPMA analysis. Furthermore, it was not possible to determine the variation of Al content of this phase at 1100 °C due to the thin layer of the ϕ phase obtained in this case. The overall composition could, however, be described by $Nd_2Fe_{14-x}Al_xB$ with $x=0.5$. The ρ phase was also found to dissolve aluminium on the expense of the iron content. An approximate composition for this phase at 1000 °C is $Nd_2Fe_{1-x}Al_xB_3$, where x is about 0.3. The Al content of the η phase was below the detection limit of the microprobe, which is believed to be less than 0.1% Al. The composition of this phase was the same in both the ternary and the quaternary systems.

Magnetic properties

The compositions of the alloys studied are listed in Table II. Tenaud *et al.*[5] have reported that the decrease in coercivity due to a Co addition can be compensated for by additions of V. They found that the optimum V addition was critically dependent on the B content. Based on the work by Tenaud *et al.*[5] a V addition of 2 at. % was used in the present study. Al is known to improve the coercivity of sintered Fe–Nd–B magnets. Schneider *et al.*[2] have reported a coercivity maximum in sintered Fe–Nd–B magnets when the amount of Al is 3 at. %, which was used in the present study. In Table II is summarized the results from the measurements of the coercivity and energy product. The post-sintering heat treatment had a large positive effect on the measured magnetic properties. The Al additions improved the coercivity as compared to the unalloyed Fe–Nd–B magnet. The substitution of 5 at. % Co for Fe, however, decreased the coercivity substantially. The positive effect of combining Co and V additions is shown, but the coercivity is still considerably lower as compared to the unalloyed magnet. This effect is probably due to new paramagnetic phases appearing in the material after sintering. The results also show that Al and Co additions alone is not enough to obtain high coercivity. If Al, Co, and V additions are combined, however, the coercivity increases well above the value of the unalloyed and the Al alloyed magnet. The coercivity after alloying with only 2 at. % V and after alloying with Al and V was almost zero and these results were not included in Table II.

These effects on coercivity can be fully understood if the appropriate phase diagrams are known. The work at our department on this area is therefore concentrated on more phase diagram studies, and the results from these studies will be published later.

Investigations of magnetic properties and microstructure of 40Cedidymium–Fe–B based magnets

S. X. Zhou and Y. G. Wang
Department of Physics, The Norwegian Institute of Technology (NTH), The University of Trondheim, N-7034 Trondheim, Norway

R. Høier
Division of Applied Physics, The Foundation for Scientific and Industrial Research at the Norwegian Institute of Technology (SINTEF-Applied Physics), N-7034 Trondheim, Norway

The influence of Si, Co, and Dy_2O_3 on magnetic properties of sintered 40Cedidymium–Fe–B magnets was investigated and related to the microstructure through transmission electron microscopy (TEM) investigations. It is found that the decrease in ${}_iH_c$ and T_c caused by the presence of Ce in the 40Cedidymium could partly be compensated by additives. Sintered magnets with ${}_iH_c = 9.2$ kOe and $(BH)_{max}$=28.2 MG Oe were successfully achieved. TEM investigations show an intragranular amorphous phase within the $R_2Fe_{14}B$ (R=Nd, Pr, or Ce) grains and three new intergranular phases at grain boundaries and junctions of the $R_2Fe_{14}B$ grains. It is suggested that the deterioration in the magnetic hardening is closely related to these new phases as well as the low magnetic anisotropy field of the $Ce_2Fe_{14}B$ compound. The intragranular phase is likely to act as nucleation positions for reverse magnetic domains.

I. INTRODUCTION

Since the simultaneous discovery of Nd–Fe–B-based permanent magnets by Sumitomo Special Metals[1] in Japan and General Motors[2] in the United States in 1983, the R–Fe–B compounds have been of continuous interest in both technological and scientific fields because of their superior magnetic properties. Magnets with energy products as high as 45 MG Oe are commercially available, and there is a growing demand for applications related to miniaturization and more efficient devices. However, despite the outstanding magnetic properties of these magnets, their applications, especially in price-sensitive areas, have been hindered by their relatively high cost compared to the established magnets such as hard ferrite. In the past several years, many investigations[3–8] have indicated that it is feasible to reduce this problem by replacing Nd with other more abundant and more inexpensive rare-earth elements, Ce, La, or unseparated rare-earth mixtures. According to Okada *et al.*,[3] 40Cedidymium, which is the typical product in the extracting process of the rare-earth elements, is a good candidate for developing inexpensive R–Fe–B magnets. However, the magnetic anisotropy field, the saturation magnetization, and the Curie temperature of the $Ce_2Fe_{14}B$ compound are much lower than those of $Nd_2Fe_{14}B$. This in turn drastically reduces the coercivity, the energy product, and the thermal stability of sintered 40Cedidymium–Fe–B magnets. In our previous work,[8] the alloy phases and the influence of Si, Co, and Dy_2O_3 on the magnetic properties of sintered 40Cedidymium–Fe–B magnets have been studied. In this paper the magnetic properties of 40Cedidymium–Fe–B sintered magnets with additions of Si, Co, and Dy_2O_3 are presented and related to the microstructure through transmission electron microscopy investigations.

II. EXPERIMENTAL PROCEDURE

40Cedidymium with the composition of 40Ce–50Nd–10Pr in wt % was synthesized using pure Nd, Ce, and Pr metals. Two series of alloys, whose compositions are 40Cedidymium$_{16.5}$Fe$_{77-x}$Si$_x$B$_{6.5}$ (alloy A) and 40Cedidymium$_{16.5}$Fe$_{73-y}$Co$_y$Si$_4$B$_{6.5}$ (alloy B), where x=0, 2, 4, 6, and 8 and y=0, 10, 20, and 30, were induction melted in an aluminium oxide–lined graphite crucible under argon atmosphere. The detailed procedures of sintered magnet production was described in Ref. 8. A series of Dy_2O_3-doped alloy (alloy C) was also processed by blending the 40Cedidymium$_{16.5}$Fe$_{63}$Co$_{10}$Si$_4$B$_{6.5}$ alloy powder with different amounts (Z wt %) of Dy_2O_3 and then the same procedure as described in Ref. 8 was followed. The magnetic properties were measured using an integrating hysteresigraph, and the Curie temperature T_c was determined by a differential scanning calorimeter (DSC) at a heating rate of 10 °C/min. Electron transparent foils were prepared using argon ion milling. The specimens were then examined in a Philips CM-30 transmission electron microscope equipped with a standard energy dispersive x-ray spectroscopy (EDS).

III. MAGNETIC PROPERTIES

The composition dependence of the magnetic properties of the sintered magnets is summarized in Table I. It is clear from this table that both ${}_iH_c$ and T_c show a monotonic increase with increasing Si content while the remanence shows a reverse trend on Si addition. The substitution of Co for Fe gives rise to a considerable increase in T_c but a decrease in ${}_iH_c$ as expected. The addition of Dy_2O_3 to the Si- and Co-containing magnet substantially increases the intrinsic coercivity, from 6.0 kOe for Dy_2O_3-free alloy to 10.5 kOe for Z=5 in wt % (≈1.8 at. % Dy in the magnet). The remanence was slightly decreased at a level of Dy_2O_3 content less than 3 wt % (≈1.4 at. % Dy in the magnet).

IV. MICROSTRUCTURE

The microstructure of the sintered magnet with composition of 40Cedidymium$_{16.5}$Fe$_{63}$Co$_{10}$Si$_4$B$_{6.5}$ blended with 3

wt % Dy_2O_3 was studied in detail. Four typical phases were found in this magnet in addition to the $R_2Fe_{14}B$ matrix, the B-rich phase and the Nd-rich phases, which are generally observed in the sintered Nd–Fe–B magnets. These new phases can be divided into two kinds. One is present within the matrix grains and the others at the grain boundaries. The dimensions of these phases vary from several hundred nanometers to several micrometers. The phase (phase A) in Fig. 1 shows a spherical configuration (particle) and is widely distributed inside the $R_2Fe_{14}B$ grains. The corresponding selected area electron diffraction (SAED) pattern reveals that it is an amorphous phase. This was also confirmed by high-resolution images. The composition of the A particles analyzed by EDS is given in Table II. It is clear that these particles are rich in rare-earth elements (Nd, Ce, and Pr). The reason for the occurrence of phase A is still unknown. Figure 2 shows two intergranular phases (phases B and C) frequently found at grain boundaries and triple point junctions between $R_2Fe_{14}B$ matrix grains. EDS results (Table II) indicate that both phases are rich in rare-earth elements, although iron was also identified. From the SAED patterns [Figs. 2(a) and 2(b)] the crystal structure of phase B was determined to be cubic with lattice constant about 11 Å, which is close to cubic Nd_2O_3 ($a=11.04$ Å) structure, and the lattice parameters of phase C are close to trigonal Nd_2O_3 ($a=3.912$ Å, $c=6.227$ Å), a polymorph of the cubic Nd_2O_3. Because oxygen cannot be examined by EDS, it is not quite certain whether these two phases are oxides. However, R oxides are easily formed during magnet processing. At the junctions of the matrix grains we found, as shown in Fig. 3, another R-rich phase (phase D) with fcc structure and lattice param-

eter of about 5.4 Å. It should be mentioned that all the four new phases observed contain a definite amount of iron.

V. DISCUSSION

It is well known that the origin of the magnetic hardening in R–Fe–B-based magnets is due to the formation of tetragonal $R_2Fe_{14}B$, with a high anisotropy field. In addition, the magnetic hardening also strongly depends on a favorable microstructure. According to Boltich *et al.*,[9] the room-temperature anisotropy fields of $Nd_2Fe_{14}B$ and $Pr_2Fe_{14}B$ are nearly the same, 70.7 and 79.3 kOe, respectively, but the anisotropy field of $Ce_2Fe_{14}B$ is only 37.1 kOe, about half of that of $Nd_2Fe_{14}B$. From this point, the low coercivity of sintered 40Cedidymium–Fe–B magnet is likely to be attributed to the low anisotropy field of $Ce_2Fe_{14}B$. However, it should be noticed that the value of ${}_iH_c = 6$ kOe, only about 50% of that of Nd–Fe–B sintered magnets,[1] seems anomalously low if we only consider the effect of $Ce_2Fe_{14}B$ in the sintered magnet. From this fact, it is strongly suggested that the deterioration in the magnetic hardening is not only due to the low magnetic anisotropy field of $Ce_2Fe_{14}B$, but also caused by an unfavorable microstructure. Usually sintered Nd–Fe–B-based magnets consist of three types of phases: the hard magnetic $Nd_2Fe_{14}B$ phase (matrix), the tetragonal boride phase $Nd_{1-\epsilon}Fe_4B_4$, and several intergranular Nd-rich phases. Moreover, the matrix does not contain any crystal defects and foreign phases. Based on the results of our investigation, the magnet under discussion clearly shows three new intergranular R-rich phases with different compositions and structures and an intragranular amorphous phase which is quite regularly distributed within the matrix grains. The influence of these new foreign phases on the magnetic hardening is not well understood, but it is suggested that the intragranular phase may act as nucleation positions of reverse domains due to the strong demagnetizing field around these positions, or as pinning sites of domain walls. In this case we may infer that it is likely to act as nucleation positions of reverse domains. The enhancement of the coercivity by the substitution of Si for Fe may be attributed to the increase of the anisotropy field of $R_2Fe_{14}B$ (R=Nd, Pr, and Ce) with Si content.[10,11] The improvement on the Curie temperature T_c by Si addition may be interpreted as being due to a decrease of negative exchange interactions between $3d$ atoms. This behavior suggests that Si atoms have a strong preference for occupying the $8j_1$ and the $16k_2$ sites, which are characterized by a negative exchange interactions (antiferromagnetic) in the $R_2Fe_{14-\delta}$ structure.

The substantial increase of the intrinsic coercivity in sintered 40Cedidymium–Fe–B magnet with increasing Dy_2O_3 content is similar to that in the Nd–Fe–B based sintered magnets reported by Ghandehari.[12] It is believed that the improvement is due to the high anisotropy field of the $Dy_2Fe_{14}B$ compound (158 kOe).

In summary, the results of the magnetic measurements indicated that the reduction of ${}_iH_c$ and T_c cased by the Ce presented in the 40Cedidymium can be partly compensated by Si, Co, and Dy_2O_3 additions. Transmission electron microscopy (TEM) studies showed that an intragranular amorphouslike phase (phase A) is widely distributed within the matrix grains, and three new intergranular phases (phases B, C, and D) locate at grain boundaries and junctions of the matrix grains. It is inferred that these phases, especially phase A, are likely to act as nucleation positions of reverse magnetic domains.

Investigation of interaction mechanisms in melt-quenched NdFeB

L. Folks, R. Street, and R. Woodward
Research Centre for Advanced Mineral and Materials Processing, The University of Western Australia, Nedlands 6009. Australia

Investigation of the magnetization processes in melt-quenched $Nd_2Fe_{14}B$ materials has been made by analysis of measurements of the time dependence of the magnetizing curves (after thermal demagnetization) and demagnetizing curves at room temperature. The quantities S (the magnetic viscosity parameter) and χ^i_{irr} (the intrinsic irreversible susceptibility) have been determined for the commercially available materials MQI (isotropic, resin bonded), MQII (slightly anisotropic, hot pressed), and MQIII (anisotropic, hot formed) produced by Delco Remy, U.S. In addition $\delta M(H)$, which compares the fraction of irreversible processes occurring at a particular field in the magnetizing mode with those occurring at the same field in the demagnetizing mode, has been determined as a function of internal field, and the results are interpreted in terms of interactions between grains. From these results it is shown that although the magnetization and demagnetization behavior of these materials differ substantially, this may be attributed to differences in the domain structure. There is no evidence that the mechanism for hardening is different from that of the sintered materials.

INTRODUCTION

The mechanisms of magnetization in $Nd_2Fe_{14}B$ magnets produced by melt quenching have been the subject of intensive investigation (e.g., for a review see Herbst[1]). There is convincing Lorentz microscopy evidence that domain boundary walls are pinned at grain boundaries in optimally quenched ribbons and in hot-pressed and die-upset powders in the demagnetized state (Mishra[2]). These observations have been used to support a strong domain wall pinning model developed by Gaunt[3] to explain the coercivity of melt-quenched materials (Pinkerton and Fuerst[4]). However Durst and Kronmüller[5] and Grönefeld and Kronmüller[6] show by theory and experiment that in fact the coercivity of the melt-quenched materials may be explained assuming that nucleation is the dominant mechanism for magnetic hardening.

Typical melt-quenched materials exhibit two steps in the magnetization curve, suggesting that at least two distinct processes are at work, but on the demagnetization curve no steps are seen, and, from the uniformity of this behavior across compositions and microstructures, it may be assumed that only one mechanism is at work.

We have measured magnetic viscosity from the magnetization and demagnetization curves for samples of melt-quenched $Nd_2Fe_{14}B$, MQI (resin-bonded, isotropic), MQII (slightly anisotropic, hot pressed), and MQIII (anisotropic die upset), supplied by Delco Remy, USA. These data have been fitted to the form $M=A+S\ln(t+t_0)$ to give the magnetic viscosity parameter S as a function of internal field H_i. In conjunction with these experiments we measured the "recoil curves" by reversing the field until H_i became zero after progressively larger magnetizing fields were applied. Wohlfarth suggested that these data could be used to give an indication of the deviations from the case of noninteracting single-domain particles.[7] Following Wohlfarth's theory, Kelly *et al.*[8] have defined

$$\delta M = 2(P_I - P_d), \tag{1}$$

where $P_I = M_I(H)/M_I(\infty)$ and $P_d = \frac{1}{2}[1 - M_d(H)/M_I(\infty)]$, which allows these deviations to be quantified. The isothermal remanence $M_I(H)$ and the dc demagnetization remanence $M_d(H)$ may be determined from the recoil curves, as the values of M when H_i becomes zero.

EXPERIMENT

All the magnetic measurements reported here were made using a vibrating sample magnetometer in conjunction with a 50 kOe solenoid. A cryostat was available to maintain the temperature of the sample during the measurements to ±0.5 K. The samples were prepared in the form of spheres $\varnothing \sim 5$ mm with sphericity ±5 μm, allowing the demagnetization factor to be accurately known. Measurements were made at 298 K on the magnetization and demagnetization curves for the three materials after thermal demagnetization. In an effort to gather comprehensive information magnetic viscosity measurements were performed in conjunction with recoil curves for the initial curve and the demagnetization curve.

The values of $M_I(H_i)$ form the isothermal remanent magnetization (IRM) curve and similarly the values of $M_d(H_i)$ form the dc demagnetization (DCD) curve. If the recoil curves can be assumed to involve only reversible magnetization processes, then the values of $M_I(H_i)$ and $M_d(H_i)$ can be said to be the irreversible components of magnetization M_{irr} associated with H_i, the measurement fields.

In the case where the recoil curves for each value of H_i are parallel to each other, the value of M_{tot} at $H_i=0$ may be adjusted to give a more accurate value of $M_{irr}(H_i)$ by taking into account the magnetic viscosity via a simple linear relation Although this linear approximation is not ideal for other than square loop materials, the values of M_{irr} derived from this method are close (within 5%) to those derived from the method outlined by Street, McCormick, and Folks.[9]

RESULTS

For MQI the recoil curves recorded during the magnetization of the samples were largely parallel and reversible. All

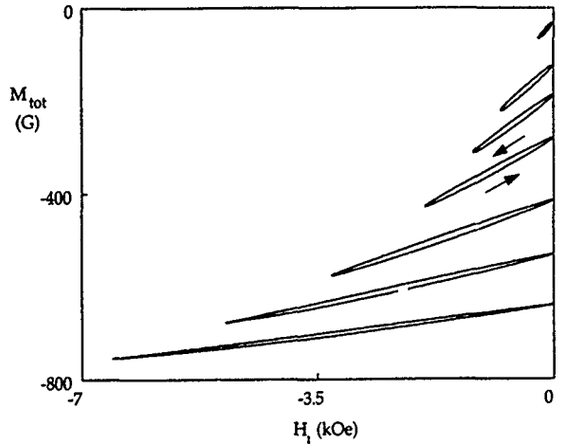

FIG. 1. A selection of recoil curves from the initial magnetization of MQIII produced by applying a magnetizing field to the sample, decreasing the field to zero, then increasing it again.

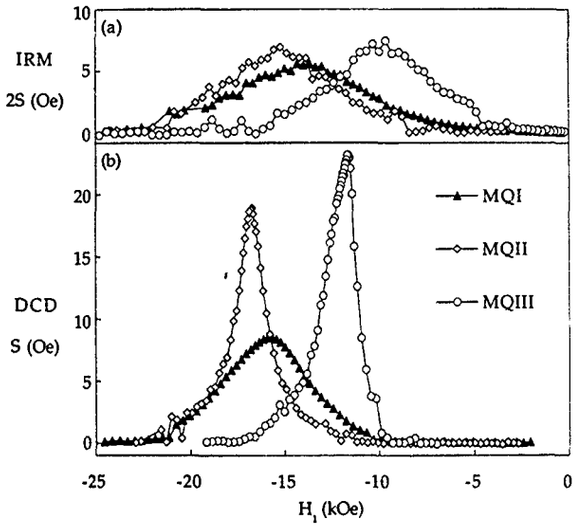

FIG. 2. Values of S vs H_t for MQI, MQII, and MQIII from (a) the initial curve (IRM) and (b) the demagnetizing curve (DCD), where S arises from fitting the time dependence data to the form $M = A + S \ln(t + t_0)$. The IRM data have been multiplied by 2 to allow direct comparison with the DCD data.

the recoil curves from both the magnetization and demagnetization measurements were slightly concave upwards at fields smaller than 2.5 kOe and linear elsewhere. For MQII and MQIII the initial recoil curves were neither parallel to each other nor truly reversible in the low-field region, as Fig. 1 shows for MQIII. At sufficiently high fields (approximately at the end of the first step) the recoil curves became parallel. For the demagnetization measurements the recoil curves were both linear and parallel to a high degree of accuracy.

The magnetic viscosity data collected for the three samples were very similar in form to that taken from conventional measurements, where no recoil curves are performed. For each of the materials the relative peak value of S is much smaller and occurs at a lower field (by $\sim$1.6 kOe) on the magnetization curve than the demagnetization curve, indicating that the irreversible processes occurring are dissimilar. The shape of the S curves, shown in Fig. 2, gives no indication of the steps which appear in the initial M vs H curves.

The values of intrinsic irreversible susceptibility χ^i_{irr}, taken as the derivatives of the IRM and DCD curve with respect to H_t, are shown in Fig. 3. For the three materials the peak in χ^i_{irr} on the demagnetization curve occurs at a slightly larger field than either of the peaks on the magnetization curve, in contrast to other reports that the two peaks occur at the same field.[6] The field at which the second peak in χ^i_{irr} occurs is the same as the field at which the single peak in S occurs during magnetization.

Figure 4 shows δM vs H_t for the materials calculated according to Eq. (1). It may be seen that the steps in the initial curves are also evident in the δM curves and that for all three materials the value of δM is positive until some point after coercivity H_c when it becomes small but negative. For each of the materials, the peaks in the δM curves coincide with the fields at which the second peak of χ^i_{irr} (and the peak of S) occur during magnetization. The sharp decreases in δM correlate closely with the peaks in χ^i_{irr} (and S) during demagnetization. These data (in agreement with the Henkel plots given by Herbst[1]) show that the proportion of particles which have aligned with the field on the initial curve is greater than that on the demagnetization curve, for a given H_t, over most of the range.

SUMMARY

For MQII and MQIII the variations of S and χ^i_{irr} suggest that the first step in the initial curve is a result of largely irreversible processes but these are not sensitive to thermal activation. This is similar to the low-field behavior of sin-

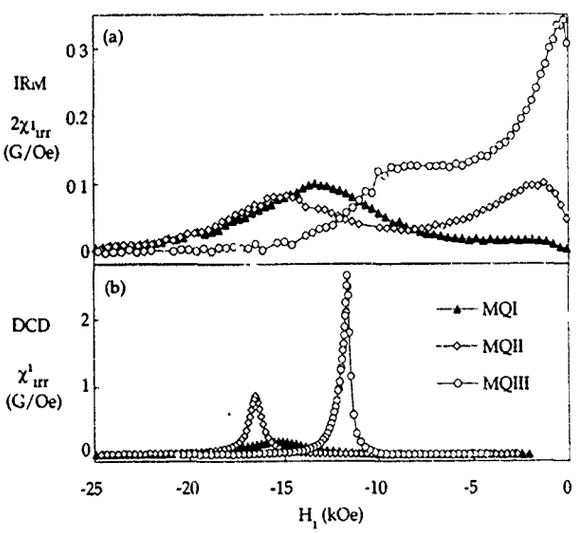

FIG. 3 χ^i_{irr} vs H_t for MQI, MQII, and MQIII from (a) the initial curve (IRM) and (b) the demagnetizing curve (DCD). The IRM data have been multiplied by 2 to allow direct comparison with the DCD data.

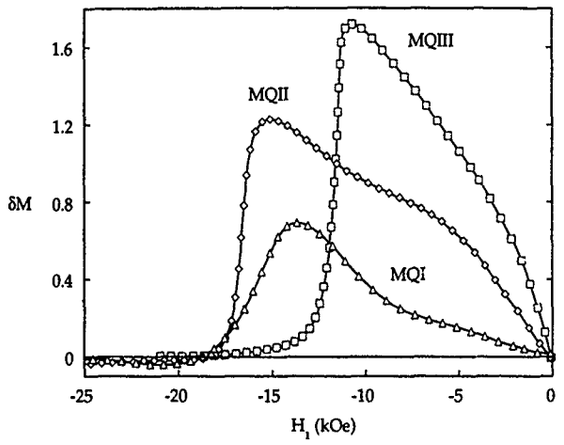

FIG. 4. δM vs H_i plot for MQI, MQII, and MQIII. The large positive values at low fields indicate the presence of larger magnetizing interactions during the initial curve than the demagnetizing curve.

tered NdFeB materials. By contrast the irreversible processes which give rise to the second step are subject to significant thermal activation, as indicated by the peak in S. This is commensurate with the opinion of Grönefeld and Kronmüller[6] that the first step arises from the movement of domain walls within multidomain grains which result from the thermal demagnetization process. The annihilation of the domain walls will be a field-dominated process in the case where there are relatively few pinning sites within the grains, and only small time-dependent effects are expected.

If half the grains within the material are initially multidomain, and they can be assumed to be noninteracting uniaxial particles; then the value of M_{irr} after the first step will be 50% of that at saturation. Comparison of the χ^i_{irr} curves with the IRM curves show that for MQII (44%) and MQIII (49%) this is approximately true, while for MQI (6%) it appears that few of the grains are multidomain after thermal demagnetization. This result may arise from the different thermal treatments of the materials, leading to either a different distribution of grain sizes or to a different density of pinning sites within the grains. However, if there were significant numbers of pinning sites within the grains, it would be expected that significant time dependence would also be evident, so the former explanation seems more likely on balance. MQIII (hot pressed and die upset) is known to have a sharp grain size distribution, and these results suggest that it is centred at some value larger than the critical size for a single domain, while the distribution for MQI appears to be centered at a size smaller than the critical size, so that only a small fraction of the grains start in a multidomain state. The average diameters of the grains in MQI, MQII, and MQIII are about 0.03 (Ref. 1), 0.08 (Ref. 10), and 0.1 (Ref. 1) μm, respectively. However, the theoretical critical domain size, below which formation of a domain wall is energetically unfavorable, is 0.3 μm (assuming no interactions with neighboring grains). These results suggest that critical domain size in bulk materials may be significantly smaller than the theoretical value for an isolated grain.

In the low-field region the recoil curves are not truly reversible, behavior which is routinely observed in strongly exchange coupled materials. This suggests that the domain wall movements within the grains (which determine the first step of the magnetization curve) are subject to exchange coupling between the hard grains and the magnetically softer grain boundary phase. The coupling energy is small compared to the magnetostatic coupling which is set in place once the domain walls have become pinned at the grain boundaries; hence it is not possible to detect this effect after saturation.

After most of the multidomain grains have been removed by the field-dominated process of domain wall annihilation, M changes slowly until some larger field, slightly smaller than H_c, when the rate of change picks up again. This point is correlated with the peak value of δM, the point at which there is the largest deviation in the behavior of the IRM and DCD curves. δM then drops rapidly to a small negative value so that the exchange coupling is in fact working to slightly demagnetize the sample at fields$>H_c$. This behavior is explained by considering that after the first step a large proportion of the grains will have adopted easy directions of magnetization close to the direction of H_a. These will be able to fully align with H_a by reversible mechanisms, leading to the small χ^i_{irr} observed on the initial curve. By contrast, on the demagnetizing curve the intergranular interactions will be working to maintain a high value of M until H_c is reached.

The time dependence of M is much smaller in magnitude everywhere on the initial curves compared with the demagnetization curves. As the multidomain grains have become single-domain grains, by means of almost unimpeded domain wall motion, they will have preferentially moved to those easy directions closest to the direction of H_a so that the remaining changes in M as M_s is approached may occur mostly by reversible processes. Only 50% of the fraction of the grains which began as single-domain particles will be contributing to the time dependence which is observed.

These results give no reason to attribute magnetic hardening in melt-quenched materials to a different mechanism from that for sintered materials. Rather, the differences in the magnetization curves are attributable to differences in the domain structure alone.

Crystal structure and low-temperature magnetic properties of melt-spun $Sm_2Co_7B_3$ compounds

C. J. Yang, W. Y. Lee, and S. D. Choi
Electromagnetic Materials Laboratory, Research Institute of Industrial Science & Technology, P.O. Box 135, 790-330 Pohang, Korea

Low-temperature magnetic properties and crystal structures of melt-spun $Sm_2Co_7B_3$ compound were characterized. The magnetic measurements in the temperature range 77–450 K indicated that a spin reorientation took place at about 150–160 K. A huge anisotropy was observed (H_a=135 kOe at 300 K, 725 kOe at 77 K) for $Sm_2Co_7B_3$, although the magnetic moment is rather low. The crystal structure of the $Sm_2Co_7B_3$ compound was analyzed in detail by Rietveld analysis of powder diffraction for the first time, and revealed that B($4h$) atoms are not placed in the Sm($2e$) layer but in between the Sm($2e$) and Co($6i_1$) layers.

I. INTRODUCTION

Recently, the $R_{n+1}Co_{3n+5}B_{2n}$ (n=1, 2,...,∞) type compounds, which are derivatives of the RCo_5 type (R=rare earth), attracted considerable interest.[1–3] All the previous studies suggested a huge magnetocrystalline anisotropy for $R_{n+1}Co_{3n+5}B_{2n}$ compounds. $SmCo_4B$ (n=1) was reported[2] to show an anisotropy field of 906 kOe at 4.2 K, and $Sm_2Co_7B_3$ (n=3) was reported[4] to exhibit an anisotropy field of 130 T at 4.2 K. Such huge anisotropies used to be explained in terms of the electrostatic interaction of the crystal field.[2,5,6] The nature of the electrostatic field effect is regarded to be associated with the point symmetry of the atomic sites in the underlying crystal structure. However, no study was reported on the exact crystal structure of the $R_{n+1}Co_{3n+5}B_{2n}$ compounds. In this work we intend to refine the crystal structure of the $Sm_2Co_7B_3$ compound by using an advanced x-ray powder technique (Rietveld method) for a future study of magnetocrystalline anisotropy, and we report low-temperature magnetic behavior to examine their application as a permanent magnet.

II. EXPERIMENT

The alloy samples of $Sm_2Co_7B_3$ composition were prepared by induction melting under an Ar atmosphere using 99.95% pure raw elements. An additional 10% Sm was added to compensate for the loss caused by Sm evaporation during melting. The cast compound was homogenized at 1000 °C for 50 h to obtain single-phase $Sm_2Co_7B_3$. Furthermore, melt-spun ribbons of identical stoichiometry were made using a substrate speed of 12 m/s, which gave a single-phase 2-7-3 compound. The magnetic measurements were carried out using cylinderical powder compacts (ϕ=3 mm, L=10 mm), which were magnetically aligned along the axial direction. The compact was prepared by bonding particles of an average 32 μm size under a magnetic field. A Toei vibrating sample magnetometer was used to examine the low-temperature magnetic behavior from liquid-nitrogen temperature up to 400 °C, and a Perkin–Elmer thermomagnetic analyzer was used to identify the magnetic transformation up to the Curie point. The crystal structural simulation was carried out by refining the observed x-ray diffraction pattern using the Rietveld program.[7,8]

III. RESULTS AND DISCUSSION

A. X-ray refinement and crystal structure

The crystal structure of $Sm_2Co_7B_3$ was identified from both the cast and melt-spun samples. Figure 1 shows the powder diffraction patterns of the melt-spun $Sm_2Fe_7B_3$ compound refined by using RIETAN program. The dots refer to the observed pattern and the solid line is the calculated fit. The dotted line shown at the bottom of figure indicates the degree of deviation of the calculated fit from the observed pattern. The x-ray refinements for both cast and melt-spun compounds commonly demonstrated a good fit to the $P6/mmm$ space group with the weighted factor R_{wp}=0.152 and the integrated intensity factor R_I=0.028.8. The determined lattice parameters are a=5.1087 Å and c=12.777 Å, which are not quite the same as those reported (a=5.088 Å, c=12.79 Å) by Ido, Konno, and Ogada,[4] who used a cast sample. The structural coordinates of the refined crystal are tabulated in Table I and the simulated model is plotted in Fig. 2. Two formula units of 24 atoms constitute one unit cell. As shown in Fig. 2, Co atoms occupy three different equivalent sites, Co($2c$), Co($6i_1$), and Co($6i_2$). This 2-7-3 compound results from replacing the Co atoms on the plane of Sm($2e$) sites in the $SmCo_5$ crystal structure by B($4h$) atoms. However, it was found for the first time that those replaced B($4h$)

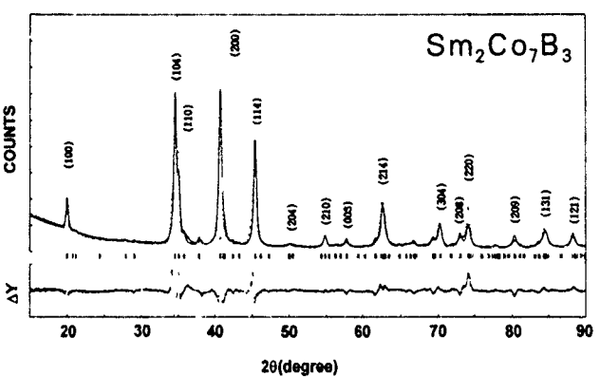

FIG. 1. Powder diffraction patterns of melt-spun $Sm_2Co_7B_3$. The dotted line refers to the observed pattern and the solid line is the calculated fit. The deviation of the calculated fit from the observed data is indicated at the bottom of the figure.

TABLE I. Refined structural coordinates of atomic sites of melt-spun $Sm_2Co_7B_3$ compounds.

Lattice parameter	Sites	Coordinates x	y	z
a=5.1087 Å	Sm(1a)	0.0000	0.0000	0.0000
c=12.770 Å	Sm(1b)	0.0000	0.0000	0.5000
	Sm(2e)	0.0000	0.0000	0.2610
$P6/mmm$	Co(2c)	0.3333	0.6667	0.0000
	Co(6i_1)	0.5000	0.0000	0.1596
R_{wp}=0.152	Co(6i_2)	0.5000	0.0000	0.3857
R_I=0.028	B(2d)	0.3333	0.6667	0.5000
	B(4h)	0.3333	0.6667	0.1990

TABLE II. Calculated interatomic distances of the $Sm_2Co_7B_3$ crystal (see the hexahedral cell in Fig. 2).

Atoms	Distance (Å)
Co(6i_2)–Co(6i_1); c axial	2.8873
Sm(2e)–Sm(1a); c axial	3.3330
Sm(2e)–Sm(1b); c axial	3.0520
Co(2c)–Co(6i_1); a,b,c atoms	4.4021
Sm(2e)–Co(6i_1); a,c,d atoms	2.8638
Sm(2e)–Co(6i_1); b,d atoms	4.6099
B(4h)–Cc(6i_1); a,c,e atoms	1 5582
B(4h)–Co(6i_1); b,e atoms	3.9342
B(4h)–Sm(2e); d,e atoms	3.0539

atoms are not placed exactly on the Sm(2e) layer but in between layers of Sm(2e) and Co(6i_2), i.e., 0.792 Å away from the Sm(2e) layer, while other B(2d) atoms substitute for the Co atoms of identical position on the Sm(1b) layer in the $SmCo_5$ crystal.

Unlike $SmCo_5$, the interlayer distance d_2 between Sm(2e) and Co(6i_2) atoms is not the same as the distance d_1 between the Co(6i_2) and Sm(1a) layers in $Sm_2Co_7B_3$. The distances d_1 and d_2 were found to be 1.295 and 2.038 Å, respectively. Therefore the schematic crystal structure which was derived merely by replacing the layer of Co atoms by B atoms of Refs. 2 and 4 is not the correct one. The calculated interatomic distances of the refined $Sm_2Co_7B_3$ crystal are tabulated in Table II, principly regarding the hexagonal cell in Fig. 2.

B. Low-temperature magnetic properties

Figure 3 shows the low-temperature magnetic properties of melt-spun $Sm_2Co_7B_3$ measured from 77 to 350 K. The magnetic moments measured along directions both parallel (∥) and perpendicular (⊥) to the axial direction vary with temperature. Both the saturation and residual moments measured along the parallel direction decrease slowly with increasing temperature and drop at about 225 K, rising again at 250 K up to the previous moment observed at 225 K. Surprisingly, the magnetization curve measured along the perpendicular direction, which was monotonically flat below 225 K, rises abruptly at 225 K. The moment values observed in both directions tend to meet each other at about 350 K. We tried to explain this behavior in connection with the spin reorientation, which will be described later. The coercivity in the parallel direction at 77 K was too high (perhaps higher than 35 kOe) to be measured in the present maximum field, 16 kOe. It decreases rapidly to 8 kOe at 300 K.

To obtain the anisotropy field of $Sm_2Co_7B_3$, a field-oriented compact sample was prepared using the single-crystal powders made from a cast compound. At 300 K an anisotropy field of 135 kOe was observed, while a huge anisotropy of 725 kOe was measured at 77 K. These anisotropy fields were estimated by extrapolating the curve through polynomial fitting. However, the experimentally saturated magnetic moment by the field of 16 kOe at 300 K was only 25 emu/g although the coercivity ($_iH_c$) observed along the perpendicular direction seemed to exceed 25 kOe. One can realize that both the anisotropy field and coercivity are un-

derestimated due to the weak field in this study comparing with that Ido and co-workers,[4,9] who derived the values from the measurement at 4.2 K under a high field (30 T). Table III summarizes the calculated average magnetic moment per formula unit, μ_B/f.u. A moment of 3.195 μ_B/f.u. was obtained in the present work, which is smaller than that of Refs. 4 and 9. Ido and co-workers[4,9] in calculating the moment assumed that the Sm ion moment is negligibly small, and an incomplete crystal model which is proved to be erroneous by our study was used. In addition, the Co atomic moment is largely decreased by neighboring B atoms.[9] Actually this case happened between the Sm($2e$) and B($4h$) layers shown in Fig. 2.

In order to clarify if the magnetic anomaly observed in Fig. 3 is a symptom of spin reorientation or not, low-temperature torque curves were measured from 77 to 300 K under a 16-kOe field and shown in Fig. 4. The sample used was a cylindrical powder compact, 3 mm diam×10 mm length. The powders of under 32 μm size were prepared from a cast ingot having a grain size larger than 30 μm and with the field oriented perpendicular to the axial direction of the sample bonded by an epoxy resin. The torque curves were measured by placing the sample with its axis parallel to rotational axis, which is perpendicular to the field direction. If the alignment is assumed to be perfect, the easy axis, [0001] of each $Sm_2Co_7B_3$ crystal, makes an angle θ with respect to the magnetization. The magnetocrystalline anisotropy in hexagonal symmetry is expressed as[10,11]

$$E=K_1 \sin^2\theta+K_2 \sin^4\theta+K_3 \sin^4\theta \cos^4\phi+\cdots,$$

where ϕ is the angle of the easy axis projected onto the crystallographic plane parallel to the field direction and perpendicular to the rotational axis. Since the sample was a multicrystalline powder compact, the last term of the right-hand side of the above expression will be disregarded. The torque $\delta E/\delta\theta$ measured at 300–200 K shown in Fig. 4 exhibits a typical variation according to the above equation. At 150–160 K the torque curve changes its periodicity, but the curve returns to its normal shape at 100 K again. Taking into account the magnetization behavior in Fig. 3 and the torque curves in Fig. 4, one can realize that some type of spin reorientation takes place at about 150–160 K. An ac susceptability measurement also suggests the spin reorientation at 150–160 K. For such an imperfectly field-aligned condition, the magnetocrystalline anisotropy energy seems to be equilibriated with the torque exerted by the external field at instantaneous moment:[10]

$$\delta E/\delta\theta=2K_1 \sin\theta\cos\theta+4K_2 \sin^3\theta\cos\theta$$

$$=HM(\theta)\cos\theta=HM_s(1-p \sin^2\theta)\cos\theta,$$

where M_s is the saturation magnetization, and p is a parameter indicating the degree of anisotropy, $[(M_{\parallel c\ \text{axis}})-(M_{\perp c\ \text{axis}})]/M_s$. Therefore whether the observed spin reorientation would be due to the anisotropy change from axial to plane or to cone is not clear, and its determination is beyond the scope of this paper.

The magnetic characteristics of high-anisotropy $Sm(Co_{1-x}Cu_x)_5$ phases are determined experimentally at 300 K in the range $x<0.6$. The saturation magnetization M_s decreases and vanishes for $SmCo_2Cu_3$. Identical behaviors of M_s and Curie temperature T_C versus x are observed in the range $x<0.6$. For significant Cu substitution rate ($x>0.35$), the decrease of the anisotropy field (H_A) when x increases is strong. For lower Cu contents, huge values of anisotropy fields make difficult the accurate determination of the substitution effect. The first anisotropy constant K_1 is calculated using the available values of H_A and M_s. A linear decrease of K_1 is observed from $SmCo_5$ to $SmCo_2Cu_3$.

I. INTRODUCTION

The Sm–Co-based permanent magnets of the 2:17 type consist of a network of fine precipitates based on $Sm(Co,Cu)_5$ distributed in a matrix based on $Sm_2(Co,Fe)_{17}$. The coercivity of these magnets is related to the exchange and anisotropy characteristics of the constitutive phases. Such magnetic properties are well known for the matrix $Sm_2(Co,Fe)_{17}$ (Ref. 1) but are rather scarce in $Sm(Co,Cu)_5$. The phase $Sm(Co_{1-x}Cu_x)_5$ derives from the substitution for nonmagnetic Cu atoms for Co in the hexagonal compound $SmCo_5$ ($CaCu_5$ structure).[2] Its Curie temperature (T_C), rather well established,[3–6] shows the regular decrease expected for increasing x. The few data[5–7] reported for its saturation magnetization exhibit the same trend. As for the anisotropy, $SmCo_5$ is characterized by a giant axial magnetocrystalline anisotropy[8] that results from the dominant contribution of Sm. The same feature can be predicted in the Co-rich $Sm(Co,Cu)_5$ phases. The experimental results published are only for $x=0.3$,[7] 0.48,[6] and 0.6.[5] The very high value of anisotropy field H_A reported for $x=0.3$, higher than H_A of $SmCo_5$,[7] questions the possible evolution of H_A with x. The purpose of the present work is first to determine by experimentation at room temperature the evolution of M_s and H_A for $Sm(Co_{1-x}Cu_x)_5$ in the x range 0–0.6, then to evaluate the constants of exchange (A) and anisotropy (K_1) using the available data of T_C, M_s, and H_A.

II. EXPERIMENT

Most of the measurements of magnetization were effected at 300 K using the axial extraction technique, in external fields H_{ext} up to 7 T. Only the specimen $Sm(Co_{0.6}Cu_{0.4})_5$ was studied in H_{ext} up to 15 T The saturation magnetization M_s was deduced from measurements on powders. The anisotropy fields H_A were obtained by comparing the magnetization curves of single crystals with the applied field oriented parallel to the basal plane and parallel to the c axis. Most of the studied specimens were obtained from alloys prepared by induction or arc melting in purified argon atmosphere. The starting materials were pieces of electrolytic Co and Cu, 99.99%, and of Sm, 99.9%. Some Sm excess was added to balance the Sm losses by evaporation and oxidization. The cast alloys were annealed at 1100 °C for 10 h and quenched. At the annealed state, the samples were characterized by standard optical metallography, electron probe microanalysis (EPMA), and x-ray diffraction by the Debye–Scherrer method. All the specimens were checked to be single phase with homogeneous composition and presenting the $CaCu_5$-type structure. When possible, single crystals were extracted from these polycrystalline materials. In other cases, powders were prepared by crushing. Several attempts were carried out to prepare single crystals using the Bridgman method in boron nitride crucibles. The EPMA characterization of the specimens often detected small amounts of precipitates with compositions $Sm_2Co_7B_3$ and $Sm_3Co_{11}B_4$. The crystal structure of these compounds presents the same symmetry and space group as $SmCo_5$ and appears in coherency with the $Sm(Co,Cu)_5$ matrix. For this reason, only the less contaminated of the prepared specimens could be used for the measurements.

III. RESULTS

Concerning the saturation magnetization, the experimental results, consistent with the few published results, enable a plot of the variation of M_s with x at 300 K. The experimental curve compares to the evolution predicted using the Jaccarino–Walker model[8] (Fig. 1). In this model, the magnetic moment is assumed identical to that in the binary $SmCo_5$ phase when one Co atom is surrounded by n Co neighbors. In the $CaCu_5$ structure, the Co atoms are located on the g sites (three) and c sites (two). Each Co atom is surrounded, respectively, by eight and nine Co neighbors. The random Cu for Co substitution is assumed. The best fit is obtained for five Co neighbors. It can be noted that for $x<0.5$ the variation of the Curie temperature given by the literature data[3–6] follows the same behaviour as M_s (Fig. 2). Moreover, the two curves $M_s(x)$ and $T_C(x)$ are homotetic for the low Cu contents ($x<0.5$) that have been earlier ob-

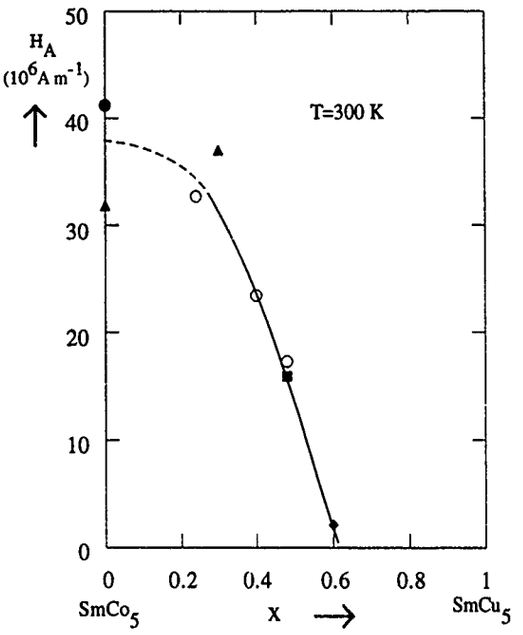

FIG. 3. Anisotropy field H_A at 300 K of $Sm(Co_{1-x}Cu_x)_5$ phases. ○ experimental data; ■ Ref. 5; ◆ Ref. 6; ▲ Ref. 7; ● Ref. 10.

served in the system $Y(Co,Ni)_5$.[9] The phases $Sm(Co_{1-x}Cu_x)_5$ are not ferromagnetic at room temperature for $x>0.65$.

Concerning the anisotropy, the curves plotted in the hard direction did not show any departure from the linear increase of M vs H_{ext}. Whatever the studied compositions, the samples never reached the saturation. Consequently the anisotropy fields were determined by extrapolation, which involves some uncertainty. The values obtained for $x=0.4$ (23.4 MA m^{-1}) and $x=0.48$ (17.3 MA m^{-1}) are very consistent with the result given by Nagel[5] for $x=0.48$ (15.9 MA m^{-1}). Concerning the lower Cu contents, the extrapolated value for $x=0.24$ (32.7 MA m^{-1}) is lower than that given by Uehara[7] for $x=0.3$ (37 MA m^{-1}). Taking into account the limited precision of the determination, the discrepancy between these two values is rather slight. Much higher differences characterize the anisotropy fields published for $SmCo_5$, 31.7 (Ref. 7) and 41 (Ref. 10) MA m^{-1}. The available data of anisotropy are used to plot the evolution of H_A vs x (Fig. 3). For x above 0.35, the accuracy of the results is sufficient to evidence that the Cu for Co substitution induces a strong decrease of the anisotropy field in $SmCo_5$. For the lower substitution rates, the rather scattered results do not enable one to state if Cu produces a smooth decrease or an unexpected change as suggested by the Uehara[7] results. Using the available data of H_A and M_s, the first anisotropy constant $K_1=\frac{1}{7}\mu_0 M_s H_A$ was calculated. The corresponding curve $K_1=f(x)$ (Fig. 4) shows a linear decrease at 300 K from $x=0.2$ to 0.6. A similar decrease is observed in $Y(Co,Ni)_5$ (Ref. 9) compounds. In the $Sm(Co,Cu)_5$ compound, the contribution of Sm to the anisotropy is the dominant one. It should vary with the Cu content, which should induce a change in the crystalline electric field and exchange field acting on the Sm^{3+} ion. Assuming that the colinearity of the magnetic configuration is maintained in an external field applied in the hard direction, the linear variation of K_1 suggests that the Sm contribution to the magnetocrystalline anisotropy also varies linearly with x.

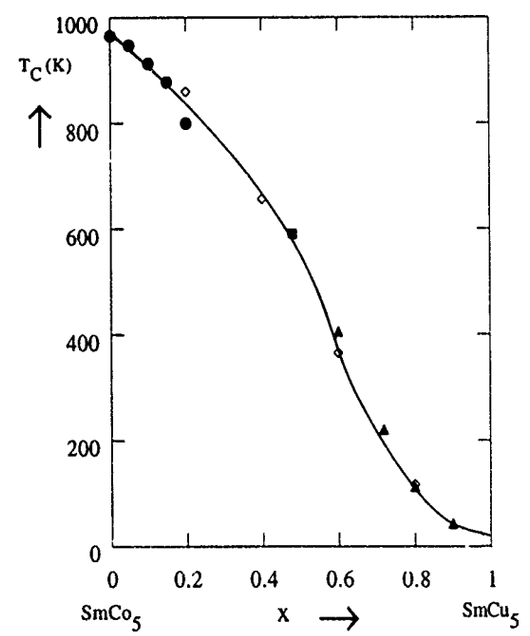

FIG 2. Curie temperature T_C of $Sm(Co_{1-x}Cu_x)_5$ as a function of x. ● Ref. 3; ▲ Ref. 4; ■ Ref. 5; ◇ Ref. 6.

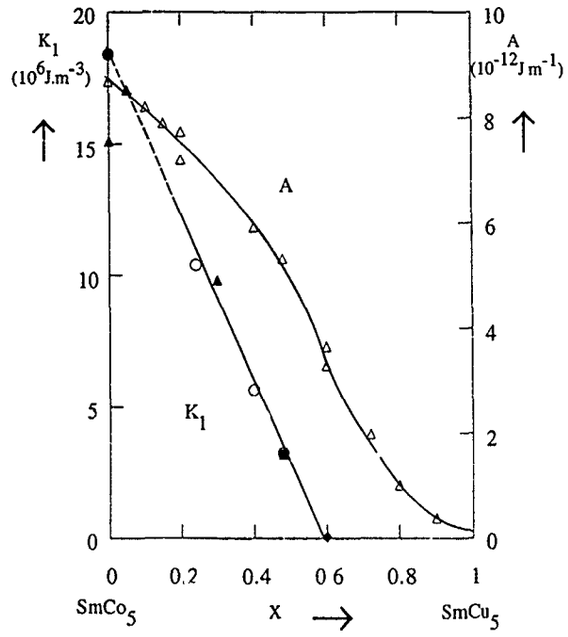

FIG. 4. Anisotropy constant K_1 at 300 K and exchange constant A variations vs x in $Sm(Co_{1-x}Cu_x)_5$. ○ experimental data; ■ Ref. 5; ♦ Ref. 6; ▲ Ref. 7; ● Ref. 10.

A rough approximation of the exchange constant A was attempted from the expression $A = 10^5 \zeta^2 T_C$, where ζ is the shorter distance between two Co atoms and assumed to be 0.3 nm (Fig. 4). Using the values of A and K_1, the Bloch wall energy γ in $Sm(Co_{1-x}Cu_x)_5$ can be evaluated using the expression $\gamma = 4\sqrt{AK_1}$. For the pinning precipitates in the permanent magnets of the 2:17 type, the composition of which is about $Sm(Co_{0.7}Cu_{0.3})_5$, the γ value is around 32×10^{-3} J m^{-2}.

Despite the large interest devoted to the $Sm(Co_{1-x}Cu_x)_5$ phases in the past, their intrinsic magnetic properties had not been extensively studied. This could be explained by two facts: the preparation of strictly homogeneous single-phase specimens is difficult and the huge magnetocrystalline anisotropy cannot be easily characterized. The present results, obtained on well-controlled materials, give a precise determination of the strong decrease of the saturation magnetization produced by Cu. They display a lower than expected decrease of the anisotropy field due to Cu. For this reason, only the anisotropy of the phases with a significant Cu content ($x>0.35$) could be accurately characterized. The obtained data, complemented by the literature results, lead to the calculation of the exchange and anisotropy constants required to evaluate the domain wall energies of the 1:5 precipitates involved in the permanent magnets of 2:17 type.

SmCo (2:17-type) magnets with high contents of Fe and light rare earths

M. Q. Huang, Y. Zheng, and W. E. Wallace
Materials Science and Engineering Department, Carnegie Mellon University, Pittsburgh, Pennsylvania 15213

The magnetic properties of SmCo (2:17-type) magnets with high contents of Fe (v=Fe/3d>0.34) and/or light rare earths (up to 0.4) were investigated. For magnets with compositions of $Sm(Fe_vCo_{bal}Zr_{0.02}Cu_{0.06}\{Ga\}_x)_{7.72}$, $v=0.35$, $x=0-0.06$, both $_iH_c$ and $(BH)_{max}$ can be improved significantly by Ga doping, from 1.0 kOe and 5.4 MG Oe for $x=0$ to 6.4 kOe and 15.4 MG Oe for $x=0.06$. For magnets with compositions of $Sm_{0.8}Pr_{0.2}(Fe_vCo_{bal}Zr_{0.02}Cu_{0.06})_{7.67}$, $v=0.30-0.31$, $_iH_c$ can be increased strikingly by a special heat treatment, from 2.5 to over 20 kOe for $v=0.30$ and from 0.5 to 15.5 kOe for $v=0.31$. Examining magnets with compositions of $Sm_{0.59}Pr_{0.41}(Co_{0.68}Fe_{0.20}Cu_{0.10}Zr_{0.02})_z$ ($z=6.68-7.75$) shows two stages of the magnetization reversal process in the range of 5.5 to 9.5 kOe and 16 to 19 kOe. Observed $(BH)_{max}$ ranged from 17 to 22.5 MG Oe.

I. INTRODUCTION

Recent progress in improving performance of 2:17-type permanent magnets has been reviewed by Ray and Liu.[1] These magnets are particularly valuable because of their high Curie temperature, low temperature coefficients of remanence B_r, and $(BH)_{max}$, compared to $SmCo_5$ and NdFeB magnets. Except for unconfirmed reports from Russian workers (*vide infra*), the highest achieved energy products are 32–34 MG Oe.[1–5] These are much less than that of NdFeB magnets[6] and are very much less than the theoretical energy product of $Sm_2(Co,Fe)_{17}$, 60 MG Oe. One can, of course, raise $(BH)_{max}$ by increasing B_r and $_iH_c$. The saturation magnetization of Sm_2Co_{17} is easily increased by replacing Co with Fe or Sm by Pr. This improvement comes, however, at the expense of coercivity. These dopants alone effect no improvement in energy product. In the present study Al and Ga are used as additional dopants, hopefully to preserve the rise in magnetization in Fe-enriched and light-rare-earth (LRF)-doped magnets without loss of coercivity. Ga doping is particularly effective in this respect.

II. EXPERIMENT

Alloys were prepared by induction melting. The ingots were crushed and then ball milled to 3–5 μm average size. They were aligned in a 170-kOe field and then isostatically pressed at 3 tons/cm^2. The green compacts were then sintered under Ar at 1190–1200 °C for 1 h, followed by a solid solution treatment at 1130–1150 °C for 1–10 h and then quenched to room temperature in flowing helium. The sintered compacts were then heated to 800–850 °C for 24–50 h, followed by slow cooling to 400 °C at a rate of ~0.8 °C/min and then quenched to room temperature. The sintered compacts were magnetized in a 170-kOe field. The various magnetic properties were obtained by techniques that are standard in this laboratory. *BH* loops were traced with a Walker Hysteresograph. X-ray diffraction (XRD) information was obtained using Cr $K\alpha$ radiation.

III. RESULTS AND DISCUSSION

A. Al, Ga substitution in magnets of high Fe content

Listed in Tables I and II are the compositions of samples 1–5 and their grain size and hard magnetic properties. Comparing Ga- and Al-free samples 1 and 2, when the Fe content, designated v, increases from 0.32 to 0.35, H_A decreases from 58 to 42 kOe, and the grain size becomes much smaller. The average grain size decreases from 54 to 26 μm. Sample 1 shows excellent hard magnetic properties $_iH_c$ = 17 kOe, $(BH)_{max}$=31.7 MG Oe, as well as a large grain size and a fine cellular structure. However, $_iH_c$ and $(BH)_{max}$ sharply diminished to 1.0 kOe and 5.4 MG Oe for sample 2. When doping with a small amount of Ga in sample 2 of high Fe content, $v=0.35$, H_A increased from 42 to 53 kOe, and the grain size grows significantly (average grain size d=33 μm). For this sample, $_iH_c$ and $(BH)_{max}$ increase to 6.4 kOe and 15.4 MG Oe, respectively (sample 3). In contrast, Al doping (sample 4) does not change the microstructure. It retains a small grain size (21 μm), smaller than the Al-free sample. Even though H_A increases from 42 to 49 kOe, it exhibits poor properties: $_iH_c$ = 0.8 kOe and $(BH)_{max}$=4.0 MG Oe.

If Zr and Cu are omitted and only doping by Ga is involved (sample 5), no hard magnetic properties develop, even though H_A was increased as much as was produced by the substitution of Ga. This indicates that obtaining acceptable coercivity by Ga substitution in 2:17-type magnets still requires Zr and Cu. Apparently they are needed to form the critical cellular structure. Ga is a low-melting element; when it is inserted into the materials it may increase the fluidity and wettability of boundary liquid phases during the sintering process, enabling larger grains to be formed and thus enhancing $_iH_c$.

No.	$(BH)_{max}$ (MG Oe)	Alloys M(emu/g)	Alloys H_A(kOe)
1	9.08	102.0	67.0
2	21.0	103.5	64.0
3	22.5	106.0	62.0
4	18.5	107.5	59.0
5	16.8	109.0	57.0

listed in Table III. When 20% of Sm is replaced by Pr, B_r and $(BH)_{max}$ increase from 11.5 kG and 28.0 MG Oe to 11.9 kG and 29.8 MG Oe, respectively. This result is similar to that reported by Liu and Ray.[2] With increasing Pr, the moments (B_r and M) increase, as Pr has higher magnetic moment than Sm, and H_A decreases, since the Pr sublattice prefers planar anisotropy in $Pr_2(Co,Fe)_{17}$ compounds. As can be seen in Table III, the $_iH_c$ drops even more sharply than H_A. When the Pr content x increases to 40%, the $_iH_c$ drops to 500 Oe.

It is to be noted that further increase of Fe content for these compositions will result in a deterioration of all permanent magnetic properties,[2] especially in $_iH_c$. In our studies for magnets corresponding to $x=0.2$ and for which the Fe content is increased to 0.30–0.31, the magnetic properties, especially $_iH_c$, can be improved significantly by optimizing the solutionizing and aging heat treatment. Results shown in Table IV show the effects of different heat treatment conditions on the magnetic properties of the $Sm_{0.8}Pr_{0.2}(Co_{bal}Fe_vCu_{0.06}Zr_{0.02})_{7.67}$ ($v=0.30$, 0.31) magnets. For $v=0.30$, the $_iH_c$ can be dramatically increased from 2.5 kOe (sample 2) to 20 kOe (sample 1) by changing the solid solution treatment from at 1150 °C for 3 h to 1130 °C for 9 h. For the magnet of $v=0.31$, no hard magnetic properties were developed when sintered at 1200 °C (sample 5). $_iH_c$ can be developed and increased from 3.5 kOe (sample 4) to 15.5 kOe (sample 3), if sintered at a lower temperature 1190 °C and isothermally treated at a higher temperature 840 °C. The basic principles which form the foundation of these considerations are contained in investigations and findings of numerous investigators.[1]

2. Effect of variation of rare-earth content

Ivanova *et al.*,[7] working with a pseudo-single-crystal specimen, reported some rather interesting magnetic properties: $4\pi M=1.24$ T, $_iH_c$ = 896 kA/m, and $(BH)_{max}=288$ kJ/m^3 for a magnet of composition $Sm_{0.59}Pr_{0.41}(Co_{0.68}Fe_{0.20}Cu_{0.10}Zr_{0.02})_z$ with $z=6.68$. Following up on this interesting study, a number of magnets with variation of z from 6.68 to 7.75 were fabricated. Listed in Table V are their magnetic properties. The demagnetization

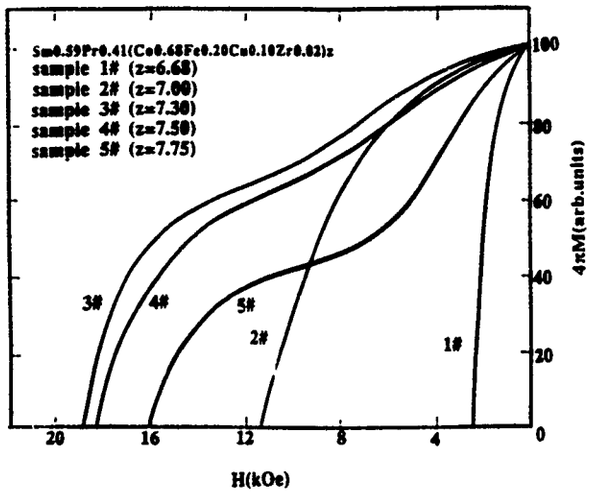

FIG. 1. $4\pi M$ vs H for samples 1,2,3,4, and 5.

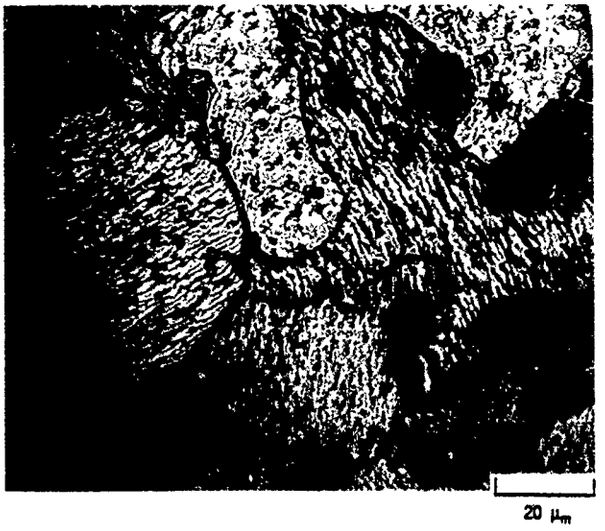

FIG. 3. Microstructure of sample 3 ($z=7.30$).

curves for the samples are shown in Fig. 1. The curves for samples 1 and 2 differ from those of samples 3, 4, and 5 in that demagnetization occurs in only one stage. Microstructure for samples 1 and 3 are shown in Figs. 2 and 3.

All these magnets exhibit reasonably good hard magnetic properties. In particular, when $z>7$, $B_r=10.5-11.3$ kG, ${}_iH_c = 11.5-18.8$ kOe and $(BH)_{max}=16.8-22.5$ MG Oe. For sample 1, $z=6.68$, the composition is much deviated from the stoichiometric composition of 2:17 compound, and a significant amount of 1:5 phase was retained in the magnet, as clearly indicated by XRD. Only a small amount of the 1:5 phase is needed to form the cellular structure needed for domain wall pinning; the rest will separate from the 2:17 phase. As seen in Fig. 2, only in some parts of the magnet was a cellular structure formed. It exhibits a lower ${}_iH_c$ of 2.6 kOe.

As z increases from 6.68 to 7.30, the 1:5 phase decreases (as evidenced by XRD) and the cellular structure develops more completely (see Fig. 3). As a consequence, ${}_iH_c$ increases from 2.6 to 18.8 kOe and $(BH)_{max}$ increases from 9.1 to 22.5 MG Oe.

For sample 3, $z=7.30$, the demagnetization curve seems to exhibit two stages of the magnetization reversal process, a lower one at ~9.5 kOe and a higher one at ~18.8 kOe (see Figs. 1 and 2). They both can be ascribed to a mechanism of domain wall pinning, but with different pinning centers. We surmise that the lower ${}_iH_c$ corresponds to the reversal process when the $PrCo_5$-type phase acts as a pinning center, and the higher ${}_iH_c$ for the $SmCo_5$-type phase as a pinning center, since the H_A of $SmCo_5$ (210 kOe) is much higher than that of $PrCo_5$ (145 kOe).[8] When z further increases from 7.30 to 7.75, the magnetic behavior of samples 4 and 5 are similar to that of sample 3.

Effect of Dy substitution on the magnetocrystalline anisctropy of $GdCo_4B$

T. Ito, H. Asano, and H. Ido

G. Kido
Institute for Material Research, Tohoku University, Sendai 980, Japan

X-ray diffraction and magnetization measurements have been performed for powdered and field-oriented samples of $Gd_{1-x}Dy_xCo_4B$ with $x=0$, 0.05, 0.1, and 0.2. It has been found that $Gd_{1-x}Dy_xCo_4B$ with $x=0.2$ has a planar magnetic anisotropy in the temperature region below room temperature; however, the samples with $x=0.05$ and $x=0.1$ have an axial magnetic anisotropy at room temperature and transform to a tilted state in the low-temperature region. By analyzing magnetization curves measured in a pulsed field up to 140 kOe at $T=4$ K and also in a static field up to 12 kOe at 78 K for the field-oriented samples with $x=0.05$ and $x=0.1$, approximate values of magnetic anisotropy constants of a Dy ion in $Gd_{1-x}Dy_xCo_4B$, K_1(Dy) and K_2(Dy), have been determined to be -2.1×10^{-14} erg/Dy and 1.3×10^{-14} erg/Dy, respectively. By comparing these values with those of $DyCo_{5.2}$, it is found that K_2(Dy) in the $CeCo_4B$-type structure is enhanced in one order by the crystallographic change from the $CaCu_5$- to the $CeCo_4B$-type structure.

I. INTRODUCTION

RCo_4B (R=rare earth) compounds have hexagonal $CeCo_4B$-type structure,[1] which is derived from the $CaCu_5$-type structure by replacing the $2c$-site Co atoms by B atoms. In our previous work,[2] we studied the magnetic properties of $GdCo_4B$ and found that the Gd-sublattice magnetic anisotropy is well explained by the magnetic anisotropy due to the dipole–dipole interaction. Since the magnetic anisotropy of $DyCo_4B$ has been known to be planar at room temperature,[3] it is impossible to make a field-oriented sample. The magnetic anisotropy of $GdCo_4B$ has been clarified, so in this work, $Gd_{1-x}Dy_xCo_4B$ compounds are prepared and the magnetization curves for field-oriented samples have been measured to study the Dy contribution to the magnetic anisotropy in these compounds.

II. SPECIMENS AND CRYSTAL STRUCTURE

Ingots of $Gd_{1-x}Dy_xCo_4B$ were prepared by melting raw materials of 99.9% purity in an arc furnace. The melting was repeated several times to homogenize the ingots which are then annealed at 800 °C for 2 days. The crystal structure has been confirmed by x-ray diffraction to be the $CeCo_4B$-type structure. The field-oriented sample was prepared by solidifying the mixture of epoxy resin and the powdered specimen (<32 μm) in the magnetic field of 20 kOe at room temperature. The x-ray diffraction pattern for the field-oriented $Gd_{0.95}Dy_{0.05}Co_4B$ is shown in Fig. 1, which shows that the sample has an axial magnetic anisotropy at room temperature.

III. EXPERIMENTAL RESULTS AND DISCUSSION

From the results of x-ray diffraction and magnetization measurements for the field-oriented samples of $Gd_{1-x}Dy_xCo_4B$, it has been found that $Gd_{1-x}Dy_xCo_4B$ with $x=0.2$ has a planar magnetic anisotropy in the temperature region below room temperature; however, the samples with $x=0.05$ and $x=0.1$ have an axial anisotropy at room temperature and transform to a tilted state in the low-temperature region. Magnetization curves for the field-oriented samples with $x=0$, 0.05, and 0.1 at 78 K are shown in Fig. 2. It is seen that the substitution of Dy for Gd in $GdCo_4B$ has a significant effect in the magnetic anisotropy. Only 5% substitution of Dy changes the axial anisotropy of $GdCo_4B$ to the planar or tilted one. To estimate the magnetic anisotropy constants K_1 and K_2, the magnetization curves in Fig. 2 have been analyzed on the basis of Eq. (1) which takes the magnetic anisotropy energy including K_1 and K_2 and the Zeeman energy:

$$H=AM^3+BM, \tag{1}$$

where H is the external magnetic field and M is the magnetization component parallel to H direction. The coefficients A and B are expressed as follows:

$$A=4K_2/M_s^4$$

and

$$B=\begin{cases}-2(K_1+2K_2)/M_s^2 & \text{for } H\|c,\\ 2K_1/M_s^2 & \text{for } H\perp c.\end{cases} \tag{2}$$

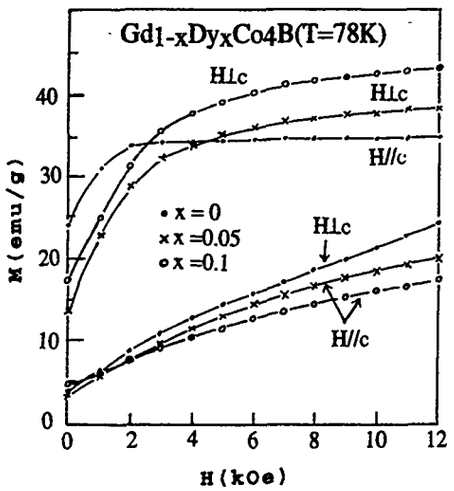

FIG. 2. Magnetization curves for the field-oriented samples of $Gd_{1-x}Dy_xCo_4B$ at $T=78$ K. The c in this figure means the field orientation direction of the sample.

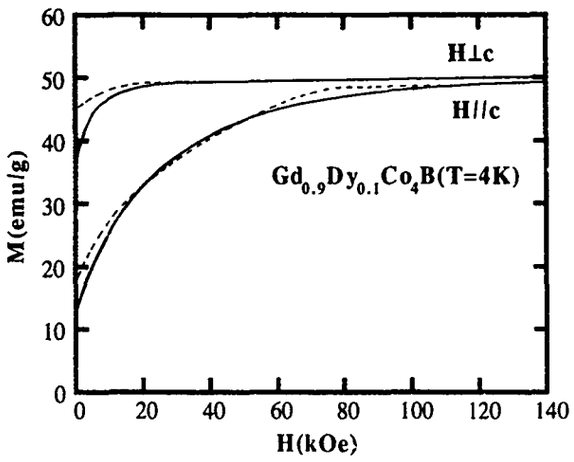

FIG. 4. Magnetization curves of the field-oriented sample of $Gd_{0.9}Dy_{0.1}Co_4B$ in a pulsed field at $T=4$ K. The dashed curves are calculated (see the text).

To remove the magnetic domain effect, we take the data in the magnetic field larger than 3 kOe and fit Eq. (1) to them in order to estimate the values of K_1 and K_2. The dashed curves in Fig. 3 are calculated with the values of K_1 and K_2 shown in the same figure. A similar analysis has been made for the data of the sample with $x=0.1$. Magnetization curves for the field-oriented sample in a pulsed field are shown in Fig. 4 for $x=0.1$ at 4 K. The dashed curves are calculated, where we take $K_1=-2.3\times10^{-15}$ erg/f.u. and $K_2=1.3\times10^{-15}$ erg/f.u. as the best values (f.u. denotes formula unit).

Though the sample is a field-oriented one, the agreement between the observed and calculated curves is fairly good. A similar analysis has also been made for the data of the sample with $x=0.05$. The anisotropy constants K_1 and K_2 estimated by the method mentioned above are plotted against composition x in Fig. 5. The data in Fig. 5 are approximate because the observed magnetization curves are for the field-oriented samples; however, the data at $T=4$ K and $T=78$ K seem to be consistent with each other. The anisotropy constants K_1 and K_2 in Fig. 5 can be expressed by

$$K_1=(1-x)K_1(\mathrm{Gd})+xK_1(\mathrm{Dy})+4K_1(\mathrm{Co}),$$

and

$$K_2=4K_2(\mathrm{Co})+xK_2(\mathrm{Dy}), \tag{3}$$

where $K_1(\mathrm{Gd})$, etc., are the magnetic anisotropy constants of a Gd ion, etc. If we use $K_1(\mathrm{Gd})=2.62\times10^{-16}$ erg/f.u., $K_1(\mathrm{Co})=-2.87\times10^{-16}$ erg/f.u., and $K_2(\mathrm{Co})=1.74\times10^{-16}$ erg/f.u., which have been estimated from the data of $GdCo_4B$ (Ref. 2) and YCo_4B (Ref. 4), approximate values of $K_1(\mathrm{Dy})$ and $K_2(\mathrm{Dy})$ can be estimated by fitting Eq. (3) to the straight lines at $T=4$ K in Fig. 5 as

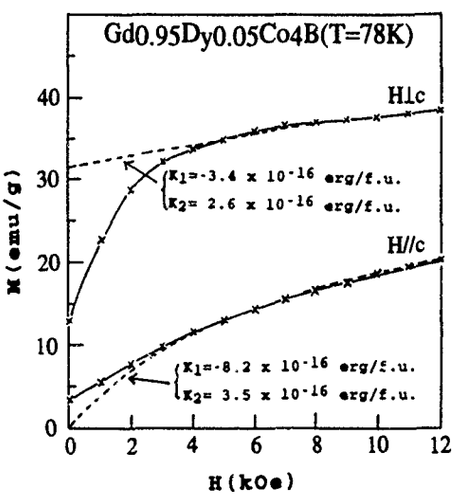

FIG. 3. Magnetization curves for the field-oriented sample of $Gd_{0.95}Dy_{0.05}Co_4B$ at $T=78$ K. The dashed curves are calculated (see the text).

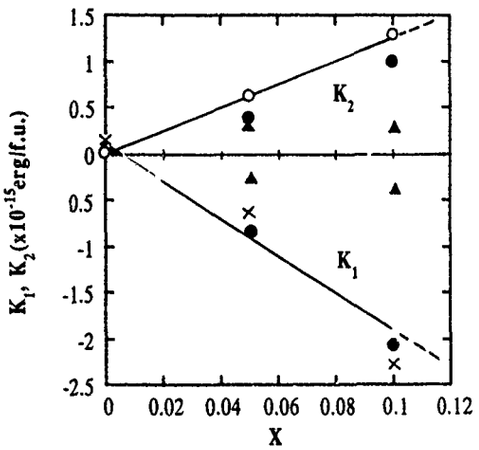

FIG. 5. Composition dependence of magnetic anisotropy constants K_1 and K_2 per formula unit in $Gd_{1-x}Dy_xCo_4B$. ○ and × are estimated from the magnetization curves with $H\|c$ measured in the pulsed field up to 140 kOe at $T=4$ K, ● and ▲ are estimated from the magnetization curves with $H\|c$ and $H\perp c$ measured in the low field up to 12 kOe at 77 K.

$$K_1(\mathrm{Dy}) = -2.1\times10^{-14}\ \mathrm{erg/Dy}$$

and

$$K_2(\mathrm{Dy}) = 1.3\times10^{-14}\ \mathrm{erg/Dy}.$$

On the other hand, K_1(Dy) and K_2(Dy) of $DyCo_{5.2}$ with $CaCu_5$ crystal structure have been estimated by Ermolenko and Rozhda[5] to be -2.92×10^{-14} and 1.4×10^{-15} erg/Dy, respectively. Comparing the magnetic anisotropy constants per Dy ion in $Gd_{1-x}Dy_xCo_4B$ with those of $DyCo_{5.2}$, we can conclude that the K_2(Dy) is strongly enhanced by the crystallographic change from $CaCu_5$-type to $CeCo_4B$-type structures. This fact is different from the situation of $SmCo_4B$ and$SmCo_5$, where K_1(Sm) is enhanced by the crystallographic change to the $CeCo_4B$ type.[6]

Recent advances in high-coercivity planar-magnetization film magnets and Bi-YIG (bismuth-substituted yttrium iron garnet) film technology have opened up the possibility of fabricating very small magneto-optic devices. In this article we demonstrate that these two technologies can be brought together to fabricate a high performance waveguide magneto-optic isolator for use in integrated optical circuits. The device operates at 1.55-μm wavelength and consists of a waveguide etched into a Bi-YIG film whose magnetization is saturated by a 22-μm-thick $TbCu_7$-type SmCo magnet with a coercivity of 4 kOe. Isolation ratios of 25 dB have been obtained in the wavelength region between 1490 and 1555 nm.

The development of optical fiber telecommunications has intensified the search for compact, low-cost magneto-optic isolators. Isolators currently in use are made of bulk crystals or thick films of modified yttrium iron garnet (YIG) and rely on bulk magnets to induce Faraday rotation in these crystals. The development of waveguide isolators, magnetized by small ferromagnetic films, would allow a considerable reduction in size and production costs.

Recent advances in Bi-YIG film technology[1,2] have made it possible to fabricate thin-film waveguide isolators[1] with zero birefringence and isolation ratios of 30 to 35 dB. Moreover, within the last decade there have also been significant advances in the fabrication of thin and medium thickness ferromagnetic films, with high magnetization[3,4] and high coercivity.[4]

In this article we demonstrate that these ferromagnetic films can be used as permanent magnets in a workable magneto-optic waveguide isolator. The work presented here extends results obtained by some of the authors in a previous study.[5] We demonstrate full saturation of the magnetization in a waveguide isolator using a more powerful film magnet than in Ref. 5, and study insertion losses and the response of the film magnet isolator as a function of wavelength.

The basic structure of the device, as shown in Fig. 1, consists of a magnetic film placed on a Bi-YIG waveguide, separated by an appropriate buffering material. In order to demonstrate the feasibility of utilizing various thin-film magnet types with waveguide Bi-YIG structures we have studied the magnetic saturation induced by two different ferromagnetic films on a Bi-YIG slab waveguide. Such saturation is important because the presence of preexisting magnetic domains in the waveguide degrades the performance of the device as a result of spurious linear magnetic birefringence, induced when the magnetization in the Bi-YIG is not collinear with the waveguide axis. Moreover, the magnet should saturate a length of Bi-YIG sufficient to generate 45° of Faraday rotation as the light traverses the isolator.

In this article we report on the performance of two different magnet types. The first is an iron–cobalt alloy single-crystal film, with alloy composition 30% iron and 70% cobalt, grown by molecular-beam epitaxy on a (110) GaAs substrate. Hysteresis studies of these films show a flat rectangular response to an applied magnetic field, with a zero-field remanent $4\pi M$ of about 21 kOe and a coercivity of 50 Oe. The film's thickness is approximately 1.5 μm. The second magnet is a 22-μm-thick samarium–cobalt polycrystalline film, with composition $Sm_{14}Co_{63}Fe_{20}Zr_2Cu_8$, sputtered on an aluminum oxide substrate. It has a remanent $4\pi M$ of 7 kOe and a coercivity of 4 kOe. M is in the plane of the film for both magnets.

The slab waveguide consists of a triple-layer single-crystal epitaxial Bi-YIG film[1] designed to support single TE and TM modes. The film was grown by standard liquid-phase epitaxy on a (111)-oriented gadolinium–gallium–garnet substrate. The top two epilayers have nominal composition $(Bi_{0.5}Y_{2.5})(Fe_{3.7}Ga_{1.3})O_{12}$, with a calcium content of 0.1 pfu. An index of refraction difference of 0.5% between them ensures waveguiding in the top layer. Each epilayer is approximately 3.5 μm thick. The sample was subjected to annealing processes described elsewhere[1] for near-planar

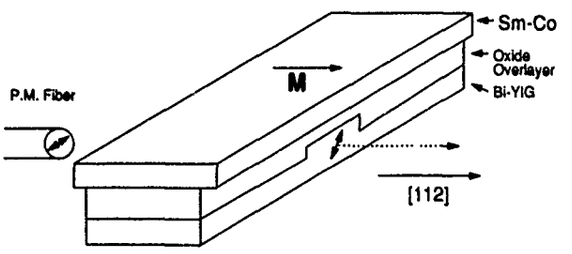

FIG. 1. Basic structure of thin-film magnet magneto-optic isolator.

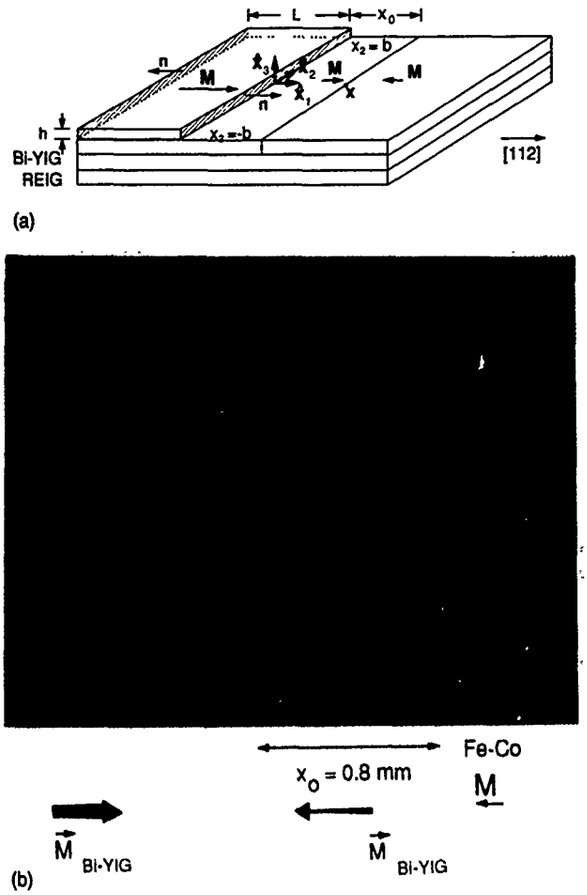

FIG. 2. (a) Shaded areas show the magnetically charged end faces of the film magnet. (b) Photomicrograph of magnetic domains in Bi-YIG epilayer (Faraday contrast) in the presence of 1.5-μm-thick Fe–Co film.

magnetization anisotropy in the upper layers, resulting in easy-magnetization axes along the [112] directions. The bottom epilayer of the three-layer structure has nominal composition $(Bi_{0.5}Er_{1.4}Sm_{0.7}Pr_{0.4})(Fe_{4.0}Co_{0.2}Al_{0.8})O_{12}$, and magnetization normal to the plane of the film. Its rare-earth composition is designed to absorb higher-order waveguide modes present in the triple-layer structure.

To study the magnetic saturation induced by the iron–cobalt alloy film in the Bi-YIG waveguide, we placed the magnetic film directly on top of the Bi-YIG sample, its magnetization parallel to the planar component of one of the easy magnetization directions of the garnet. The slab waveguide magnetization is partially saturated by the fringing field of the film magnet, which is nearly planar in the waveguide. The iron–cobalt film is found to saturate $x_0 = 0.8$ mm of the Bi-YIG sample, as shown in Fig. 2. The magnetization direction in the Fe–Co film is normal to the edge of the film, as shown in Fig. 2(a), and saturation is measured away from the magnet. The photomicrograph in Fig. 2(b) was obtained using Faraday contrast with a polarization microscope. In the figure the opposite directions of quasi-planar magnetization in the waveguiding epilayer appear as light- and dark-shaded regions parallel to the Fe–Co edge.[2] The mazelike pattern in the Bi-YIG corresponds to vertical magnetization domains present in the absorbing (bottom) epilayer. These domains exhibit a higher Faraday contrast than those corresponding to the quasi-horizontal magnetization of the waveguiding epilayer because of their larger vertical components of magnetization. In the isolator, the fringing fields of these domains are neutralized by the permanent magnet and do not limit the ultimate isolation ratio of the device.

In order to obtain the micrograph shown in Fig. 2(b), a separate external magnet was first placed in proximity to the YIG sample in order to saturate the Bi-YIG magnetization in a direction opposite to that later obtained with the Fe–Co film in place. This magnet was then removed and the film magnet positioned on the YIG; the domains then relaxed to their equilibrium configuration. The resulting domain configuration in the waveguiding epilayer, observable by Faraday contrast, provides a measure of the magnetic saturation induced by the Fe–Co film in the Bi-YIG sample, and yields 0.8 mm, as indicated above.

Using the expressions in Eqs. (1) and (2) given below, for the magnetic field induced by each of the two magnetically charged pole faces in a magnetic film,[5,6] we estimate a saturation field of 5.8 Oe for the waveguiding epilayer in the Bi-YIG sample used in these experiments. The equations, derived in Ref. 5,

$$H_1(x_1,0,x_3) = 2\mathbf{M}\cdot\mathbf{n}\left(\arctan\frac{x_3}{x_1} - \arctan\frac{x_3-h}{x_1}\right), \quad (1)$$

$$H_3(x_1,0,x_3) = \mathbf{M}\cdot\mathbf{n}\ln\left[\frac{x_1^2+x_3^2}{x_1^2+(x_3-h)^2}\right] \quad (2)$$

are valid for the case where the distance between the pole face and the point **x**, where the field is evaluated, is much smaller than the lateral dimension b of the film, shown in Fig. 2(a). **M** is the magnetization density, **n** is the unit vector normal to the face, and the Cartesian coordinates are as shown in the figure. The pole face is at $x_1 = 0$, and the thickness of the film h is assumed to be 1.5 μm in the above calculation.

The thicker samarium–cobalt film magnet, on the other hand, has a more drastic effect on the Bi-YIG magnetization. Placed in close proximity to the edge of the garnet, its magnetization normal to the edge, the magnet's fringing field is strong enough not only to saturate the waveguiding layer, but in addition the vertical domains of the absorbing epilayer are eliminated up to a distance of 0.5 mm from the edge. Faraday contrast analysis reveals that the waveguiding epilayer remains magnetically saturated horizontally beyond a distance of 2 mm from the magnet. Calculations using Eq. (1) show that for the saturation field of 5.8 Oe calculated above, the saturation length is $x_0 = 4.2$ mm for this Sm–Co film.

A workable waveguide isolator must be long enough to generate 45° of Faraday rotation in the light input. For example, typical lengths for bismuth-substituted YIG films with near-planar magnetization range from 1 mm to several millimeters, depending on the level of bismuth doping in the Bi-YIG film. Since a single magnetically charged pole face of the samarium–cobalt magnet saturates more than 2 mm of the waveguiding epilayer, the magnet's return flux, which has additive contributions from both pole faces in the horizontal direction, will be sufficient to saturate the full length

of a channel waveguide to achieve 45° rotations.[7] In fact, using Eq. (1) one can show that the return flux is weakest at the axial midpoint of the ridge waveguide, where the horizontal component of the field is twice that generated by each magnetic pole face.

In order to test the performance of the proposed film magnet waveguide isolator we first fabricated ridge waveguides in the Bi-YIG sample and then characterized the device performance via its isolation ratio and insertion losses. To fabricate the waveguide isolator, the linear birefringence was reduced to zero at a wavelength near 1.5 μm by etch-tuning the thickness of the garnet film.[1,8] Ridge waveguide patterns were then etched into the surface, parallel to one of the easy-magnetization directions, and a thin silica overlayer was sputtered over it to further tune the zero-birefringence wavelength and to provide a buffer between the magnet and the waveguide, thereby reducing absorption losses.

The Faraday rotation in the Bi-YIG waveguide was measured to be 127°/cm at a wavelength of 1.5 μm. Thus, in order to provide 45° of rotation, the sample was cut to a length of 3.55 mm and its edges optically polished.

Performance measurements on this isolator using the 1.5-μm-thick Fe–Co magnet have been reported by some of us elsewhere.[5] These tests showed that the magnet saturates nearly 75–90% of the length of the waveguides. Isolation ratios of 21 dB were obtained.

For the tests with the Sm–Co magnet reported here, linearly polarized light from a tunable laser source was coupled into one end of a ridge waveguide through a polarization maintaining single-mode fiber. In order to reduce the effect of the residual linear birefringence over a broad range of wavelengths, the input polarization direction was tilted by 22.5° to TE, following Dammann *et al.*[9] The light emerging from the other end was collected by a microscope objective, passed through a metallic thin-film near-infrared polarization analyzer, and focused onto a germanium photodetector coupled to a multimeter.

Insertion losses in the isolator were measured by comparing the output of the polarization-maintaining fiber to that of the ridge waveguide. A total 6 dB of insertion loss was found, of which approximately 1.5 dB is due to reflections at the input and output facets, 1 dB is due to absorption losses in the waveguide itself, and the remainder, or 3.5 dB, is from coupling losses into and out of the waveguides. In order to reduce reflection losses, the facets of the device can be antireflection coated. Moreover, we expect that coupling losses can be significantly reduced with a more efficient coupling mechanism.

In order to measure the performance of the device, we cut the samarium–cobalt film together with its aluminum oxide substrate into a rectangular shape, 3.8 mm along the direction of magnetization, and 1 cm in the in-plane perpendicular direction. The structure was then placed film down on the Bi-YIG sample, its magnetization parallel to the waveguiding ridges, as shown in Fig. 1. This magnetic film was found to saturate the full length of the ridge waveguides, for 45° of rotation in the input polarization.[7]

To measure an effective isolation ratio for our device the analyzer was set at the extinction angle. After measuring the power transmitted through the analyzer, the samarium–cobalt film was rotated 180° so that its magnetization was oriented antiparallel to the original direction of magnetization, and the transmitted power was measured again. Following Wolfe *et al.*,[1] the ratio of detected intensities for the two magnetization directions was taken as the isolation ratio for the ridge waveguide isolator. Our measurements show isolation ratios close to 25 dB in the wavelength range of our tunable laser source, from 1490 to 1555 nm. These results are plotted in Fig. 3. Forward excess losses due to birefringence are less than 0.5 dB.

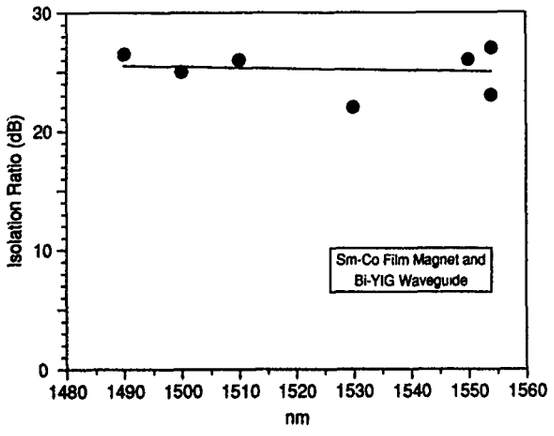

FIG. 3. Isolation ratio in Bi-YIG waveguide isolator with Sm–Co film magnet.

Investigation of Pr-Fe-B magnets with high performance (abstract)

F. Z. Lian, F. Pourarian, S. Simizu, S. G. Sankar, and W. E. Wallance
Advanced Materials Corporation, Department of Material Science and Engineering, Carnegie Mellon University, Pittsburgh, Pennsylvania 15213

Pr-Fe-B magnets with high performance based on 2:14:1 structure were investigated. The effect of fabricating processes on the oxygen content and on the magnetic properties was studied. The coercivity ${}_iH_c$ decreases, but the Br and $(BH)_{max}$ of the magnets increase with the decrease of the Pr content. The decrease in the α-Fe content of the alloys annealed at 1000 °C for more than 360 h results in the enhancement of the magnetic properties of the magnets. Under the optimum conditions, the magnetic properties for $Pr_{14}Fe_{79.5}B_{6.5}$ magnets are found to be ${}_iH_c$=656 kA/m, Br=1.42 T, $(BH)_{max}$=374 kJ/m^3. The microstructures of the magnets were investigated. The effect of the secondary phases in the grain boundary on the coercivity of the magnets was studied.

In situ and dynamic observation of NdFeCoB magnet by high voltage transmission electron microscope (abstract)

In situ and dynamic observation of microstructural characteristics of sintered Nd-Fe-Co-B magnet has been carried out using JEM-1000X high voltage transmission electron microscope (HVTEM). Magnetic properties of the sample studied are as follows: Br=1.28 T, Hc=589 kA/m, $(BH)_{max}$=302.4 kJ/m^3. HVTEM observation results are as follows: (1) At room temperature, the grains of the matrix phase are found to be nearly perfect crystals. In some grains, there exist some spherical inclusions that are embedded in the matrix. Structural analysis of these inclusions has been made by electron diffraction. (2) When the temperature is lower than 400 °C, we found no obvious changes. (3) When the temperature is higher than 400 °C, some small precipitates began to occur in the matrix. (4) When the temperature reaches 500 °C, the precipitates grow and become needlelike and perpendicular to each other. (5) When the temperature reaches 700 °C, the tetragonal symmetry of the matrix phase is completely damaged. (6) No remarkable changes were found for the Nd-rich grain boundary phase when the temperature increases from 25 to 600 °C. (7) Temperature dependence of coercivities of the sample has been explained by the structure changes.

Influence of electron damping and reservoir on the magnetic phase diagram of chromium alloys

S. H. Liu
Solid State Division, Oak Ridge National Laboratory, P. O. Box 2008, Oak Ridge, Tennessee 37831-6032

The magnetic phase diagram of chromium alloys sensitively depends on both electron damping and the presence of an electron reservoir. If the damping energy Γ vanishes and the power ρ of the reservoir is infinite, then lightly doped CrMn alloys would experience a first-order transition from an incommensurate (I) to a commensurate (C) spin-density wave (SDW) state with decreasing temperature. Either damping or a finite reservoir may flip the phase boundary from one side of the triple point to the other, allowing a commensurate-to-incommensurate transition with decreasing temperature as observed experimentally. Both damping and a finite reservoir suppress the first-order jumps in the SDW order parameter and wave vector. When $\rho \leq 2$, the C-I transition is second order for all temperatures. When $\rho > 2$, the transition is second order near the tricritical point but first order at lower temperatures. Unlike electron damping, an electron reservoir does not shift the paramagnetic phase boundary and triple point.

The nesting[1,2] of the octahedral electron and hole Fermi surfaces in chromium alloys is responsible for most of its unique properties. The Coulomb attraction[3] between electrons and holes produces a spin-density wave (SDW) with wave vector close to the nesting wave vector. For pure chromium, the hole surface is slightly larger than the electron surface. Consequently, both the nesting wave vector Q and the SDW wave vector Q' are incommensurate with the lattice. The nesting of the Fermi surfaces and the Néel temperature are enhanced by doping with manganese, which adds electrons, and worsened by doping with vanadium,[2] which contributes holes to the conduction band.

Early experiments[2,4] on lightly doped CrMn alloys revealed a first-order transition from commensurate (C) to incommensurate (I) phases of the SDW with decreasing temperature. By contrast, the theoretical phase diagram[5] without damping and with a fixed chemical potential contains a first-order incommensurate-to-commensurate (I-C) transition with decreasing temperature. This phase diagram is drawn in the solid curves of Fig. 1 for the case $\rho=\infty$. Here $T_N^* \approx 77$ meV is the fictitious Néel temperature of perfectly nested chromium without impurities. The energy z_0 is proportional to the mismatch between the electron and hole surfaces in $\mathbf{k}$ space. As indicated, this mismatch decreases with manganese doping and increases with vanadium doping.

Two explanations have been proposed for the observed C-I transition. Because scattering from impurities breaks electron–hole pairs,[6] electron damping suppresses both the SDW order parameter and the Néel temperature. In previous work,[5] we found that electron damping also favors the incommensurate over commensurate phases of the SDW. Since the ratio of the damping energy Γ to thermal energy increases with decreasing temperature, damping may flip the phase boundary from one side of the triple point to the other,

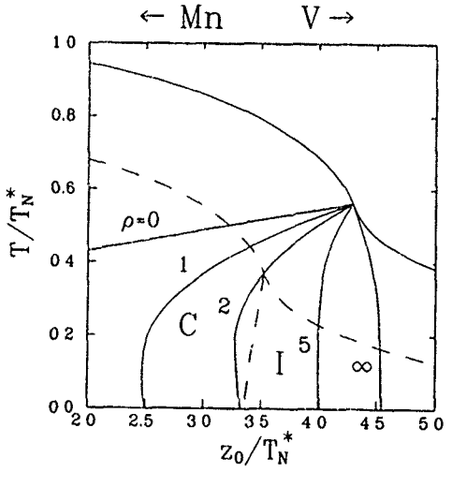

FIG. 1. T/T_N^*-vs-z_0/T_N^* phase diagram of chromium alloys. The solid curves are plotted for $\Gamma=0$ and with the indicated reservoir power. The dashed curve is plotted for $\Gamma/T_N^*=0.3$ and $\rho=\infty$. While the commensurate phase lies to the left of the boundaries, the incommensurate phase lies to the right, as shown for the dashed phase diagram with damping.

resulting in the observed first-order C-I transition. The phase diagram with $\Gamma/T_N^*=0.3$ is given by the dashed curves of Fig. 1. As well as lowering the paramagnetic phase boundary, damping also suppresses the triple point of z_0.[5] As Γ increases for a fixed z_0, the size of the drop in the SDW order parameter g at the C-I phase boundary decreases. When Γ exceeds some critical value $\Gamma_c(z_0)$, the Néel temperature vanishes and the alloy becomes paramagnetic. About 4% vanadium is required to drive CrV alloys paramagnetic.[2]

The C-I transition can also be explained by imposing particle conservation. Much theoretical work on chromium alloys,[3,6] including our previous studies,[5,7] assumed that the chemical potential was unaffected by the formation of the SDW and the concurrent gap $\Delta \propto g$ in the electron–hole energy spectrum. This requires an infinite reservoir of electrons, which replenishes the electron–hole band and keeps the chemical potential constant. An electron reservoir is supplied[1,8] by the electron balls midway between reciprocal-lattice points Γ and H and by the hole pockets at N. The reservoir power ρ is just the ratio of the density of states of the reservoir band to that of the electron–hole band.

When the power ρ of the electron reservoir is finite, the chemical potential will decrease and the effective mismatch $\tilde{z}_0$ between electron and hole surfaces will increase with decreasing temperature. As seen from Fig. 1, this increase of the energy mismatch favors the incommensurate regime. When ρ is sufficiently small, the phase boundary will flip from one side of the triple point to the other and produce a C-I transition. Unlike damping, however, the reservoir does not affect the paramagnetic phase boundary or the position of the triple point.

Unfortunately, previous studies of the reservoir's effects were inconclusive. The early work of Rice[9] approximated the octahedral hole and electron Fermi surfaces by spheres of unequal radii. While qualitatively correct, this approximation fails in the incommensurate phase, when the detailed structure of the Fermi surfaces becomes important. More recently, Angelescu, Nenciu, and Tonchev[10] constructed a Ginzburg–Landau free energy which produces unphysical gaps in the T-vs-z_0 phase diagram. Machida and Fujita,[11] on the other hand, were primarily concerned with the effects of higher harmonics in the SDW and erroneously concluded that the phase transitions were always second order.

To clarify the effects of an electron reservoir, we have calculated the free energy of chromium alloys in the presence of a finite reservoir but without damping. The SDW wave vector must now be written

$$Q'=\frac{2\pi}{a}[1+\delta(\Lambda-1)]+\frac{2\pi}{a}\,\kappa\,\frac{\tilde{z}_0-z_0}{T_N^*}(\Lambda-1), \qquad (1)$$

where $\kappa=aT_N^*/4\pi v_F\approx 0.013$, $v_F\approx 5.1\times10^7$ cm/s is the Fermi velocity, and $a\approx 5.45$ Å is the lattice constant of the bcc lattice. The nesting wave vector Q of the electron and hole surfaces is given by Eq. (1) with $\Lambda=0$. The deviation of Q from the reciprocal-lattice vector $2\pi/a$ is determined by the difference $\tilde{z}_0(T)-z_0$ and by the wave-vector mismatch $\delta\approx 0.04$. For a finite reservoir, $\tilde{z}_0(T)>z_0$ and the nesting wave vector Q decreases as the temperature is lowered.

The difference between the nesting wave vector Q and the SDW wave vector Q' is determined by $0\leq\Lambda(T)\leq 1$ and reflects the compromise[7] between the nesting of each side of the hole octahedron with the smaller electron octahedron. When $\Lambda=1$, the SDW wave vector is commensurate with the lattice; when $\Lambda=0$, the nesting and SDW wave vectors are identical. For an infinite reservoir, Λ jumps to 1 as $z_0\propto\delta v_F/a$ decreases through the phase boundary.[5] As z_0 decreases in the commensurate regime, the nesting continues to improve and T_N continues to grow until it reaches a maximum of T_N^* when $z_0=0$. For a finite reservoir, the suppression of the chemical potential with decreasing temperature tends to lower Q'. By maintaining the constancy of the chemical potential and $\tilde{z}_0$, the reservoir opposes the growth of the second term in Q' with decreasing temperature.

In the presence of a finite reservoir, the free energy is given by[11]

$$F(z_0,T)=\min_{g,\Lambda}\{\sup_{\tilde{z}_0}[F^{(0)}(\tilde{z}_0,g,\Lambda,T) -\tfrac{1}{32}\rho_{eh}(1+\rho)(\tilde{z}_0-z_0)^2]\}, \qquad (2)$$

where ρ_{eh} is the density of states of the electron–hole surfaces and $F^{(0)}(\tilde{z}_0,g,\Lambda,T)$ is the free energy of chromium for an infinite reservoir with $\tilde{z}_0$ replacing z_0. As defined by Eq. (2), the solution for g and Λ will minimize the free energy $F(z_0)$ subject to the constraint that it be an extremum with respect to $\tilde{z}_0$. Since the reservoir power ρ does not enter $F^{(0)}(\tilde{z}_0)$, the self-consistent solutions which minimize $F(z_0)$ need only be extrema of $F^{(0)}(\tilde{z}_0)$. In fact, this set of self-consistent solutions $\{g,\Lambda\}$ may *maximize* the infinite-reservoir free energy $F^{(0)}(\tilde{z}_0)$. By contrast, Angelescu, Nenciu, and Tonchev[10] define the free energy so that the minimization with respect to g and Λ precedes the extremization with respect to $\tilde{z}_0$. As a result, the extremum condition will have *no solution* for ranges of the energy mismatch z_0. To avoid this unphysical situation, the order of operations in Eq. (2) must be maintained.

The infinite-reservoir free energy $F^{(0)}(\tilde{z}_0)$ is taken from Ref. 5 in the absence of damping:

$$F^{(0)}(\tilde{z}_0,g,\Lambda,T)=\rho_{eh}g^2\ln\left(\frac{T}{T_N^*}\right)-\rho_{eh}\sum_{n=0}^{\infty}\left(T\int_{-\infty}^{\infty}dz\,\ln\left|1-g^2\frac{2i\nu_n-\tilde{z}_0+2z}{(i\nu_n-z)\{(i\nu_n-\tilde{z}_0+z)^2-[\tilde{z}_0(\Lambda-1)/2]^2\}^2}\right|-g^2\frac{1}{n+\frac{1}{2}}\right), \qquad (3)$$

where $\nu_n=(2n+1)\pi T$ are the Matsubara frequencies. The self-consistent solutions for $\{g,\Lambda\}$ are obtained from the extremum conditions

$$\frac{\partial F^{(0)}(\tilde{z}_0,g,\Lambda,T)}{\partial g}=0, \tag{4a}$$

$$\frac{\partial F^{(0)}(\tilde{z}_0,g,\Lambda,T)}{\partial \Lambda}=0, \tag{4b}$$

just as in Ref. 5 except that now both minima and maxima sets of solutions are retained and tabulated as functions of $\tilde{z}_0$. The extremum condition with respect to $\tilde{z}_0$ is given by

$$z_0=\tilde{z}_0-\frac{16}{\rho_{eh}(1+\rho)}\frac{\partial F^{(0)}(\tilde{z}_0)}{\partial \tilde{z}_0}. \tag{5}$$

Notice that $\tilde{z}_0$ is independent of ρ_{eh} and depends only on the reservoir power ρ. Since the free energy $F^{(0)}(\tilde{z}_0)$ increases as $\tilde{z}_0$ grows and the nesting worsens, we find that $\tilde{z}_0>z_0$ as anticipated earlier.

We plot the resulting phase diagram in the solid lines of Fig. 1. In the absence of a reservoir, $\rho=0$ and the incommensurate SDW is stable at $T=0$ for all z_0. Generally, a small reservoir will suppress the jumps in the order parameter and chemical potential. When $\rho\leq 2$, the set of maxima incommensurate solutions $\{g,\Lambda\}$ smoothly joins the set of minima commensurate solutions to produce a *second-order* transition at all temperatures. In this regime, the $T=0$ phase boundary is given exactly by

$$\frac{z_0^{C\text{-}I}}{T_N^*}=2\sqrt{2}\,\frac{\pi}{\gamma}\,\frac{\rho}{1+\rho}\approx 4.99\,\frac{\rho}{1+\rho}, \quad \rho\leq 2 \tag{6}$$

where $\gamma\approx 1.78107$ is Euler's constant. Using spherical Fermi surfaces at zero temperature, Rice[9] found that the *C-I* phase transition becomes second order when $\rho<0.31$, a much smaller value than obtained here with octahedral Fermi surfaces.

If $\rho>2$, the phase transition is first order at low temperatures but becomes second order at higher temperatures, where the first-order jumps in the order parameter are smaller and more easily destroyed. For example, when $T=0.4T_N^*$, the phase transition is second order for $\rho<7.01$. With second-order transitions at all temperatures, the phase diagram of Machida and Fujita[11] exaggerates the incommensurate regime. But like Rice[9] and the present authors, Machida and Fujita agree that the incommensurate regime is stable for all z_0 at $T=0$ when $\rho=0$.

For any value of ρ smaller than about 10, the phase boundary flips from the right to the left of the triple point, producing a *C-I* transition. Since the reservoir power is certainly less than 10, we conclude that damping is not needed to explain the *C-I* transition. However, damping is required to understand the decrease of the SDW wave vector and order parameter when chromium is doped with isoelectronic impurities like molybdenum or tungsten. [2]

The slight bulge of the *C-I* phase boundaries to the left would seem to permit a *C-I-C* transition with decreasing temperature. This bulge is most noticeable for intermediate values of ρ near 2 but is present for all nonzero values of ρ which allow a *C-I* transition. We believe that even a small amount of damping will wipe out the bulge and eliminate the possibility of a *C-I-C* transition.

This work suggests that whenever ρ is finite, the *C-I* phase transition will become second order sufficiently close to the triple point. Experiments[2] on the *C-I* transition have been performed far enough away from the triple point that the observed transition is first order. While it would be interesting to test this prediction closer to the triple point, first-order jumps in the order parameter and wave vector may be difficult to distinguish from second-order transitions in this regime.

Comparing our phase diagram with the experimentally observed *C-I* phase transition within a narrow window of manganese concentrations, we would conclude that ρ lies between 4 and 8. By contrast, the band-structure calculations of Asano and Yamashita[8] indicate a much smaller value of $\rho\approx 1$. However, the nested electron–hole band may itself oppose changes of the chemical potential and provide an additional, effective reservoir of electrons. Alternatively,[12] the presence of a charge-density wave which strongly favors the commensurate regime may balance the small size of the electron reservoir.

To conclude, we have investigated the effects of damping and an electron reservoir on the phase diagram of chromium alloys. While either sufficiently strong damping or a sufficiently small reservoir can explain the *C-I* transition, we believe that a combination of the two is required to explain the detailed phase boundary. Experiments close to the tricritical point may reveal second-order *C-I* transitions and confirm the importance of a finite electron reservoir.

Spin fluctuation effect in the ordered Fe_2N alloy

Guan-mian Chen, Ming-xi Lin, and Ji-wu Ling
State Laboratory for Magnetism, Institute of Physics, Chinese Academy of Sciences, Beijing 100080, China

The temperature and field dependence of the magnetization of a Fe_2N alloy has been measured and compared with the calculation of the Moriya–Kawabata theory and Stoner–Edwards–Wohlfarth model. It is shown that Fe_2N is a very weak itinerant ferromagnet, and the Moriya–Kawabata theory and the electron gas approximation give a good description. Spin fluctuations and their interaction play a significant role in determining the thermomagnetic properties of the Fe_2N alloy.

I. INTRODUCTION

Fe_2N is an ordered interstitial alloy with orthorhombic structure[1] and the highest N content (about 11.1 wt %) in the Fe–N solid solution. Much research has been carried out on Fe_2N, but there was still controversy regarding magnetic properties[2,3] until we identified it as a weak itinerant ferromagnet (WIF).[4] In our previous paper, the magnetic properties of Fe_2N were analyzed based on the Stoner–Edwards–Wohlfarth (SEW) model, which gives results in agreement with the magnetization and susceptibility measured below T_c, but deviates at $T>T_c$. This is not surprising since the SEW model is essentially a mean-field theory and only single electron excitation is taken into account.

This paper reports detailed results of the temperature and field dependence of the magnetization of Fe_2N and makes a comparison with numerical calculations based on the self-consistent renormalization (SCR) theory by Moriya and Kawabata,[5] which considers the collective excitation of the electron–hole pairs (spin fluctuations) and their interaction, and is expected to give better agreement at higher temperature.

II. FIELD DEPENDENCE OF THE MAGNETIZATION AT $T=0$

The α-FeOOH powder of average size 6 μm was reduced in pure flowing H_2 gas at 425 °C for 10 h, followed by nitriding in flowing NH_3 gas at 450 °C for 12 h. The sample was detected by x-ray diffraction as consisting of single phase and in good agreement with Jack's result[1] for Fe_2N in both line positions and intensities. Magnetization was measured from 1.5 to 30 K by the sample-drafting induction method in a superconducting solenoid with magnetic fields up to 80 kOe.

According to the SCR theory, in the electron gas approximation, the reduced magnetization ζ of the WIF can be expressed as[5,6]

$$\frac{1}{\alpha}\ (1+\tfrac{2}{27}\zeta^2)=1+\frac{3}{2\alpha\zeta kT_F}\left(\mu_B H-\frac{\partial\Delta F}{\partial M}\right), \qquad (1)$$

where the magnetization (per gram), $M=M(H,T)$, is a function of the field and temperature, the reduced moment $\zeta=\zeta(H,T)=M(H,T)/N$, with N the total electron number per gram, T_F is the Fermi temperature, $1/(\alpha-1)$ is the Stoner enhancement factor, and ΔF is the correction of the Hartree–Fock term in the free energy due to the spin fluctuation.

At $T=0$, the contribution of the spin fluctuation $\partial\Delta F/\partial M=0$, Eq. (1) becomes

$$\zeta^2(H,0)=\frac{27}{2}\ (\alpha-1)+\frac{81}{4}\frac{\mu_B}{kT_F}\ H/\zeta(H,0). \qquad (2)$$

This is to be compared with the SEW model[7]:

$$\zeta^2(H,0)=\zeta^2(0,0)+\frac{2\chi_0}{N}\ \zeta^2(0,0)H/\zeta(H,0). \qquad (3)$$

Here $\chi_0=(\partial M/\partial H)_{H=0,T=0}=NN(E_F)\mu_B^2/(\alpha-1)$ is the susceptibility at zero field and temperature, and $N(E_F)$ is the density of states at the Fermi energy.

From Eqs. (2) and (3), using the experimental magnetization $\zeta(0,0)=0.06\mu_B$ and $\zeta(H=5\ \text{kOe},0)=0.092\mu_B$, we can calculate the entire field dependence of the magnetization. The result obtained is in excellent agreement with the experimental $M(H,0)$ curve, as shown in Fig. 1, indicating Fe_2N is an unsaturated weak itinerant ferromagnet.

According to both the SCR theory [Eq. (2)] and the SEW model [Eq. (3)], the Arrott plot, i.e., the M^2-vs-H/M curve, is a straight line for $T=0$ as shown in Fig. 2. From Eq. (2), $\alpha=\frac{2}{27}\zeta^2(0,0)+1=1.000\,267$ and $T_F=1.52\times10^4$ K are determined for the SCR theory. From Eq. (3), $\chi_0=1.1\times10^{-3}$ emu/g Oe is determined for the SEW model. In the electron gas approximation, including the Stoner enhancement, $\chi_0=3N\mu_B^2/4kT_F(\alpha-1)$. From this expression and the experimental χ_0 value, T_F is also estimated as 1.53×10^4 K.

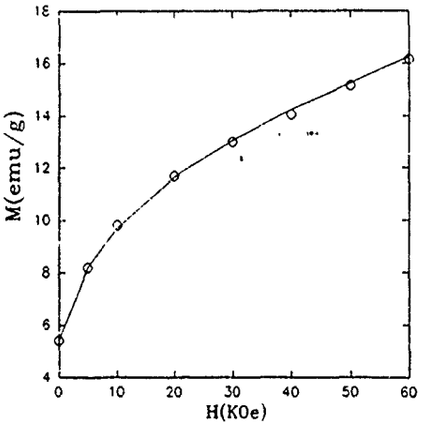

FIG. 1. Magnetization of Fe_2N as a function of field at $T=0$. Dots are the experiments and the solid line is according to the SCR theory and SEW model.

 0021-8979/94/75(10)/6293/3/$6.00 © 1994 American Institute of Physics

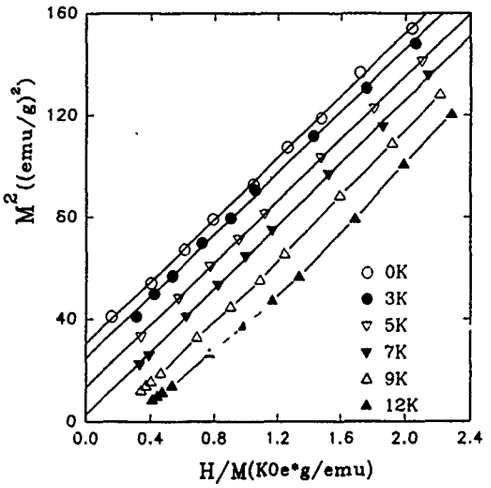

FIG. 2. Arrott plot of Fe_2N from $H=1.5$ to 20 kOe.

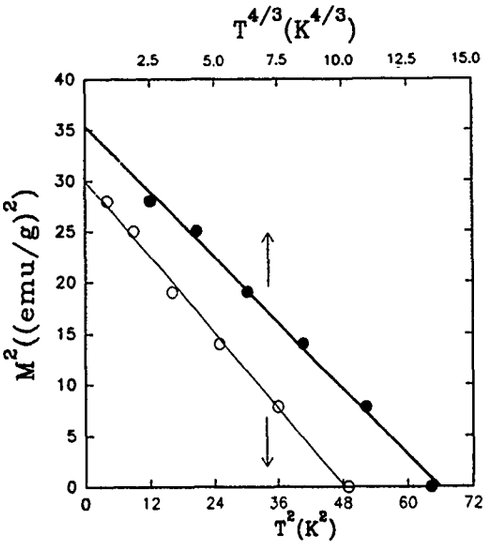

FIG. 3. Square of the magnetization of Fe_2N at $H=0$ plo. against $T^{4/3}$ and T^2 curves.

Thus, in the electron gas approximation, both the SCR theory and SEW model give the same description to the zero-temperature magnetization $M(H,0)$.

Table I presents those basic parameters for Fe_2N and some typical weak itinerant magnets for comparison.

III. TEMPERATURE DEPENDENCE OF THE SPONTANEOUS MAGNETIZATION AT $T<T_c$

According to the SCR theory, near T_c, the spontaneous magnetization $M(0,T)$ can be expressed as $M^2\sim(T_c^{4/3}-T^{4/3})$, but according to the SEW model,[8] at $T<T_c$, $M^2\sim(T_c^2-T^2)$.

The two relations are good criteria for verifying which model is more appropriate to describe the weak itinerant magnet. The experimental $M(0,T)$ value is obtained by extrapolating the Arrott plot (Fig. 2) to $H=0$ for $T<T_c$. However, since these parallel lines are very sharp and crowded in Fig. 2, error was introduced in the extrapolation.

$M^2(0,T)$ is plotted against $T^{4/3}$ and T^2 in Fig. 3, and they are all essentially straight lines. From Fig. 3 it is hard to tell which model is better. There are two possible reasons: First, both models are essentially able to describe the magnetic properties of Fe_2N at $T<T_c$.[4] Second, the precision of our magnetic measurement is not good enough to determine the correct expression of $M(0,T)$, especially due to the error in the extrapolation as mentioned above.

IV. MAGNETIZATION AT NONZERO FIELD AND FINITE TEMPERATURE

The Arrott plot of Fe_2N (Fig. 2) at $T<T_c$ is a series of parallel lines over a wide range of field strength. Since they are very crowded in the temperature scale, only a few points of temperature are plotted in Fig. 2 for clarity. Their slope is essentially independent of the temperature, indicating that the field dependence of the magnetization at $T<T_c$ can be described by the SEW model[7] as given by

$$M^2(H,T)=M^2(0,0)[1-(T/T_c)^2+2\chi_0 H/M(H,T)].$$

However, the Arrott plot at $T>T_c$ becomes concave and deviates from a straight line and the SEW model.

The numerical calculation of Eq. (1) was carried out according to the SCR theory [see Eqs. (6), (9), and (10) of Ref. 6] based on the electron gas approximation and $\zeta\ll 1$,

TABLE I. Basic parameters of Fe_2N and other typical itinerant ferromagnets: p_s is the zero-temperature moment [per transition-metal (TM) atom], b is the slope of the M^2-vs-H/M curve at $T=0$, C is the Curie constant above T_C, and p_c is the effective moment deduced from the Curie constant.

	Fe_2N	$ZrZn_2$	Ni_3Al	Sc_3In	$Ni_{0.429}Pt$
p_s (μ_B/TM atom)	0.06	0.112	0.077	0.045	0.051
T_C (K)	7	16.9	40.6	5.5	23
b (10^{-2} emu^3/g^{3}Oe)	6.4	0.16	0.517	0.2	0.124
C (10^{-2} emu K/g)	0.74	0.094	0.231	0.267

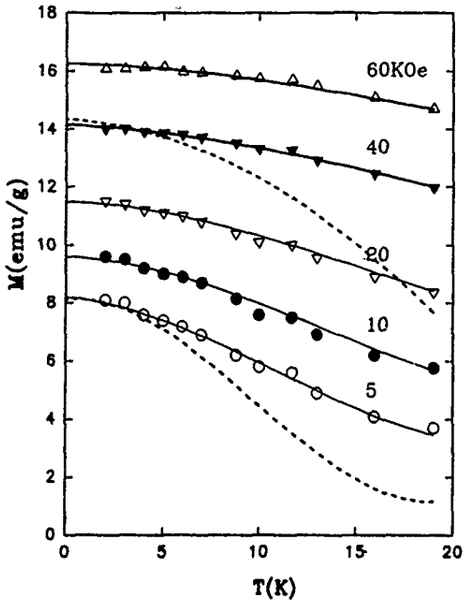

FIG. 4. Magnetization $M(H,T)$ as a function of the temperature at various fields. Solid lines are fitted to the SCR theory and the dashed lines are fitted to the SEW model.

using the α value determined above. The cutoff wave vector q_c is chosen as $\sqrt{2}$. The best fit with the experimental data is obtained when $T_F=1.52\times10^4$ K.

According to both models,[5] the Curie temperature can be determined by the following equations:

$$T_c=\left(\frac{\alpha-1}{9.902\alpha}\right)^{3/4}T_F=5.7\ \text{K}\quad\text{for the SCR theory,}$$

and

$$T_c=\left(\frac{12(\alpha-1)}{\pi^2}\right)^{1/2}T_F=245\ K\quad\text{for SEW model.}$$

It is easy to see that the SCR theory estimation is very close to the experimental value, 7 K, determined from Fig. 3, while the SEW model gives an estimation about 40 times larger.

The calculated $M(H,T)$-vs-T curves (solid line) and the experimental data are shown in Fig. 4. They are in very good agreement over a wide field range. This is the second example which shows good fit with the SCR theory among all weak itinerant magnets known update besides the first one (Sc_3In) reported earlier.[6] For comparison, the $M(H,T)$ curve from the SEW model is also drawn in Fig. 4 (dashed lines): it deviates obviously from experiments when $T\geq T_c$.

Takeuchi and Masuda[6] calculated the $M(H,T)$ curve of Sc_3In by the SCR theory, which coincides excellently with experiments. However, their T_F value from the $M(0,T)$ curve is ten times smaller than the value obtained from the $M(H,T)$ curve at $H=5$ and 10 kOe, i.e., 2.07×10^4 K and 2.2×10^5 K, respectively. They considered that this discrepancy probably resulted mainly from the oversimplified assumption of the electron gas model. For Fe_2N, the largest difference of T_F obtained from $M(0,T)$ and $M(H,T)$ measurement is within 20%. This indicates that the field and temperature dependence of its magnetization can be well described by the SCR theory and electron gas approximation.

In summary, it is shown that Fe_2N is a uniform, very weak itinerant ferromagnet, close to the Stoner criterion. Its T_c and zero-temperature magnetic moment p_s are among the smallest compared to other WIF (Table I). However, strongest effect of spin fluctuation is observed for Fe_2N as shown by the large effective moment p_c determined from the Curie constant above T_c. Fe_2N has the largest ratio p_c/p_s among all WIF known to date. As shown in this paper the SCR theory and electron gas approximation interpret the thermomagnetic properties of Fe_2N over a rather wide field and temperature range both below and above T_c. The SEW theory holds when $T<T_c$, but deviates at $T\geq T_c$, indicating that the spin fluctuation and its interaction play significant role.

Isoelectronic early *n-d* impurities in Fe: Magnetic and hyperfine field properties

N. A. de Oliveira, A. A. Gomes, and A. Troper
Centro Brasileiro de Pesquisas Fisicas (CBPF), Rua Dr. Xavier Sigaud 150, 22290-180, Rio de Janeiro, RJ, Brazil

The hyperfine fields and the local magnetic moments in a series of alloys of isoelectronic transition impurities diluted in iron are discussed. We intend to show that, even within a very simplified model, period effects for isoelectronic impurities at the beginning of an *n-d* series (e.g., Sc, Y, and Lu) are dominated by the charge difference effect, inducing a very strong repulsive potential. We find that the local impurity magnetic moments are very close to each other, leading to hyperfine fields, in fair agreement with experimental data. Our calculation accounts for the general trends of the local impurity moments in ferromagnetic Fe, despite quantitative deviations that do occur, due to the very simple structure of this model. We point out, however, that our calculation is a starting point for a more refined one, dealing with rare-earth impurities (such as Eu, Gd, and Tb) placed in the Fe host, where the strong charge effects are present, together with *f*-spin scattering.

We focus our interest in Sc, Y, and Lu elements, which are isoelectronic *d* impurities at the beginning of a transition series, diluted in a Fe host to study comparatively the relative importance of period effects and the charge difference between the host and impurity. This study is a first step to discuss theoretically the whole series of rare-earth elements diluted in Fe, like Gd*Fe* and Eu*Fe* where some controversial experimental data were obtained.[1,2] In the Eu*Fe* case, additional interest is connected to the Eu valence and its effect on the hyperfine field. Within a classical Koster–Slater formulation, the impurity problem in magnetic hosts has been discussed many years ago[3] for 3*d* impurities in Fe. The change in sign of the impurity *d* magnetic moment with respect to the host moment could then be explained.[3–5]

Since intense experimental effort has been made to measure the magnetic and hyperfine field properties in such diluted alloys,[2] we decided to describe the observed properties within the simplest possible theoretical framework. The motivation is to check to which level our calculation gives a qualitative description of the experimental data. In particular, the case of Eu impurities diluted in Fe may be understood only by including the possibility of valence changes and thereby an orbitally induced hyperfine field.

The main difference between this work and Ref. 3 is that here we phenomenologically introduce the polarization of the *s-p* host conduction band, taking it as being antiparallel to the *d* host magnetization m_d^h. So, we put[6]

$$m_c^h = -\alpha m_d^h, \tag{1}$$

where α is a parameter obtained from a fitting of the *s-p* conduction-electron polarization in transition metals; this corresponds to $\alpha=0.08$.

At the impurity site, the total magnetization $\tilde{m}(0)$ is given by the sum of the impurity *d* moment $\tilde{m}_d(0)$ and the *s-p* magnetization written above. Then

$$\tilde{m}(0)=\tilde{m}_d(0)+m_c^h=\tilde{m}_d(0)-\alpha m_d^h. \tag{2}$$

Strictly speaking, the inclusion of the *s-p* contribution introduces a small shift in the local moment, relevant mainly around the change in sign of the impurity moment. However, the importance of the *s-p* contribution concerns the hyperfine field.

The Hamiltonian of Ref. 3 is generalized here in order to include the change in Coulomb interaction due to period effects[7]:

$$H=\sum_{ij\sigma} T_{ij}^{(d)} d_{i\sigma}^{\dagger} d_{j\sigma} + \frac{U}{2} \sum_{i\sigma} n_{i\sigma}^{d} n_{i-\sigma}^{d} + \Delta U n_{0\sigma}^{d} n_{0-\sigma}^{d} + \sum_{ij\sigma} T_{ij}^{(c)} c_{i\sigma}^{\dagger} c_{j\sigma}, \tag{3}$$

where $T_{ij}^{(\alpha)}$ ($\alpha=d$, $c=s$-p) are the hopping terms, and U is the host *d*-band Coulomb repulsion taken as 1.1 in units of the band width. $\Delta U = U_{nd}^{\text{imp}} - U_{3d}^{\text{host}}$, $n=4$ and 5, is the change in Coulomb correlation at the impurity site (located at the origin) due to period effects. The numerical values were taken $-0{,}8$ and -1.0, respectively, for 4*d* or 5*d* impurities.

The $c_{i\sigma}^{\dagger}$ and $c_{i\sigma}$ create and destroy, respectively, electrons in the wide *s-p* band whereas $d_{i\sigma}^{\dagger}$ and $d_{i\sigma}$ are creation and annihilation operators for electrons in the correlated and narrow *d* band. A Hartree–Fock description is assumed *ab initio* and $n_{0-\sigma} = d_{0-\sigma}^{\dagger} d_{0-\sigma}$ is the *d* occupation number at the origin of electrons with spin $-\sigma$. The solution of the Hamiltonian given by Eq. (3) is made as in Refs. 3 and 7, i.e., via the solution of the Koster–Slater problem. The next step is to obtain the Friedel sum rule for both spin-dependent

TABLE I. Calculated hyperfine fields (in kG) for isoelectronic impurities Sc, Y, and Lu in Fe. The experimental data are collected from Refs. 2, 4, and 5.

Lu*Fe*	−0.20	−0.16	−0.17	−0.33

local potentials V_σ and the difference between these Hartree–Fock V_σ potentials and the occupation numbers.

The hyperfine fields are estimated using the Fermi–Segrè coupling constants and the core polarization terms given in Ref. 8. We emphasize the very simplified content of these descriptions, in spite that our results are quite satisfying as shown in Tables I and II.

In particular, from Table II we note that the local magnetic moments of Sc, Y, and Lu are very close, thus supporting the idea that the important effect is the charge difference between the host and impurity. Then period effects are almost wiped out in these early isoelectronic transition elements by the charge difference effect.

However, if one refines the present calculation, in this same tight-binding scheme, to include the difference in hopping between the impurity and next-neighbor atoms, numerical values of the magnetic moment can be improved for Y and Lu. This correction accounts for the difference in the radial extent of the wave functions at the beginning and end of the *n-d* series.

Concerning experimental data, it should be noted that local magnetic moments are obtained from neutron diffraction experiments with an accuracy less than those obtained for the hyperfine fields. In view of that, our present model accounts satisfactorily for the observed hyperfine data, as shown in Table I.

Finally, calculations for magnetic and hyperfine properties for Gd*Fe* and Eu*Fe* alloys, using Lu*Fe* results as a starting point, are now in progress.[9]

Electronic structure and the Stoner I parameter for RPd_3 compounds (R=La, Ce, Pr, and Nd)

T. Nautiyal, A. Kashyap, and S. Auluck
Physics Department, University of Rookee, Roorkee 247667, India

M. S. S. Brooks
Joint Research Centre, European Institute for Transuranium Elements, Postfach 2340, DW-7500 Karlsruhe 1, Germany

Gardner *et al.* have made measurements of the magnetic susceptibility in a large range of temperature for a complete series of RPd_3 compounds (R=rare earths). Some band structure calculations exist on $LaPd_3$ and $CePd_3$. However, the question of magnetic ordering has not been addressed in existing theoretical work. With a view to understand the magnetic behavior of these compounds we have performed self-consistent band structure calculations for $LaPd_3$, $CePd_3$, $PrPd_3$, and $NdPd_3$. Our calculations predict magnetic ordering only in $PrPd_3$ and $NdPd_3$ and hence are consistent with the experimental findings.

I. INTRODUCTION

Rare-earth (R) metals and compounds are known to possess very interesting and complicated magnetic properties.[1] The magnetic ordering in RPd_3 compounds has been studied experimentally by Gardner *et al.*[2] and Elsenhans *et al.*[3] With a view to understand this experimental data, we have calculated the electronic structure of some RPd_3 compounds with R=La, Ce, Pr, and Nd. The series of intermetallic rare-earth compounds RPd_3 has the Cu_3Au structure with Pd atoms at the face centers and R atoms at the corner of the cube. We have studied the ground-state properties of these compounds and tried to explore the magnetic ordering in these using the Stoner criterion. Our calculations also give the systematics of various band parameters (e.g., effective masses and bandwidths) as we progress through the first four members of RPd_3 series.

Earlier leading theoretical work on these compounds includes that by Koenig and Khan (KK),[4] and Yanase and Hasegawa (YH).[5] $CePd_3$ has a large residual resistivity ρ_0 and its resistivity $\rho(T)$ shows a maximum at 110 K with a negative $d\rho/dT$ at high temperature. Experiments show that small amounts of La, when Ce is replaced by La, halt the rapid drop in $\rho(T)$ below 110 K. YH (Ref. 5) have tried to explain the large residual resistivity of $CePd_3$ as being due to the small Fermi surface sheets arising from $4f$ electrons. They have performed the calculations using the full potential linear augmented plane wave method. KK (Ref. 4) have performed extensive linear muffin-tin orbital (LMTO) calculations for $LaPd_3$ and $CePd_3$ exploring the effects of spin-orbit (SO) coupling, and treatment of $4f$ states and $5p$ orbitals. They have calculated the optical conductivity for $LaPd_3$ and $CePd_3$. No electronic structure calculations appear to exist for $PrPd_3$ and $NdPd_3$.

II. METHOD OF CALCULATION

We have used the scalar relativistic LMTO method[6,7] in which all relativistic terms except SO interaction have been included. KK (Ref. 4) have observed that the overall effect of including SO interaction is rather secondary as most of the data can be explained without it. We have taken the $5p$ orbitals of R atoms in the frozen core. Calculations are performed at the experimental value of 4.235 Å and 4.126 Å of the lattice constant for $LaPd_3$ [as quoted by KK (Ref. 4)] and $CePd_3$,[8] respectively. For $PrPd_3$ and $NdPd_3$ the calculations were performed at a lattice constant of 4.126 Å, which is close to the experimental values of 4.1300 and 4.1181 Å, respectively.[2] We have used equal Wigner–Seitz (WS) radii (S) at the R and Pd sites. KK (Ref. 4) show that the f states of Pd are not very important. We have therefore used angular momentum expansion up to the f states in R atom and up to the d states in Pd atoms. This results in a 43×43 matrix, which speed up the computation. We have used 84 **k** points for the Brillouin zone summations for which the tetrahedron method[9] has been used. The exchange-correlation potential used is the Barth–Hedin potential.[10]

III. RESULTS AND DISCUSSION

To get insight into the band structure of these compounds, we have calculated some important band parameters (Table I). μ and W are the self-consistently calculated effective mass and bandwidth, respectively, which can be calculated in terms of standard potential parameters.[7] W_{tl} is the unhybridized bandwidth that may be calculated using the canonical band theory.[11] A comparison of W with W_{tl} enables one to analyze quantitatively the effect of hybridization on the bandwidths. For the unhybridized band of atom t and orbital quantum number l, the bandwidth W_{tl} is given by[11]

$$W_{tl}=\left(\frac{12}{n_{tl}}\ |S_{tl}^{tl}|^2\right)^{1/2}\Delta_{tl}$$

and

$$\Delta_{tl}=1/[\mu_{tl}S_t^2(S/S_t)^{2l+1}]$$

with $n_{tl}=(2l+1)n_t$; n_t=number of t type of atoms in the unit cell; S_t=WS radius of t-type atomic sphere; μ_{tl} is the corresponding effective mass, and $|S_{tl}^{tl}|^2$ is the second moment of the canonical tl band and in simplified form is given by[11]

$$|S_{tl}^{tl}|^2=\frac{[4(2l+1)^2](4l)!}{(2l)!(2l)!}\ P_{nt}n_t(S/d_{nt})^{2(2l+1)},$$

TABLE I. μ, effective mass (in atomic units); W_{tl}, the canonical bandwidth (in mRy); W, the calculated bandwidth (in mRy); η $(=W/W_{tl})$; and $\tilde{\eta}$, the ideal ratio for f states of R atom and d states of Pd atom.

	R-f					Pd-d				
Compound	μ	W	W_{tl}	η	$\tilde{\eta}$	μ	W	W_{tl}	η	$\tilde{\eta}$
$LaPd_3$	49.0	4.0	731	184.7	15.98	8.4	231	304	1.32	1.21
$CePd_3$	33.7	6.1	154	25.4	15.98	7.9	258	339	1.32	1.21
$PrPd_3$	34.7	5.9	109	18.4	15.98	7.9	259	340	1.32	1.21
$NdPd_3$	39.1	5.2	92	17.6	15.98	7.9	258	340	1.32	1.21

where P_{nt} is the number of nearest neighbors of a t atom of the same kind and d_{nt} is the distance of this t-type atom from these nearest neighbors. The details of such a calculation for calculating W_{tl} for Cu_3Au structures are given in the work of Podgorny.[12] We used $S_t/S=1$ as WS radii are the same at both the sites. η is the ratio of the calculated bandwidth and canonical bandwidth, whereas $\tilde{\eta}$ is the ideal ratio when there is no difference between the two kinds of atoms. Thus a comparison of η and $\tilde{\eta}$ is a good measure of degree of hybridization in a compound. As expected for these compounds, the effective mass for the f electrons is very high and canonical bandwidths very small. Our results show that there is broadening of the f bands of R atoms and d bands of Pd atoms, when $\eta > \tilde{\eta}$. The broadening for the d states of Pd remains almost the same for all these compounds. However, in the case of $LaPd_3$, the f states of the La atom seem to be very sensitive to the presence of Pd atoms. This sensitivity is much less in $CePd_3$ and decreases as one goes to $PrPd_3$ and $NdPd_3$.

The l-projected charge occupancy and density of states (DOS) are presented in Table II. It shows that there is little difference in the ionicities at the R sites and the Pd sites in the various compounds. In each compound more than one electron is lost by the R atom to the three Pd atoms in the unit cell. This is in accordance with Pauling's electronegativity difference. Interestingly, the magnitude of this charge transfer is quite large compared to that in relatively simpler systems such as transition-metal compounds, e.g., Ni_3X (X =Al, Fe, Mn) (Ref. 13), where the difference of the electronegativity of the two constituents is much smaller. The charge occupancies from KK (Ref. 4) (not listed in Table II) are in good agreement with ours. Inclusion of Pd f states in KK's work does not make an appreciable difference.

Since the DOS versus energy curve from our work is in good agreement with that from KK (Ref. 4) for $LaPd_3$ and $CePd_3$, we decided not to show the curves here. The angular momentum and site-resolved DOS shows a very fast rise for f states at the R site as one goes through this series. Thus the derived coefficient of electronic specific heat γ is large for $PrPd_3$ and $NdPd_3$. The γ value for $LaPd_3$ from this work as well as from KK (Ref. 4) is nearly eight times the experimental value.[14] This is not the usual case with theory, and

perhaps suggests the need for a higher level of sophistication for such calculations. The calculated γ values for $CePd_3$, however, are less than the experimental value and give a large enhancement factor of $\lambda \simeq 2.1$, 5.6, and 14 for this work, KK (Ref. 4) and YH (Ref. 5), respectively. Differences in the total DOS, $N(E_F)$, values determined from the three calculations is understandable as the Fermi level (E_F) lies near a very sharp peak [Fig. 3 of KK (Ref. 4)], where the DOS changes very fast for a small shift in E_F.

The RPd_3 compounds form an interesting series in terms of their magnetic ordering behavior. Elsenhans *et al.*[3] detected unusual magnetic ordering phenomenona by systematic neutron scattering experiments on some members of this series in the temperature range 7 mK$\leq T \leq$300 K. In an effort to verify the consistency of our calculations, we have examined the Stoner criterion for these compounds. The multiband Stoner product $IN(E_F)$, where I is the Stoner parameter and $N(E_F)$ is total DOS, appropriate for compounds is defined by[15]

$$IN(E_F)=N(E_F)\sum_{l}\sum_{ll'}\frac{N_{tl}}{N(E_F)}\,I_{tll'}\,\frac{N_{tl'}}{N(E_F)},$$

where the interatomic exchange integrals $I_{tll'}$ are evaluated self-consistently; and N_{tl} is the site and angular momentum resolved DOS/spin. The calculated Stoner products are displayed in Table II. We obtain $IN(E_F)<1$ for $LaPd_3$ and $CePd_3$, indicating absence of magnetic ordering in these compounds which is in agreement with experiment.[2] The Stoner product is >1 for $PrPd_3$ and $NdPd_3$, implying the likelihood of magnetic ordering. Experiments[2] show that $PrPd_3$ and $NdPd_3$ are affected at low temperatures by the presence of crystal field. Magnetic measurements reveal that $PrPd_3$ shows the onset of antiferromagnetic ordering at 1.05 K. The reciprocal susceptibility-versus-temperature curve for $NdPd_3$ shows a negative intercept, suggesting the presence of a small antiferromagnetic exchange interaction in $NdPd_3$.[2] Measurements by Elsenhans *et al.*[3] establish $NdPd_3$ as having an incommensurate magnetic ordering and estimate the Neel temperature of $NdPd_3$ as 0.73 ± 0.02 K. Simple calculations such as ours do not determine the type of magnetic ordering. Nevertheless, they are consistent with the experiments. Because of the antiferromagnetic ordering in these compounds, very large calculated values of total DOS for $PrPd_3$ and $NdPd_3$ are not alarming. It is well known[16] that performing the calculations for the actual antiferromagnetic configuration would result in a dramatic drop in $N(E_F)$ because of the creation of a gap in the antiferromagnetic phase.

We also performed a calculation on these compounds for an expanded lattice to obtain a coarse estimate of the bulk modulus of these compounds as $B=-V\Delta P/\Delta V$ (P =pressure and V=volume). The estimated values, given in Table II, consistently lie between those for metals R and Pd. The LMTO method is known to give a good estimate of the ground-state properties for compounds.[17] Hence we expect these values to be reasonably accurate. Unfortunately, as far as we know, the value of B for these compounds has not yet been measured.

IV. CONCLUSIONS

We presented the systematics of some ground-state properties of the RPd_3 (R=La Ce, Pr, and Nd) compounds. The calculations are for the nonmagnetic phase. We obtain a very large DOS for $NdPd_3$ and $PrPd_3$, which shows that the nonmagnetic phase is unstable to the formation of a magnetic compound. The Stoner product <1 for $LaPd_3$ and $CdPd_3$ implies absence of magnetic ordering. The results are consistent with the experiments[2,3] that show the lack of magnetic ordering for $LaPd_3$ and $CePd_3$ and antiferromagnetic ordering for $PrPd_3$ and $NdPd_3$. η, the ratio of calculated bandwidths with the canonical bandwidths, is greater than $\bar{\eta}$ for all, indicating broadening of bands. The hybridization has maximum impact on the rare-earth f state $(\eta/\bar{\eta})_{R\text{-}f} > (\eta/\bar{\eta})_{\text{Pd-}d}$ with different magnitude in each compound. Interestingly, however, the broadening of Pd-d states in all these compounds is the same. Location of the Fermi level on a sharp peak explains the difference in the DOS values for $CePd_3$ from this work and earlier works.[4,5] We have also presented an estimate for the bulk modulus of these compounds.

Dhar *et al.* [J. Phys. F **18**, L41 (1988); and *Proceedings of the International Conference on Strongly Correlated Electron Systems Sendai, Japan, 1992* (Plenum, New York, 1987)] have recently measured the low-temperature specific heat of YbSbPd and YbSbNi. Their measurements yield large values for the specific heat coefficient (1384 states/Ry cell for YbSbPd and 865 states/Ry cell for YbSbNi), and suggest a magnetic transition at low temperature. With a view to understand the ground state of these compounds, we have performed self-consistent scalar relativistic linear muffin-tin orbital band structure calculations. Our paramagnetic calculations for YbSbPd and YbSbNi give the density of the states at Fermi level to be 82.94 and 27.96 states/Ry cell, respectively. These give enhancement factors of 16.7 and 30.1 for YbSbPd and YbSbNi. We present results of our calculations of the band structure as well as the Stoner I parameter for these compounds.

INTRODUCTION

The properties of Yb-based ternary rare-earth compounds, characterized by $4f$ shell conduction band hybridization, have been studied extensively in recent years (see, for example, Ref. 1). One expects and does see many of the interesting Kondo related properties. These materials have been broadly classified as valence fluctuators, Kondo lattices, and heavy fermions. These compounds are characterized by an enhanced electronic coefficient of heat capacity γ, found to be an order of magnitude larger than that in ordinary metals. Keeping in view the importance of these rare-earth compounds and the fact that several interesting physical properties in YbSbPd and YbSbNi have recently been reported,[2,3] we present scalar relativistic band structure calculations within the local density approximation (LDA), using the linear muffin-tin orbital (LMTO) method in the atomic sphere approximation[4,5] (ASA) for these two compounds.

The salient features of these two compounds are (i) Yb ions are trivalent, (ii) their electrical resistivity shows an overall metallic behavior with large magnitude, (iii) their heat capacity shows appreciable magnetic field dependence, (iv) YbSbNi is a possible low carrier heavy-fermion compound as compared to YbSbPd, and (v) both the compounds crystallize in the MgAgAs structure.[6,7] The cubic MgAgAs structure consists of the interpenetrating face-centered-cubic lattices with different atoms lying along the body diagonal at $(\frac{1}{4},\frac{1}{4},\frac{1}{4})$, (0,0,0), and $(\frac{3}{4},\frac{3}{4},\frac{3}{4})$.

In this article, we discuss our method of calculation in Sec. II, and results and discussions are given in Sec. III. Conclusions are given in Sec. IV.

METHOD OF CALCULATION

The self-consistent LMTO-ASA method has been used. The calculations are performed semirelativistically for 89 **k** points in the irreducible Brillouin zone using the von Barth–Hedin exchange correlation potential.[8] Within spheres around each atomic center the wave function is expanded in muffin-tin orbitals with the basis set of s, p, and d orbitals, except for the Yb atom for which s, p, d, and f orbitals are chosen. Because of the open nature of the MgAgAs structure an empty sphere is included on the vacant site $(\frac{1}{2},\frac{1}{2},\frac{1}{2})$. We have performed calculations for the lattice constant of 6.2369 Å for both the compounds,[9] and for simplicity the Wigner–Seitz radii for all atoms are taken to be equal (1.5356 Å). Both compounds have 29 electrons [16 of Yb, 3 of Sb, 10 of X (X=Pd or Ni)] in the valence states. The Yb f electrons are treated as valence electrons. Although there is controversy in literature concerning the treatment of the f electrons of Yb in the LDA, we have adopted the simplest approach (as done by other workers.[10,11] The density of states (DOS) is calculated using the variation of the linear tetrahedral method prescribed by Jepsen and Andersen.[12]

RESULTS AND DISCUSSIONS

The band structures calculated along the symmetry direction are shown in Figs. 1 and 2, respectively, for YbSbPd and YbSbNi. Bands from 4 to 18 are plotted for YbSbPd and for YbSbNi 5 to 20 bands are plotted to keep the figures manageable. For both the compounds the bands near E_f are

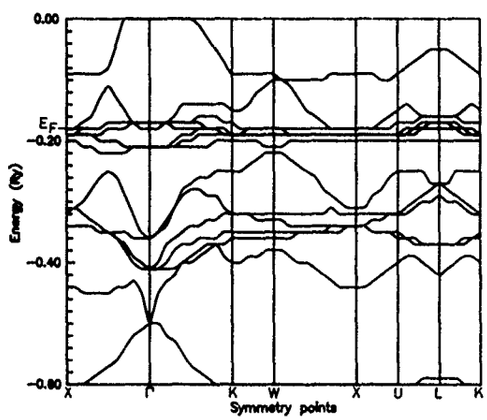

FIG. 1. Band structure of YbSbPd.

 0021-8979/94/75(10)/6301/2/$6.00 © 1994 American Institute of Physics

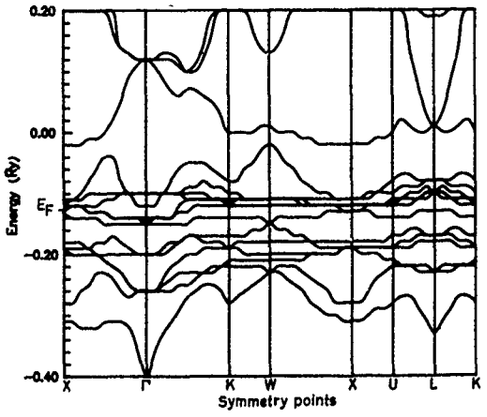

FIG. 2. Band structure of YbSbNi.

very flat, predicting a large contribution from the f bands of Yb. In the case of YbSbPd the bands near E_f (E_f=−0.177 Ry) are more flat as compared to YbSbNi and the bandwidths are smaller, giving a probability of higher DOS at the Fermi energy (E_f). Otherwise the band structures are similar. For both the compounds four bands (14, 15, 16, and 17) cross the Fermi level and the trend of the bands at E_f is similar; therefore one may expect similar Fermi surfaces. The calculation for the Fermi surface topology and extremal areas of the Fermi surface orbits is in progress.

The total density of states (T-DOS) for YbSbPd and YbSbNi are shown in Fig. 3. The peak in both figures at different energy sites has major contributions from different

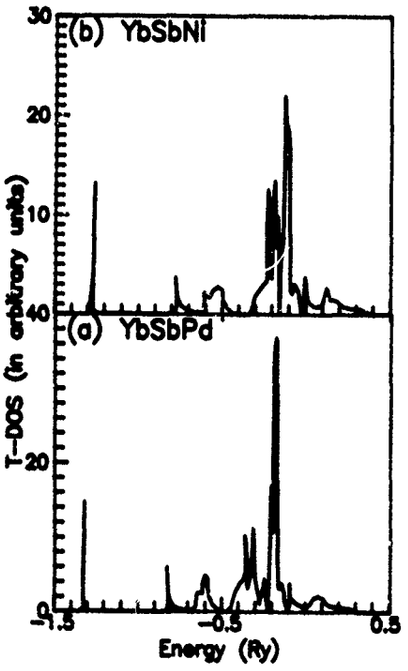

FIG. 3. Total density of states (TDOS) (a) for YbSbPd and (b) for YbSbNi.

angular momenta corresponding to different atoms. In case of YbSbPd [i.e. Fig. 3(a)] the peak at −1.3 Ry is due to the s of Yb, at −0.6 Ry due to the s in Sb, and the next two peaks at −0.4 and −0.3 Ry have major contribution from the d states of Pd, and similarly for YbSbNi [Fig. 3(b)], the peak at −1.3 Ry is due to s of Yb, at −0.2 and −0.18 Ry are due to d's of Ni. In both compounds the l-decomposed DOS shows a dominant Yb f character near E_f. For both compounds the E_f lies on the left of the peak in T-DOS curves. The T-DOS at E_f in case of YbSbPd is 82.94 and 27.96 states/Ry cell for YbSbNi. These, when compared with the projected DOS from the heat capacity data (1384 and 865 states/Ry cell, respectively, for YbSbPd and YbSbNi), give an enhancement factor of 16.7 for YbSbPd and 30.1 for YbSbNi. These values of enhancement factors are smaller than the enhancement factor of 650 calculated by McMullan and Ray[11] for YbBiPt. The T-DOS at E_f for YbSbPd is found to be larger than that for YbSbNi due to the fact that for YbSbPd the bandwidth of the dominating Yb f electrons (0.267 Ry) is smaller than that for YbSbNi (0.332 Ry). The rest of the bands have more or less the same bandwidths.

Our calculations give the values of Stoner product $IN(E_f)$ to be 1.083 for YbSbPd and 0.284 for YbSbNi, respectively. Therefore, our calculations predict a possibility of a magnetic ground state for YbSbPd.

CONCLUSIONS

We have presented results of scalar relativistic LMTO-ASA calculations for two Yb-based compounds which are known to show heavy-fermion character. Band structures for both are quite similar. Our calculations give enhancement factors of 16.7 for YbSbPd and 30.1 for YbSbNi, smaller than that obtained for YbBiPt by McMullan and Ray.[11] Since all the atoms are heavy, there is need to do a relativistic LMTO calculation, and this may lead to change in DOS at the Fermi energy and hence in the enhancement factor. We have also calculated the Stoner I parameter. Our calculations show that for YbSbNi, $IN(E_f)$ is smaller than 1, while for YbSbPd it is larger than 1, suggesting some magnetic ground state in latter. However, relativistic calculations need to be performed before one can draw any definite conclusions.

Electronic structure and Curie temperature of $YFe_{12-x}Mo_xN_y$ compounds

A. S. Fernando, J. P. Woods, S. S. Jaswal, D. Welipitiya, B. M. Patterson, and D. J. Sellmyer
Behlen Laboratory of Physics and Center for Materials Research and Analysis, University of Nebraska, Lincoln, Nebraska 68588-0111

The electronic structures of $YFe_{12-x}Mo_xN_y$, where $x=1.0$, 2.0 and $y=0$, 0.7, have been studied with photoemission and spin-polarized calculations. The peak near the Fermi level in the energy distribution curves (EDC) becomes successively broader with larger Mo concentration. The features in the calculated density of state at 1.3 and 2.7 eV are not readily seen in the EDC, and this may be due to lifetime effects in these compounds. Finally, changes in Curie temperature (T_c) with the change of N or Mo concentration are compared with prediction of the theory of Mohn and Wohlfarth. Reasonable agreement is obtained in the N case but not in the Mo case, the latter most likely due to hybridization of Fe and Mo *d* bands.

I. INTRODUCTION

Superior permanent-magnet materials require large saturation magnetization, high Curie temperature (T_c), and large uniaxial anisotropy. The best permanent magnetic materials are rare-earth(R)–transition-metal(T) compounds. The transition metals Fe and Co have large magnetic moments and high Curie temperatures, and the R-T compounds often have large uniaxial magnetic anisotropies. The Fe-rich ternary compound $Nd_2Fe_{14}B$ has an energy product as high as 45 MgOe,[1-4] but the relatively low T_c (≈300 °C) of this material limits its application. Permanent-magnet materials research is currently investigating other Fe-rich R-T compounds. The RT_{12} body-centered-tetragonal compound with the $ThMn_{12}$ structure does not exist in the binary phase, but the structure is stabilized with the partial substitution of a nonmagnetic element (M) for Fe. The compounds $RFe_{12-x}M_x$ with M=Ti, V, Cr, Mo, W, and Si have been fabricated and their magnetic properties examined.[5] The addition of interstitial nitrogen increases the Curie temperature of the materials and the magnetic anisotropy may change.[6] For example, T_c of $NdFe_{11}Ti$ increases by 30% upon nitriding and the magnetic anisotropy changes from in-plane to uniaxial.[7]

The magnetic properties of the compound $YFe_{12-x}Mo_x$ with $x=0.5$, 1, 2, 4 have been published.[8] T_c decreases with increased Mo concentration, and increases with nitriding; the volume increases both with increased Mo and N concentration. The Mo atoms substitute for Fe atoms on the (i) site with the largest magnetic moment.[9]

The magnetic properties of the compounds are determined by the electronic configuration, and the increase in T_c of Y_2Fe_{17} (Ref. 10) and $NdFe_{11}Ti$ (Ref. 11) upon nitriding has been modeled using electronic structure calculations and the spin-fluctuation theory of Mohn and Wohlfarth.[12] Briefly,

$$(T_c)_{M-W}=CM_0^2/\chi_0, \tag{1}$$

where M_0 is the magnetic moment per Fe site, χ_0 is the enhanced susceptibility, and C is a constant. In earlier work the electronic structure of $Sm_2Fe_{17}N_y$ with $y=0$ and $y=2.6$ has been measured with photoelectron spectroscopy (PES), and a decrease in the density of state (DOS) at E_F is observed as nitrogen is added which agree with the calculated DOS.[13] In this paper the electronic structure of $YFe_{12-x}Mo_xN_y$ with $x=1$, 2, and $y=0$, 0.7 is examined with PES, and the calculated partial DOS for Fe, Y, and Mo in $YFe_{11}Mo$ are given. Comparison with the expected changes in T_c are presented.

II. EXPERIMENTAL PROCEDURE

Bulk samples of $YFe_{12-x}Mo_x$ with $x=1$, 2 were prepared by arc melting the elemental constituents in a water-cooled copper boat in flowing-argon gas atmosphere. All the starting elements used were at least 99.98% purity. The alloys were melted several times to insure homogeneity. The samples were wrapped separately in Ta foils and heat treated in vacuum below 3×10^{-6} Torr at 1100 °C for about 50 h,[8] and subsequently quenched in water. X-ray diffraction measurements on powder samples using Cu K_α radiation showed that the samples were composed of primarily the $ThMn_{12}$ structure with a small amount of α-Fe. The magnetization of the samples was measured at 5 and 300 K with superconducting quantum interference device (SQUID) and alternating force gradient magnetometers, respectively, and the saturation magnetic moments agree with published results.[8]

The arc-melted buttons were spark cut into discs ~1 mm thick to expose an interior surface which was then polished to provide an optically smooth surface for PES measurements. The samples were mounted on a tungsten sample manipulator using 0.25-mm-diam tantalum wires in an ultrahigh vacuum chamber with a base pressure of 2×10^{-10} Torr. Each sample was cleaned *in situ* with several cycles of 2 keV Ar sputtering and subsequent annealing at 350 °C. Auger electron spectroscopy (AES) was employed to monitor surface cleanliness and to estimate the nitrogen concentration. After cleaning the sample, nitrogen was introduced by ion implantation with a kinetic energy of 2 keV and a current density of 25 μA/cm^2 for 10 min.[17] The subsequent nitrogen concentration was measured with AES as $y=8.3\pm0.8$. The samples were then radiantly heated to 350 °C for several minutes to promote nitrogen diffusion from the nitrogen-rich surface into the subsurface region. The nitrogen-rich surface layer was subsequently removed with Ar sputtering to expose the subsurface nitride and the resulting surface nitrogen concentration measured with AES was $y\approx0.7\pm0.3$. Quantitatively, the nitrogen concentration per formula unit of 0.7 at the sur-

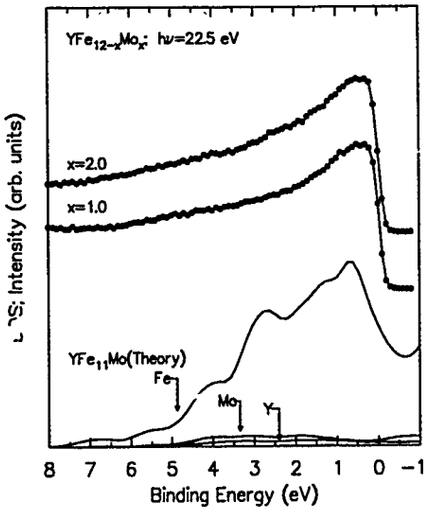

FIG. 1. Calculated partial spin-polarized DOS of Fe, Mo, and Y in $YFe_{11}Mo$ and experimental energy distribution curves (EDC) for clean $YFe_{12-x}Mo_x$ ($x=1.0$, 2.0). The EDCs are normalized to the area under the EDC curves between 0 and 3.5 eV and shifted vertically. The zero on the binding energy axis refers to the Fermi energy (E_F).

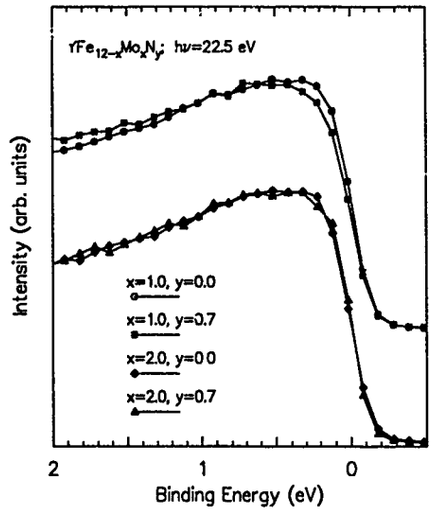

FIG. 2. Expand view of the experimental EDCs of $YFe_{11}MoN_y$ for $y=0.0$, $y=0.7$ (upper two curves) and of $YFe_{10}Mo_2N_y$ for $y=0.0$, $y=0.7$ (lower two curves). The zero on the binding energy axis corresponds to the Fermi energy.

face of 1:12 compounds here and previously published[11] is in agreement with published bulk values[7] and supports the assertion that the bulk atomic structure is present up to the surface which is probed by AES and PES. The electronic structure was measured with PES experiments which were performed at the Synchrotron Radiation Center in Wisconsin. The photoelectron energy distribution curves (EDC) presented were obtained with a photon energy of 22.5 eV and a total energy resolution of 0.14 eV.

III. ELECTRONIC STRUCTURE

The EDCs from the Ar-sputter-cleaned and annealed $YFe_{12-x}Mo_x$ samples with bulk values of $x=1.0$, 2.0, and the calculated partial DOS for each element in $YFe_{11}Mo$ are shown in Fig. 1. The EDC curves have been normalized to the same areas between 0 and 3.5 eV binding energy and the baseline for each EDC is shifted vertically. The DOS are determined with self-consistent spin-polarized calculations using linear-muffin-tin orbitals in the scalar relativistic approximation.[14] A supercell consisting of four formula units was used to simulate the ternary compound with correct stoichiometry. The total DOS (not shown) is the sum of the three partial DOS curves, and the total DOS is dominated by the Fe DOS, due to the large atomic percentage (85%) of Fe in the compound. The present Fe DOS is substantially different from Fe DOS in $NdFe_{11}Ti$ compounds[11] and the difference is due to the strong hybridization with Mo.

The EDCs are comparable to the calculated DOS with a 1–2 eV wide peak at the Fermi energy. The features in the calculated DOS at 1.3 and 2.7 eV are not readily discernible in the EDC, and this may be due to lifetime effects in these compounds.[15]

The change in EDCs at E_F after nitriding $YFe_{11}Mo$ and $YFe_{10}Mo_2$ compounds are shown in Fig. 2. The $YFe_{11}Mo$ sample (upper two curves) shows a significant decrease in EDC at E_F upon nitriding; the $YFe_{10}Mo_2$ sample (lower two curves) does not show any significant change in EDC at E_F upon nitriding. The comparison of EDCs for $x=1$ and $x=2$ without nitrogen (upper two curves) and with nitrogen (lower two curves) are shown in Fig. 3. The EDCs at E_F for $YFe_{11}Mo$ and $YFe_{10}Mo_2$ show no significant change; the nitrided samples $YFe_{11}MoN_{0.7}$ and $YFe_{10}Mo_2N_{0.7}$ show a slight increase in EDC at E_F as the Mo:Fe ratio is increased.

In previous experiments on 1:12 and 2:17 compounds[11,13] the change in the EDCs at E_F was compared

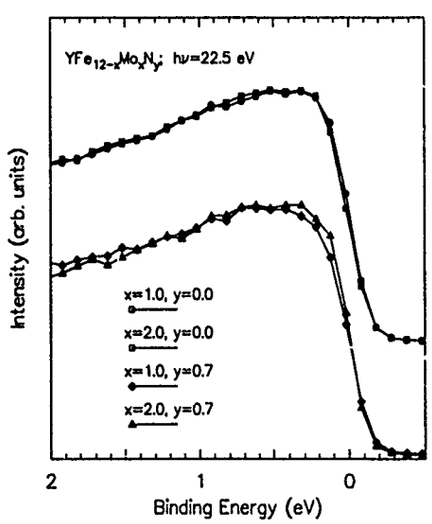

FIG. 3. Expand view of EDCs of unnitrided (upper two curves) and nitrided (lower two curves) samples of $YFe_{12-x}Mo_x$ ($x=1.0$, 2.0). The zero on the binding energy axis refers to the Fermi energy.

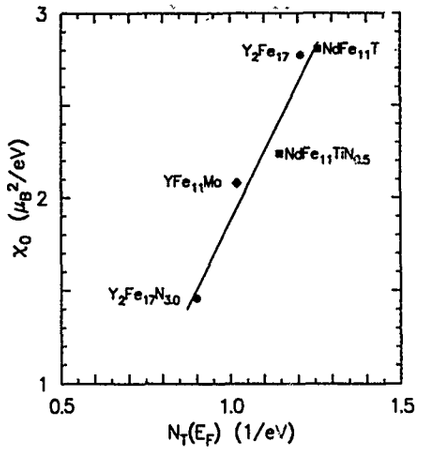

FIG. 4. Calculated χ_0 vs calculated $N_T(E_F)$ for the samples listed.

to the calculated[10,16] total DOS, $N_T(E_F)=N_\uparrow(E_F)+N_\downarrow(E_F)$, where $N_\uparrow(E_F)$ and $N_\downarrow(E_F)$ are the up- and down-spin DOS at the Fermi level, respectively. The calculated DOS, Stoner parameter, and magnetic moments used with Mohn and Wohlfarth theory predict a change in T_c upon nitrogenation which agrees very well with measured change in T_c. In the present experiment the calculated DOS is available only for the $YFe_{11}Mo$ compound, and a comparison of changes in $N_T(E_F)$ as the nitrogen concentration or the Fe:Mo ratio changed is not possible.

In order to compare changes in the measured electronic structure with changes in the magnetic properties (T_c and M_0), a dependence of χ_0 on $N_T(E_F)$ is required. Calculated values of χ_0 for listed samples, where $\chi_0^{-1}=[1/N_\uparrow(E_F)+1/N_\downarrow(E_F)-2I]/4\mu_B^2$ are plotted as a function of $N_T(E_F)$ in Fig. 4. There is a linear dependence between χ_0 and $N_T(E_F)$ in the small range of $N_T(E_F)$ for the 1:12 and 2:17 Fe-based compounds considered. With this plot, the electronic structure is related to T_c and M_0 as $M_0^2/T_c \propto \chi_0 = AN_T(E_F)+B$, where A and B are constants and $B/A=-0.48\ \mathrm{eV}^{-1}$. Upon alloying with either N or Mo, the new value of T_c (T_c') can be related through Eq. (1) to the measured changes in magnetization and electronic structure by

$$(T_c'/T_c)_{M-W}=(M_0'^2/M_0^2)(\chi_0/\chi_0'), \tag{2}$$

where χ_0/χ_0' is given by $[N_T(E_F)-0.48]/[N_T'(E_F)-0.48]$. The values of $N_T(E_F)$ are obtained from the experimental EDC curves. The ratio $(T_c'/T_c)_{\mathrm{exp}}$ measured directly, and $(T_c'/T_c)_{M\text{-}W'}$ are shown in Table I.

As shown in Table I, these two values agree fairly well when nitrogen is added to the two parent compounds. However, when the nitrogen concentration is held fixed and the Fe:Mo ratio is varied, there is a large disagreement between these two values. The disagreement is due to the fact that substitution of Mo for Fe in going from $YFe_{11}Mo$ to $YFe_{10}Mo_2$ lowers the Fe concentration and causes a strong hybridization of the Fe and Mo d bands thus changing the proportionality constant in Eq. (1).

TABLE I. Calculated values of $(T_c'/T_c)_{M-W}$ and $(T_c'/T_c)_{\mathrm{exp}}$ for $YFe_{12-x}Mo_xN_y$ samples.

x,y	$(M_0'/M_0)^2$ [a]	(χ_0/χ_0') [b]	$(T_c'/T_c)_{M-W}$ ±8%	$(T_c'/T_c)_{\mathrm{exp}}$ [a]

IV. CONCLUSIONS

PES experiments probing the electronic structure agree approximately with the calculated DOS. The samples with fixed Mo concentration follow the Curie-temperature theory of Mohn and Wohlfarth upon nitriding. However, the theory does not correctly predict changes in T_c on alloying with Mo. The reason for this appear to be that nitrogen goes into the lattice interstitially and mainly expands the lattice, whereas Mo substitution for Fe causes a significant change in the electronic structure of the material.

Low-temperature magnetic properties of the $Co_{56-x}B_{32+x}C_{12}$, $x=0$, 2, 4, and 4.5 ternary amorphous alloys are investigated by using low-field ac magnetic susceptibility measurement techniques and also a superconducting quantum interference device magnetometer. The ac susceptibility data show that these alloys undergo a paramagnetic to ferromagnetic state transition at cryogenic temperatures. The Curie temperature T_c decreases linearly with decreasing Co content at a rate 31 K per Co at %, suggesting a percolation limit for the disappearence of ferromagnetism at around 50 at % Co. A scaling analysis performed on magnetic isotherms obtained near T_c; even for the sample almost close to the percolation limit, yields critical exponent values consistent with the 3D-Heisenberg model for an ideal ferromagnet. Thus in these Co-based amorphous alloys, long-range order persists to the concentrations almost at the percolation limit and the mean-field theory is found to describe well the paramagnetic to the ferromagnetic state phase transitions.

I. INTRODUCTION

The ternary amorphous Co-B-C system with stoichiometry in the extended concentration regime provides us a unique opportunity to study the magnetic properties of Co close to the percolation limit for the disappearance of ferromagnetism. It has been found[1,2] that the amorphous alloys $Co_{88-y}B_yC_{12}$, with $y=12$, 16, 24, and 32 are simple ferromagnets, and the T_c decreases linearly with decreasing Co content. Contrary to the results of magnetic studies of similar but Fe-based transition metal-metalloid amorphous alloys like $(Fe_xNi_{1-x})_{75}P_{16}B_6Al_3$,[3] no spin-glass behavior has been observed in all the above-mentioned Co-based amorphous alloys. The absence of spin-glass behavior in Co-based alloys could be expected from the well-known phenomenological Bethe–Slater curve[4] predicting the dependence of the exchange coupling constant J with the Co-Co separation distance.

In order to have a better picture of the ferromagnetic state of the CoBC amorphous alloys near the percolation limit for the disappearance of ferromagnetism, we attempt a scaling analysis near the paramagnetic (PM) to ferromagnetic (FM) state transition of the amorphous alloys $Co_{56-x}B_{32+x}C_{12}$ with $x=0$, 2, 4, and 4.5. The extracted values of the critical exponents β and δ are compared with those predicted[5] by the 3D-Heisenberg model. In addition we present the magnetic phase diagram of the above CoBC amorphous alloys.

II. EXPERIMENTAL

Ingots of nominal composition $Co_{56-x}B_{32+x}C_{12}$, with $x=0$, 2, 4, and 4.5 were prepared in a arc-melting furnace under continuous flow of argon gas, and subsequently melt spun under a very low pressure of argon atmosphere. This was necessary, since the melting of these alloys is relatively difficult because of the high metalloid content resulting in a low electrical conductivity for these ingots. The obtained ribbons were 5–60 cm in length, 10 μm thick, 0.5 mm wide, and shiny. They were found to be x-ray amorphous, while the composition was determined with energy dispersive x-ray analysis (EDAX) using a scanning electron microscope. ac susceptibility measurements were performed using a calibrated and balanced mutual inductance bridge, employing a two phase PAR lock-in signal analyzer, so we were able to measure both components of χ_{ac}, the real (χ'), and the imaginary (χ'') simultaneously. The results were corrected for demagnetizing effects. For the dc magnetic studies we employed a Quantum Design superconducting quantum interference device (SQUID) magnetometer.

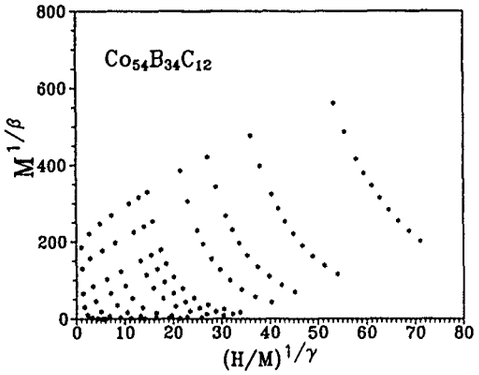

FIG. 4. Modified Arrott plots for $Co_{54}B_{34}C_{12}$.

III. RESULTS AND DISCUSSION

In Fig. 1 are presented the real part χ' of the ac susceptibility data of the amorphous alloys $Co_{56-x}B_{32+x}C_{12}$ where $x=0$, 2, 4, and 4.5. For all of the alloys studied, $\chi'(T)$ shows a single transition from a paramagnetic to a ferromagnetic state as the temperature decreases. It is obvious that, below the Curie transition temperature (T_c), that $\chi'(T)$ increases monotonically down to 4.2 K, with no indication of spin-glass behavior. Only in the $\chi'(T)$ data of the alloys with 51.5 at % Co there is some indication of decreasing of $\chi'(T)$ at around 6 K. However, we did not find any clear signature for the possible existence of a spin-glass state and $\chi''(T)$, for example, is zero. The magnetic phase diagram for the composition range studied is obtained and is shown in Fig. 2. It is found that the Curie temperature (T_c) decreases with decreasing Co content at a rate of 31 K per at % Co, suggesting a percolation limit for the disappearance of the ferromagnetism in these alloys at around 50 at % Co. In order to perform a scaling analysis near the paramagnetic to ferromagnetic state transition, we obtained a set of magnetic isotherms around $T=T_c$, for the alloys with 52 at % and 54 at % of Co content. By plotting the magnetization $M^{1/\beta}$ versus the ratio of the field over the magnetization $(H/M)^{1/\gamma}$, where the critical exponents values β and γ have been varied in the range $\beta=0.3$–0.6 and $\gamma=1.2$–2, we obtained the modified Arrott plots which are presented in Figs. 3 and 4. These plots are indeed straight lines near the transition temperature as should have been expected for ideal ferromagnets. To cross examine now the values of the critical exponents β and γ, the isotherms are plotted according to the scaling relation $\log_{10}(m)$ vs $\log_{10}(h)$. Here m and h are the reduced magnetization and the reduced field, respectively, where

$$m=M(\epsilon,H)/|\epsilon|^{\beta}, \quad h=H(\epsilon,M)/|\epsilon|^{\beta+\gamma}, \quad \epsilon=(T-T_c)/T_c.$$

We have varied the T_c by 0.5 K, the β from 0.3 to 0.6, the γ from 1.2 to 2.5, and $|\epsilon|=0.02$–0.2. The correct values of T_c, β, and γ are the values which in the high-field regime cause the collapse of the two branches of the isotherms in a $\log_{10}(m)$ vs $\log_{10}(h)$ diagram almost onto the same line (in reality the two branches for the high-field regime converge towards the same limit). The obtained values of the exponents β, γ are found to be the same with those found using the modified Arrott plots method and are presented in the Table I, while the scaling is presented in the Figs. 5 and 6. In addition to this, assuming that the static scaling hypothesis is valid, then we can calculate the value of δ from the relation $\beta+\gamma=\beta\cdot\delta$, which also is shown in the Table I. Comparing the obtained values of the critical exponents β, γ, and δ, with those predicted for the 3D-Heisenberg model (these values are also included in Table I), we see that in the case of $x=4$ (52 at % Co), there is excellent agreement between experiment and theory, while in the case of $x=2$ (54 at % Co) there is a slight deviation. The latter might indicate that this particular alloy, below T_c, exhibits a nonideal ferromagnetic order.

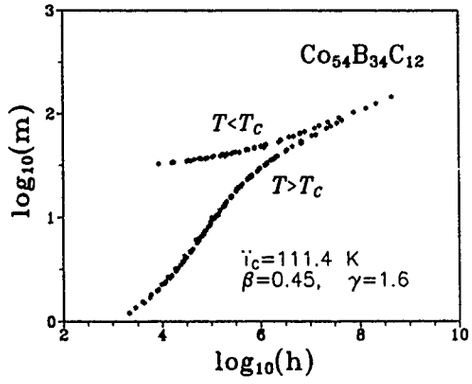

FIG. 6. $\text{Log}_{10}(m)$ vs $\log_{10}(h)$ for $Co_{54}B_{34}C_{12}$.

IV. CONCLUSION

Successfully melt-spun $Co_{56-x}B_{32+x}C_{12}$ ($x=0$, 2, 4, and 4.5) amorphous alloys have been found to exhibit a single paramagnetic to ferromagnetic state transition, at temperatures below room temperature. In addition it is found that T_c is decreasing with decreasing Co content at a rate of 31 K per Co at %. A scaling analysis performed near T_c showed that one alloy ($x=4$) has critical exponent values in excellent agreement with values predicted by mean-field theory, while these values for the $x=2$ alloy deviate slightly from theory.

High-field magnetization behavior in random anisotropy amorphous Co-Er alloys

H. Lassri, L. Driouch, and R. Krishnan
Laboratoire de Magnétisme, C.N.R.S. 92195 Meudon, France

Amorphous $Co_{1-x}Er_x$ ribbons with $x=55$ and 65 were prepared by the melt-spinning technique. Magnetization measurements were carried out in the temperature range 4–100 K under high magnetic fields up to 20 T. Even at 20 T the saturation is not fully attained. Assuming that Co has no moment in the alloy with $x=65$ the Er moment is found to be $7.0\mu_B$ which indicates a speromagnetic spin structure. The Co moment in the alloy with $x=55$ is then found to be $0.1\mu_B$, which is negligibly small. By analyzing the approach to saturation using Chudnovsky's theory we have extracted some fundamental parameters.

I. INTRODUCTION

Amorphous alloys based on rare-earth metals are interesting materials to study the various fundamental parameters, such as ferromagnetic, antiferromagnetic interactions, random anisotropy, etc.[1,2] We have reported on the amorphous Co-Er-B alloy,[3] where we have shown that Er has a conical spin structure resulting from strong random anisotropy and that under sufficiently high magnetic fields the antiferromagnetic interaction between Er-Co breaks down. It has also been shown that for rare-earth metal concentrations higher than about 60 at %, the transition metal moment would vanish.[4] Therefore we wanted to study the binary Co-Er system rich in Er, in order to get more information on the magnetic state of Er. The magnetization of this system was studied earlier[4] but under an external field of only 1.4 T which, as it will be shown here, is far too small for saturation. We report here our magnetization studies on amorphous $Co_{45}Er_{55}$ and $Co_{35}Er_{65}$ alloys under applied fields up to 20 T. We have also analyzed the approach to saturation using Chudnovsky's theory and obtained some magnetic parameters of interest.

II. EXPERIMENTAL DETAILS

Amorphous $Co_{1-x}Er_x$ alloys with $x=55$ and 65 were prepared by the usual melt spinning technique under inert atmosphere. Linear velocity of the copper wheel was in the range 30–40 m/s. The diameter of the orifice of the quartz crucible was 0.5 mm.

The amorphous state was verified by x-ray diffraction. The exact composition was determined by electron probe microanalysis. The magnetization was measured in the temperature range 4–100 K and under applied fields up to 20 T.

III. RESULTS AND DISCUSSION

The ribbons were about 1 mm wide and 30 μm thick and were all amorphous as shown by the characteristic broad x-ray diffraction peak.

The field dependence of the magnetization at different temperatures for the two alloys was similar and Fig. 1 shows the result for the alloy with Er=65 at %. It can be seen that even at 20 T, the saturation is not yet complete. So the saturation magnetic moment M_0 was calculated at H_∞, using H^{-2} dependence, which will be justified in the next section. The magnetization of the alloy with $x=65$ can be considered to arise only from the Er atoms as we pointed out earlier. Under this assumption, from the alloy moment of $4.56\mu_B$ we find the Er moment $\mu_{Er}=7.0\mu_B$/atom, which is smaller than $9.0\mu_B$, theoretically expected for the ground state. This indicates that the Er spin structure is not collinear. This spin structure arises from the random anisotropy which is larger than the ferromagnetic $J_{Er\text{-}Er}$ interaction. It is interesting to note that this situation is different from what we had observed earlier for Co-Er-B alloys,[3] where the Co atoms bear a strong moment and therefore a fairly strong antiferromagnetic interaction $J_{Co\text{-}Er}$ tends to maintain the Er spins in one hemisphere.[3] It is to be noted that our value of μ_{Er} is much higher than that reported by Xingbo and Miyazaki,[4] as is expected, because their measurements were carried out under fairly low fields. Now taking our experimental value of $\mu_{Er}=7.0\mu_B$ for the alloy with $x=55$, and from the alloy moment of $3.8\mu_B$, the Co moment is calculated to be $0.1\mu_B$ which is indeed negligibly small.

The Curie temperature (T_C) of the alloys was obtained from the Arrott's plots and the result for $x=65$ is shown in Fig. 2. The Curie temperature T_C was found to be 30 and 40 K for $x=65$ and 55, respectively. These relatively low values indicate the weak ferromagnetic Er-Er interactions.

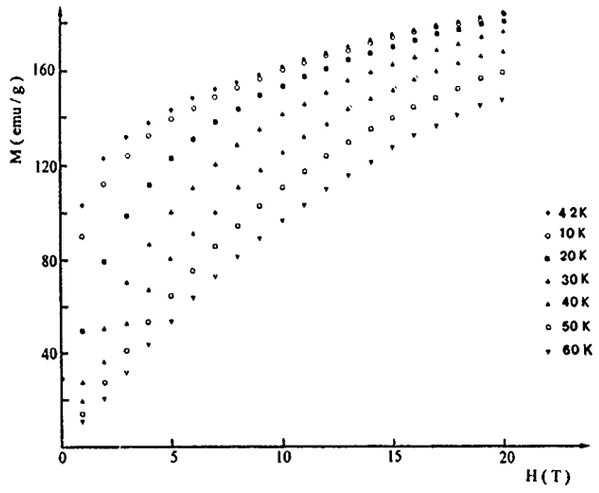

FIG. 1. The field dependence of the magnetization at various temperatures for the alloy $Co_{35}Er_{65}$.

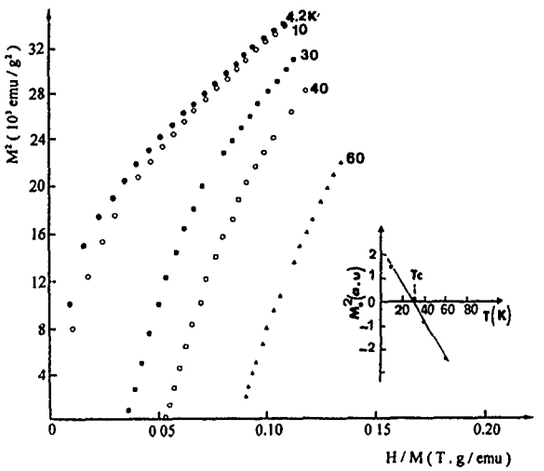

FIG. 2. The Arrott plot for the alloy $Co_{35}Er_{65}$. The inset shows M^2 vs T.

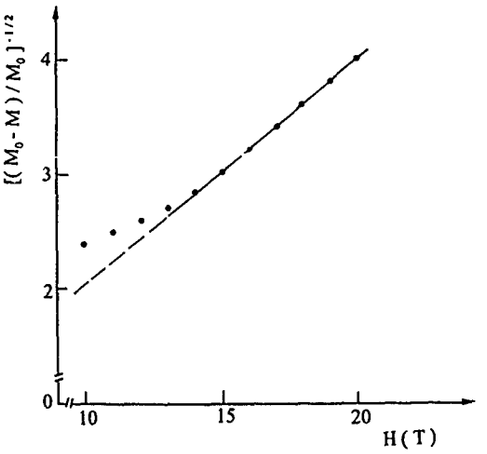

FIG. 3. The H dependence of the quantity $[(M_0-M)/M_0]^{-1/2}$ for the sample $Co_{35}Er_{65}$ at 4 K.

Chudnovsky[5,6] has proposed a theory to explain the approach to saturation in terms of various fundamental parameters, which has been applied by several authors to analyze their results.[7,8] Two cases are to be distinguished; first when the applied field is smaller than the exchange field ($H_{app}<H_{exch}$) and the second when ($H_{app}\gg H_{exch}$). In our present case considering the low Curie temperatures of the Er-Co samples, the second case is more appropriate. In this high-field regime one can write

$$(M_0-M)/M_0=\delta M/M_0=1/15[H_r/(H+H_{ex})]^2, \quad (1)$$

where M_0 is the magnetization extrapolated value to H_∞ and H_r is the random local anisotropy field and is related to the local anisotropy energy K_r by the relation

$$2K_r/M=H_r. \quad (2)$$

In some cases H_{ex} has been neglected since it is small compared to the external field and H_r has been calculated.[8] However, with some algebraic manipulations, as we describe below, it is also possible to consider H_{ex} and obtain not only H_r but also H_{ex}

Equation (1) can be rewritten as

$$(\delta M/M_0)^{-0.5}=B(H+H_{ex}), \quad (3)$$

where $B=\sqrt{15}\times(H_r)^{-1}$. So by plotting $(\delta M/M_0)^{-0.5}$ as a function of H, one can obtain H_r from the slope B and the exchange field H_{ex} from the intercept. Figure 3 show such a plot for Er=65. The data point align well in the high-field regime $H_{app}\gg H_{ex}$. But one observes a deviation from the linear dependence in the intermediate regime where the random anisotropy and the exchange field influence the magnetization behavior. This field region is known as the crossover field H_{co} and will be discussed later. The value of H_r was obtained by linear regression. Table I shows the various magnetic parameters calculated from the Fig. 3. It must be cautioned, however, that the value of H_{ex} should be taken with some caution and considering the relatively low value *vis a vis* H_{app} it could vary by a factor of 2 or 3. Nevertheless, this gives an order of magnitude of the parameter. For $x=65$, we find $K_r=1.8\times10^8$ erg cm^{-3} (which has been calculated from H_r) and this agrees well with the value obtained by Hadjipanayis *et al.*[8] for an amorphous Er-Au-B alloy, where Er are the only magnetic atoms.

From the crossover field H_{co} mentioned above, it is possible to calculate the important structural parameter R_a, which is the distance over which the local anisotropy axes are correlated. From Chudnovsky's theory[9] we can write

$$H_{co}=2A/M_0(R_a)^2, \quad (4)$$

where A is the exchange constant. However, generally this crossover field is difficult to observe experimentally in crystalline and amorphous materials where T_C and hence the exchange field is high.[9] Fortunately the present alloys offer a possibility to observe H_{co}. As we had mentioned when discussing the M dependence on H^2, one observes a deviation from the linear behavior (Fig. 3), which precisely corresponds the crossover field where the regime changes to the low field one. From Fig. 3 H_{co} is found to be close to 11 T. In Eq. (3) all parameters except A are known. It is possible to calculate by combining the models proposed by Hasegawa,[10] Heiman *et al.*[11] as described below. From the mean-field model the exchange constant A can be written[10] (considering only Er since Co has no moment) as

$$A=n_{Er\text{-}Er}J_{Er\text{-}Er}(g_{Er}-1)^2J^2x^2/a_{Er\text{-}Er}, \quad (5)$$

where x is the Er concentration, $n_{Er\text{-}Er}$ indicates the number of maximum permissible pairs of Er atoms per volume extending to the first nearest neighbors, $a_{Er\text{-}Er}$ the interatomic distance between Er atoms, x the Er concentration, and the

TABLE I. Some magnetic properties of $Co_{1-x}Er_x$ alloys at 4 K.

x	M_0 (emu g^{-1})	T_C (K)	A (10^{-8} erg cm^{-1})	H_{ex} (T)	H_r (T)	K_r (10^8 erg cm^{-3})
55	179	40	1.9	0.4	19	1.5
65	197	30	1.7	0.4	20	1.8

rest of the symbols have the usual meaning. Several authors[12] have assumed that $n_{Er\text{-}Er}=2$ and $a_{Er\text{-}Er}=3.5$ Å.

One can express the Curie temperature, after Heiman *et al.*[11] as

$$3kT_C=2xZ_{Er\text{-}Er}J_{Er\text{-}Er}J_{Er}(g_{Er}-1)^2(J_{Er}+1), \quad (6)$$

where $Z_{Er\text{-}Er}$ denotes the number of Er neighbors around Er atom which is generally taken as 12 in such amorphous alloys and the other symbols have their usual meaning. $g_{Er}=1.2$, $J_{Er}=7.5$.

Combining Eqs. (5) and (6) we can eliminate the term $J_{Er\text{-}Er}$ and get

$$A=xJ_{Er}kT_C/[4(J_{Er}+1)a_{Er\text{-}Er}]. \quad (7)$$

Knowing all the parameters in the above Eq. (7) A can be calculated. For example, for $x=65$, A is found to be 1.7×10^{-8} erg cm. Using this value of A in Eq. (4), we calculate $R_a=1.5$ Å. This rather small value indicates that there is practically no correlation in the direction of the easy axis from one rare-earth site to another. This is in agreement with the fact that this alloy is a speromagnet. One finds in transition metal-rich alloys, generally, that R_a is about 5 Å, which corresponds to a few atomic sites.[13]

Magnetic properties and crystallization of amorphous Fe-Nd-B alloys at constant Nd concentration

Bao-gen Shen, Lin-yuan Yang, Hui-qun Guo, and Jian-gao Zhao
State Key Laboratory of Magnetism, Institute of Physics, Chinese Academy of Sciences, P.O. Box 603, Beijing 100080, People's Republic of China

The B-content dependence of magnetization, Curie temperature, and crystallization temperature for amorphous $(Fe_{1-x}B_x)_{100-y}Nd_y$ alloys with $y=4$, 7, and 12 were studied. Spontaneous magnetization shows a monotonic decrease with x, and the noncollinear spin structures have been proposed to explain the observed results. It is found that the Curie temperature of the samples increases at first with increasing B concentration x, and shows a maximum value at a certain B concentration, then decreases monotonically with x. The composition dependence of T_c is explained by the average molecular-field model. An exceptionally strong rise of crystallization temperature with x is found, and demonstrates that the thermal stability of amorphous Fe-Nd-B alloys has a remarkable enhancement by the substitution of B for Fe.

I. INTRODUCTION

Since the discovery of the Fe-Nd-B permanent magnet materials, the magnetic properties of rapidly quenched Fe-Nd-B alloys have been studied extensively. Recently, some researchers have developed an interest in the study of magnetic properties of rapidly quenched Fe-Nd-B alloys with lower Nd concentration. Most of these studies focus on their hard magnetic properties, while investigations on magnetic properties and crystallization of amorphous Fe-Nd-B alloys are relatively fewer. To obtain more information about magnetic behaviors of rapidly quenched Fe-Nd-B alloys, we extended the study of amorphous Fe-Nd-B alloys to a wide composition range.[1] In our previous paper, a study on magnetic properties and crystallization of amorphous $(Fe_{1-x}Nd_x)_{100-y}B_y$ with $y=6$, 18.5, and 25 as well as the effects of heat treatment on their hard magnetic properties has been reported.[2-6] This paper focuses on the study of B-concentration dependence of magnetization, Curie temperature, and crystallization temperature of amorphous $(Fe_{1-x}B_x)_{100-y}Nd_y$ alloys at constant Nd concentration of $y=4$, 7, and 12.

II. EXPERIMENTAL

Alloys with composition $(Fe_{1-x}B_x)_{100-y}Nd_y$ ($0.104 \leq x \leq 0.365$, $y=4$; $0.065 \leq x \leq 0.323$, $y=7$; $0.067 \leq x \leq 0.413$, $y=12$) were prepared by arc melting in a purified argon atmosphere. The ingots were melted several times to insure the homogeneity, and then melt spun in an argon atmosphere on the outside of a rotating copper drum of 20 cm diameter with a surface speed of about 47 m/s, resulting in ribbons about 1 mm wide and 20–30 μm thick. No crystallinity in the ribbon samples was detectable by x-ray diffraction. The Curie temperature of the samples was determined from the magnetization curve in a field of about 45 Oe or the temperature dependence of the ac susceptibility in a weak field lower than 1 Oe. The measurements on the low-temperature magnetization were performed by an extracting sample magnetometer at fields up to 65 kOe. The crystallization temperature of the samples was determined from the differential scanning calorimetry (DSC) traces with a heating rate of 20 K/min.

III. RESULTS AND DISCUSSION

Figure 1 shows the B-concentration dependence of the Curie temperature T_c of amorphous $(Fe_{1-x}B_x)_{100-y}Nd_y$ alloys at constant Nd concentration of $y=4$, 7, and 12, together with that of amorphous $Fe_{1-x}B_x$ alloys for comparison. Pronounced effects of the composition on Curie temperature are observed. It can be seen from Fig. 1 that the T_c of the samples increases at first with increasing B concentration x, and shows a maximum value at a certain B concentration, then decreases monotonously with x. This variation of T_c is similar to those of amorphous $Fe_{1-x}B_x$ alloys,[7] in which T_c showed a maximum at about 30 at. % B. The

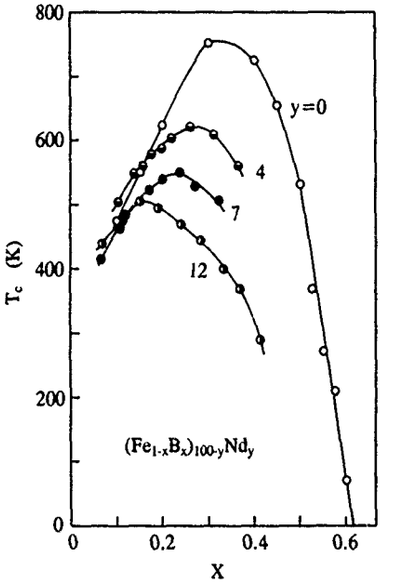

FIG. 1. B-concentration dependence of the Curie temperature T_c of amorphous $(Fe_{1-x}B_x)_{100-y}Nd_y$ alloys with $y=0$ [7] (○), $y=4$ (◒), 7 (●), and 12 (◑).

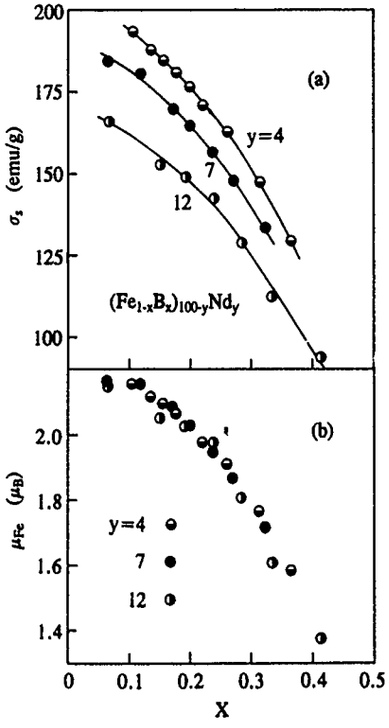

FIG. 2. B-concentration dependence of the spontaneous magnetization $\sigma_s(1.5)$ at 1.5 K (a) and the average magnetic moment μ_{Fe} per Fe atom (b) for amorphous $(Fe_{1-x}B_x)_{100-y}Nd_y$ alloys with $y=4$ (◒), 7 (●), and 12 (◑).

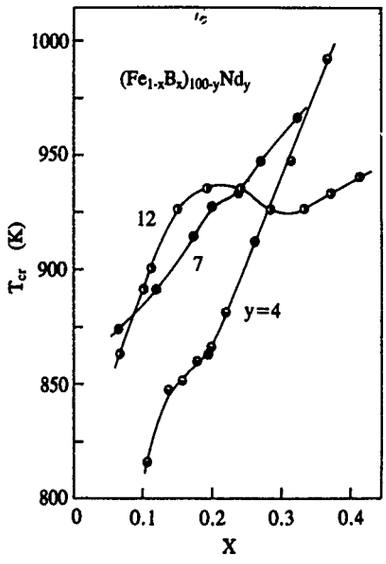

FIG. 3. B-concentration dependence of the crystallization temperature T_{cr} of amorphous $(Fe_{1-x}B_x)_{100-y}Nd_y$ alloys with $y=4$ (◒), 7 (●), and 12 (◑).

maximum value of T_c is found to shift to lower B concentration, when the neodymium is added in the Fe-B alloys. According to the average molecular-field model, the Curie temperature is directly proportional to the exchange integral between magnetic atoms and the number of nearest-neighbor magnetic atoms. The exchange integral of alloys is affected by element species and interatomic distance. For the Fe-rich amorphous Fe-Nd-B alloys, the T_c depends mainly on Fe-Fe exchange interactions. The addition of Nd is found to decrease the T_c of amorphous Fe-B alloys with the same B concentration, as shown in Fig. 1. This implies that the substitution of Nd for Fe would decrease the exchange interactions between Fe-Fe atoms. For $(Fe_{1-x}B_x)_{100-y}Nd_y$, the increase of T_c with x at lower B concentration can be attributed to the increase of the Fe-Fe interaction as a result of the increase in Fe-Fe spacing by the interstitial B atoms. At higher B concentration, the decrease of T_c with x may be due to the decrease of Fe-Fe interactions and the number of Fe-Fe atom pairs.

The magnetization data at 1.5 K were measured for amorphous $(Fe_{1-x}B_x)_{100-y}Nd_y$ alloys at constant Nd concentration. The spontaneous magnetization $\sigma_s(1.5)$ was obtained by fitting the magnetization curves according to the approach to the saturation law,

$$\sigma(H)=\sigma_s(1.5)(1-a/H-b/H^2). \quad (1)$$

The $\sigma_s(1.5)$ as a function of B concentration is shown in Fig. 2(a). The $\sigma_s(1.5)$ is found to decrease monotonously with increasing B concentration x. It has been shown previously that in the amorphous $(Fe_{1-x}Nd_x)_{81.5}B_{18.5}$ and $(Fe_{1-x}Nd_x)_{94}B_6$ alloys by a smooth extrapolation of the $\sigma_s(1.5)$ vs x curves to $x=1.0$, the values of $\sigma_s(1.5)$ of both the $Nd_{81.5}B_{18.5}$ and $Nd_{94}B_6$ are obtained to be 40 emu/g.[6] Therefore, the Nd atom moment is found to be $1.02\mu_B$, which is only about 30% of the moment of a free Nd^{3+} ion ($3.27\mu_B$). This implies the existence of a noncollinear spin structure in amorphous Fe-Nd-B alloys. The fact that the magnetization curves are difficult to saturate, especially at higher Nd concentration, supports the existence of the noncollinear spin structures in the amorphous Fe-Nd-B alloys. The Nd moment is distributed on a cone of half angle θ_{Nd}, which is 112° as calculated from the formula $\mu_{Nd}=(1/2)\mu_{Nd}^{3+}(1+\cos\theta_{Nd})$. It is found that the value of θ_{Nd} in amorphous $Fe_{1-x}Nd_x$ films is 106°–111° as x increases from 0.04 to 0.9.[8] These results demonstrate that in amorphous Fe-Nd-B alloys the Nd moment is slightly influenced by the boron concentration. Accordingly, the θ_{Nd} is roughly constant for all x due to the very strong local random anisotropy of Nd. For amorphous $(Fe_{1-x}B_x)_{100-y}Nd_y$ alloys, if the θ_{Nd} is assumed to be 112°, that is, the Nd magnetic moment is $1.02\mu_B$, the average magnetic moment per Fe atom μ_{Fe} is found to drop monotonically with increasing B concentration, as shown in Fig. 2(b). The decrease of μ_{Fe} with x can be attributed to the decrease of the number of Fe atoms and the coordination of the nearest Fe atoms.

Figure 3 shows the B-concentration dependence of the crystallization temperature T_{cr} measured at a scanning rate of 20 K/min for amorphous $(Fe_{1-x}B_x)_{100-y}Nd_y$ alloys at constant Nd concentration of $y=4$, 7, and 12. The T_{cr} is found to depend strongly on B concentration. The substitution of B for Fe plays an important role in the enhancement of the thermal stability of amorphous Fe-Nd-B alloys. In the samples with $y=4$ and 7, the T_{cr} increases monotonical with increasing B concentration x. For $y=12$, the T_{cr} first increases sharply with increasing B concentration x, it goes through a broad maximum at about $x=0.29$ (17 at % B) to

lower values and then increases again with x. A similar concentration dependence of T_{cr} was observed in amorphous $Fe_{1-x}B_x$ alloys.[9] Previous studies have shown that in many metal-metalloid amorphous alloys T_{cr} exhibits a maximum near the equilibrium eutectic composition. The maximum value of T_{cr} in the $(Fe_{1-x}B_x)_{100-y}Nd_y$ alloys with $y=12$ is exhibited near 17 at % B, which is just the eutectic composition of the ternary Fe-Nd-B system. It is found that the T_{cr} of amorphous Fe-Nd-B alloys studied in this work are 120–210 K higher than those of amorphous Fe-B alloys with the same B concentration. This demonstrates that the thermal stability of amorphous Fe-Nd-B alloys has a remarkable enhancement by the substitution of some Nd for Fe. When a small amount of Nd, having a great affinity to B and its atomic radius being larger than Fe, is added in the Fe-B alloys, the viscosity of the alloy increases and the diffusion coefficient reduces, therefore the thermal stability of the amorphous alloys is enhanced. In general, the ternary amorphous alloys would be more stable against crystallization than the binary ones, and the corresponding crystallization temperature would become higher.

Experimental results are reported on the torsion dependence of bistability of CoSiB amorphous alloys. Switching field and remanence magnetization are measured with applied torsion up to 20π rad/m for as-quenched wire as well as for stress-annealed wire, with and without preannealing. Measurements are performed both for M_z-H_z and M_z-H_ϕ hysteresis loop. The results show that the bistability of Co-rich amorphous wire strongly depends on the torsion-induced helical anisotropy.

I. INTRODUCTION

Bistability of magnetic state of amorphous $3d$ wires makes these systems attractive for applications.[1] In particular, the influence of tension and torsion to the effect is of current interest.[2,3] If magnetostriction is small, remagnetization processes can be very sensitive to actual distribution of local magnetic anisotropy in the wire. Such dependence was found recently[4] in nearly zero-magnetostrictive CoFeSiB amorphous wires. In Co-based wires, magnetostriction is one order of magnitude smaller than in Fe-rich ones. Then, experimental data are needed to evaluate the usefulness of these wires as bistable elements.

Recently, we have reported on the influence of applied tension[5,6] on the hysteresis loop of current annealed cobalt-based amorphous wire. Special attention has been paid to the switching field H^*, namely, the value of the applied magnetic field, for which the bistability takes place. The aim of the present paper is to perform a similar study on the influence of torsion stress on the bistable behavior of the same current-annealed cobalt-based alloy wire previously investigated in Refs. 5,6, in order to establish the mechanisms responsible for the bistability.

II. EXPERIMENTAL TECHNIQUE

Amorphous wires of nominal composition $Co_{72.5}Si_{12.5}B_{15}$ were obtained by means of the in-rotating-water technique by UNITIKA Ltd. Co, Japan. The diameter of wires is 120 μm and its length is 10 cm. The shape magnetostriction λ of this wire is known to be about -3.5×10^{-6}. Hysteresis loops M_z-H_z and M_z-H_ϕ are obtained by conventional induction method with frequency 50 Hz. During measurement, a torsion ζ is applied up to one turn (20π rad/m). Circular magnetic field H_ϕ is produced by ac electric current, flowing along the sample. The values of switching field, due to this current, are calculated at the surface of a wire. More details on the measurement technique are described in Ref. 3.

Two kinds of thermal treatment have been applied: stress annealing with and without preannealing. Both kinds of annealing are by means of electric current. The current of preannealing is 525 mA. Annealing conditions are: stress of 550 MPa, current I_{ann} of 400 or 450 mA. The value 400 mA corresponds to Curie temperature of the alloy (593 K).

III. EXPERIMENTAL RESULTS

Remanence magnetization m_r is found to be very similar for M_z-H_z (Fig. 1) and M_z-H_ϕ experimental data. Also, the data on m_r are almost the same for both annealing currents, 400 and 450 mA. For as-quenched sample, remanence magnetization is remarkably lower, than that for the annealed wire. Both curves saturate with torsion about $\zeta=35$ rad/m. Above this value of ζ, the data on m_r for annealed sample do not depend on annealing time. For lower values of torsion, the differences between the curves $m_r(\zeta)$ for different annealing times are significant only for preannealed samples. There, $m_r(\zeta=0)$ for M_z-H_ϕ experiment shows a maximum with annealing time at about $t_{ann}=15$ min (Fig. 2). For M_z-H_z data this dependence also exists, but its character is not clear.

The torsion dependence of the switching field H^* for the M_z-H_ϕ experiment is regular, almost linear and at first sight

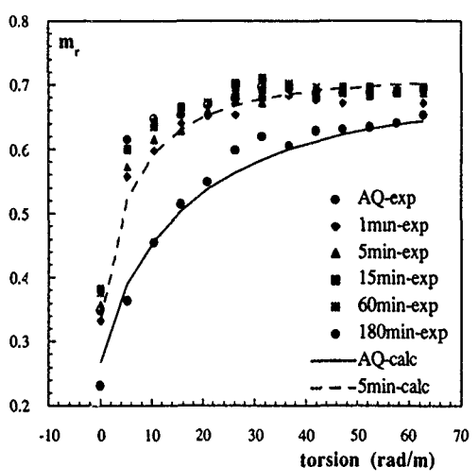

FIG. 1. Remanence magnetization against applied torsion. Annealing current is 400 mA. Experimental data from the M_z-H_z hysteresis loop are compared with calculations according to the paper (Ref. 3). The values of the parameter r_0 are 31 μm (as-quenched) and 35 μm ($t=5$ min).

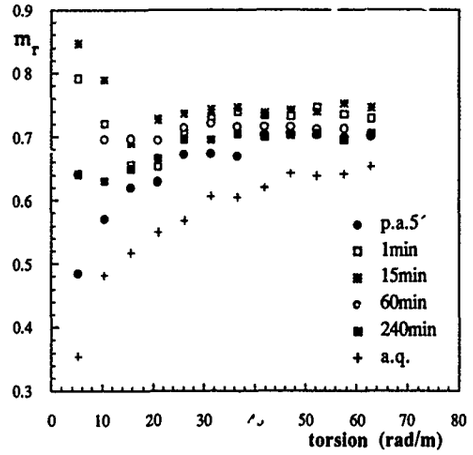

FIG. 2. Remanence magnetization for preannealed wire, measured in M_z-H_ϕ experiment, for I_{ann}=450 mA.

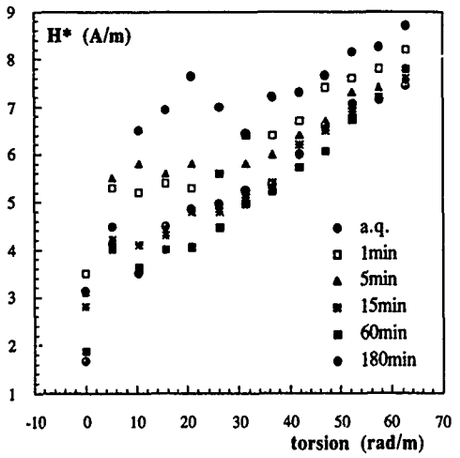

FIG. 4. Switching field from M_z-H_z measurement, against torsion, for I_{ann}=400 mA.

does not depend on thermal treatment (Fig. 3). The slope of the curve $H^*(\zeta)$ is slightly reduced with torsion only for short annealing times. For M_z-H_z experiment, the switching field H^* for I_{ann}=400 mA decreases with annealing time. For I_{ann}=450 mA the dependence $H^*(\zeta)$ does not change with t_{ann}. On the contrary, for as-quenched wire this curve shows a maximum at about ζ=21 rad/m (Fig. 4). For I_{ann}=400 mA we can observe how this maximum is shifted towards smaller values of applied torsion, when annealing time increases. For I_{ann}=450 mA this maximum is visible only for as-quenched wire (Fig. 5). The values of H^* for the M_z-H_ϕ experiment are close to those for the M_z-H_z one.

IV. DISCUSSION

Experimentally observed difference between remanence magnetization m_r for as-quenched sample and annealed samples (Fig. 1) indicates that for as-quenched sample a kind of instability of amorphous structure is present. Its existence is confirmed by the maximum of switching field H^* in M_z-H_z experiments. In the case of H^*, this instability can be removed in a continuous way by annealing in Curie temperature, or immediately by annealing in higher temperatures. In the case of m_r, the effect disappears immediately even for short annealing time and I_{ann}=400 mA. This indicates that the switching field is much more sensitive to the details of local distribution of magnetization in the region between inner core and outer shell. The same effect, but much more strong, was found recently[4] in nearly zero-magnetostrictive amorphous wires.

Thermal treatment changes magnetic softness and initial (ζ=0) value of remanence magnetization. But, as ζ increases, torsion-induced helical anisotropy is expected to stabilize the radius of inner core and the spatial distribution of internal stresses. To describe the effect of torsion on remanence magnetization, we approximate the distribution of the density of magnetic anisotropy within the wire by a function

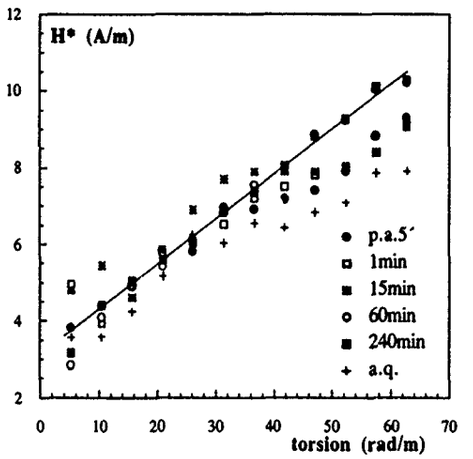

FIG. 3. Switching field from M_z-H_ϕ measurement, for I_{ann}=450 mA, with preannealing. The data for t_{ann}=240 min are fitted with straight line.

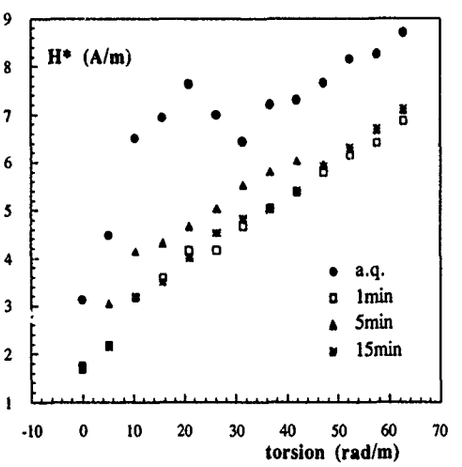

FIG. 5. Switching field from M_z-H_z measurement, without preannealing, for I_{ann}=450 mA.

$$k(r)=k_0[1-(r/r_0)^n],$$

where k_0 is the density of anisotropy at the wire axis, r_0 is the initial ($\zeta=0$) value of the radius of inner core, and n is a parameter introduced to describe the shape of the function $k(r)$. This parametrization was found to be useful[6] to describe the tension dependence of bistability in the wire with the same composition. With this function, remanence magnetization can be calculated[3] as an average of the cosine of local magnetization with the wire axis. Actually, we get good accordance with experimental data, applying the same values of the parameters k_0 and n, which were found previously[6] from tension dependence of m_r and H^* ($k_0=-1575$ and -1785 MPa, $n=0.4$ and 0.2 for as-quenched wire, and for $t_{ann}=5$ min, respectively). However, the fitting values of r_0 are changed (example giving, from 24 to 31 μm for as-quenched wire). The results of the calculations are presented in Fig. 1. These values indicate that reduced remanence magnetization is remarkably larger than the ratio of the volume of inner core to the volume of a wire.

The torsion dependence of switching field is known[3] to be dominated by torsion-induced helical anisotropy $k\zeta$. The order of magnitude of both densities of magnetic anisotropy, $k(r)$ and $k\zeta$, is the same in the average over the volume of a wire. However, the latter dominates near $r=r_0$, where nucleation processes occur. These processes are known to determine the value of switching field for the propagation mechanism.[7] Still, our measurements of H^* can hardly be fitted by a square root of torsion-induced anisotropy. This difficulty is particularly clear for long annealing times (Fig. 3). Additional enhancement of the curve $H^*(\zeta)$ for higher values of torsion can be produced by the torsion-induced canting of local magnetic moments by an angle α. In such a case, appropriate expression for switching field is known[8] to contain the multiplying factor $(\cos\alpha)^{-1/2}$. According to our evaluations, this correction is of order of 3%.

The values of switching field measured from the M_z-H_ϕ hysteresis loop should be evaluated at the radius of inner core. This radius cannot be determined accurately. However, any reasonable estimation gives the value of H^* lower, than this one for M_z-H_z experiment. More detailed discussion on this difference for nearly zero-magnetostrictive wires is given elsewhere,[4] and those arguments are valid only partially for the nonzero-magnetostrictive system, which is discussed in this paper. Here we would like to state only, that these differences are expected to be enhanced by helical magnetization in the region between inner core and outer shell.

Concluding, measurements of torsion dependence of bistability in Co-rich amorphous wires indicate that the domain structure of a wire is stabilized by torsion. Switching field measured from the M_z-H_z hysteresis loop is found to be sensitive to local magnetic state of the boundary between inner core and outer shell. Outer shell gives remarkable contribution to remanence magnetization.

We report measurements of the intensity and position of the satellites arising from the helimagnetic structure of Ho in 1.4 and 3 T *b*-axis magnetic fields. There are a number of lock-in effects at commensurate values of the spiral wave vector τ; here we report on those in the temperature range 115–132 K. We confirm our previous observation of the lock-in at $\tau=5/18$ between 125 K and the Néel temperature (132 K). We have discovered a two-phase region in which the 5/18 phase coexists with an incommensurate phase. In this two-phase region, the proportion of the 5/18 phase increases with temperature from onset at 119 K to full lock-in at 125 K. The existence of this two-phase region may have significant influence on interpretation of the magnetic phase diagram.

There is, by now, a large body of results obtained using neutron scattering to study the magnetic phases of holmium,[1–9] in addition to research with ultrasonic,[10–12] magnetization,[13] specific heat,[14] x-ray,[15,16] and dilatometric[17–19] techniques. Yet there is much that is undiscovered about the magnetic structure of this rare earth metal. Our recent studies[6–8] have focused on the lock-in behavior of the spiral wave vector τ. In a *c*-axis magnetic field we have discovered lock-ins at commensurate values of $\tau=1/5$ and 1/4 reciprocal lattice units (rlu) at 43 and 96 K, respectively. Investigations[8,9] in a *b*-axis field have shown lock-ins at $\tau=1/4$ rlu, and a higher temperature lock-in at $\tau=5/18$ rlu at about 125 K which persists up to the Néel transition. It is interesting to note that this value of 5/18 also appears to be the ultimate value reached in zero field, or *c*-axis fields up to 3 T.[5] In this case, however, the width of any commensurate region must be small as it has, so far, evaded detection. There are also intensity anomalies of the (10τ) peaks at the boundaries of these locked-in regions that have not yet been explained. The work reported here concentrates on the temperature region from 115 K to the Néel transition in 1.4 and 3 T *b*-axis magnetic fields. We have refined our earlier observation of the lock-in at $\tau=5/18$ rlu and have also observed an anomalous intensity variation as the lock-in is approached. We have found evidence that, before full lock-in is achieved, there is a temperature region in which two phases coexist; one with an incommensurate value of τ and the other commensurate (at $\tau=5/18$ rlu). We find, based on these and previous measurements, that this effect is not caused by inhomogeneity of the applied field or in the sample. A two-phase region enables us to interpret the meaning of phase boundaries previously observed[13] in the phase diagram.

The experiments were performed at the Chalk River Laboratories of AECL Research in Chalk River, Ontario, using the *N*5 triple-axis neutron spectrometer. The measurements were made at zero-energy transfer (elastic scattering) with the monochromator set to an energy of 8.2 THz. The sample, a single crystal of holmium with dimensions roughly 2×1×1 cm, was mounted in the *M*2 cryostat[20] that allows 350° access for the neutron beam and a temperature range from 4.2 K to room temperature. The sample orientation was such that we could observe $(h0l)$ reflections. The temperature was read and controlled with a platinum resistance thermometer mounted in the base of the probe (the temperatures were high enough that magnetoresistance effects in the thermometer were negligible).

The helimagnetic structure of holmium below the Néel transition is generally incommensurate with the period of the lattice, with a temperature-dependent wave vector τ. Thus, a τ of 1/4 rlu represents four lattice units along the *c* axis in real space before the structure repeats. The magnetic satellites are a distance $\pm$"τ" rlu in the c^* direction away from the nuclear scattering peaks in reciprocal space. All of the peaks move in reciprocal space as the temperature changes, because of thermal expansion. We therefore measured τ as the distance between the nuclear peak at (100) and its satellite at (10τ). The (100) peak and the satellite at (10τ) were scanned in the c^* direction. Gaussian fits were made to the peaks, and the difference between the centers of the peaks yielded our value for τ. The fits to the centers of the peaks show a standard deviation of 0.0001 rlu and we estimate our absolute values of τ to be good to $\pm$0.0005 rlu. τ generally varies smoothly with temperature, but in a magnetic field the temperature dependence decreases as τ locks in at certain commensurate values.

The lock-in studied here extends from the Néel temperature down to a lower, field-dependent temperature which is 125 K in a 3 T *b*-axis field. This is the first known transition from a paramagnetic phase directly to a commensurate phase observed in a rare earth metal. Some previous work[4] had suggested that this lock-in occurred with $\tau=8/29=0.2757$ rlu but our measurements[9] have previously indicated that the correct τ value for this lock-in is $5/18=0.2778$. Our latest results, shown in Fig. 1, confirm that 5/18 is indeed the lock-in value and that 8/29 is outside the error range. We have also observed this lock-in in a 1.4 T *b*-axis field. The temperature region where the lock-in occurs in 1.4 T is smaller, since the energy gained by transition to the commen-

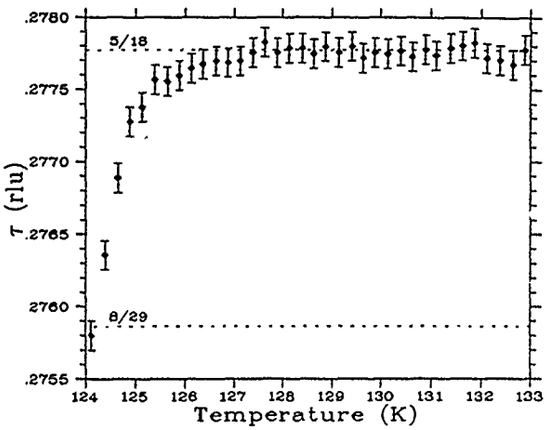

FIG. 1. τ vs temperature in a 3 T b-axis applied magnetic field. τ values of 5/18 and 8/29 are shown by dashed lines. These data clearly support a lock-in at τ=5/18.

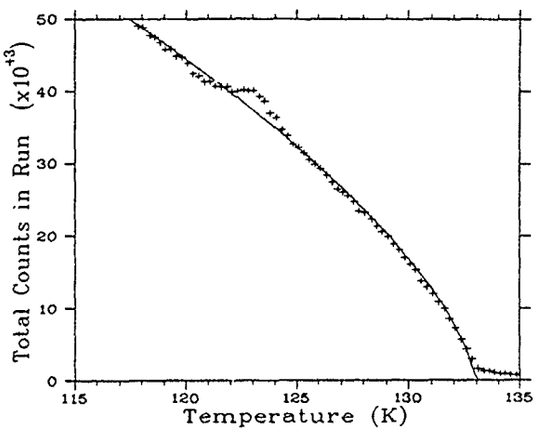

FIG. 3. A plot of total counts in each run vs temperature. The curve is a fit to $A(1-(T/T_N))^{2\beta}$, with β=0.327 and T_N=132.9 K. The anomaly in the two-phase region has some similarity to that seen on entering other locked-in regions.

surate structure is smaller in the lesser field. The ratio of the temperature widths at 3 T and 1.4 T (7 K/1.5 K) is equal to the square of the ratio of the fields (3 T/1.4 T)^2. The τ value at lock-in is still very close to 5/18 rlu in 1.4 T b-axis field.

Figure 2 shows that the peak widths arising from fits to the (10τ) peak with a single Gaussian have a curious feature. Outside the 119–125 K range, the full width at half maximum (FWHM) of both the (10τ) and the (100) peaks are stable at 0.0072 rlu. However, inside this temperature region the width of the (10τ) peak rises strongly while the width of the nuclear (100) peak stays constant. The intensity of the (10τ) satellite also shows an anomaly here (Fig. 3). This is similar to intensity variations we nave found at the boundaries of other lock-in regions. The smooth curve, of a critical exponent form, in Fig. 4 shows the anomaly clearly: the fit is good everywhere except in the 119–125 K range. If we look at the single Gaussian fit to the scan (shown by the dashed line in Fig. 4) we see that it is clearly lopsided. This led us to believe that a two-Gaussian fit might be more suitable: If this widening arises from the coexistence of two phases with different τ's, then a two-Gaussian fit is a more appropriate representation of the physical situation. The width of each of the two Gaussians should then be the same as that outside the two-phase region (0.0072 rlu). We also assumed that, rather than having two coexisting incommensurate phases, one of the phases should be commensurate, because of the proximity to the commensurate lock-in at τ=5/18 rlu. We therefore fixed the position of one peak at τ=5/18 rlu and allowed the other, incommensurate, peak to move (from an initial value of τ=0.2668 rlu to 5/18). These restrictions reduce the number of parameters in the fitting procedure to the same number that were used previously with the single-Gaussian fit. The solid line in Fig. 4 shows that the two-Gaussian fit to the data is, indeed, much better than the single-Gaussian fit. The in-

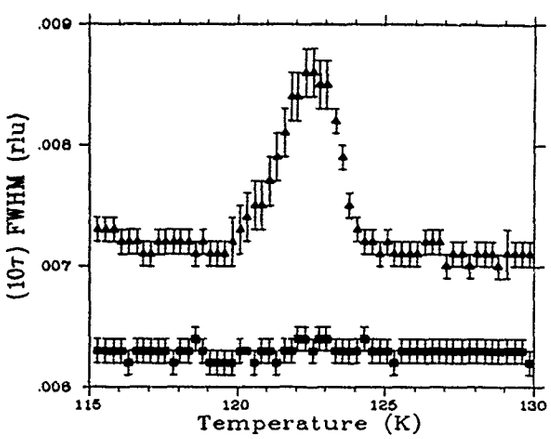

FIG. 2. The full width at half maximum vs temperature for the (10τ) satellite peak (▲) and the (100) nuclear peak (■), using a single Gaussian fit in a 3 T b-axis field. Notice the sharp rise in apparent width of (10τ) in the two-phase region. The data for (100) have been displaced downwards by 0.001 rlu, for clarity.

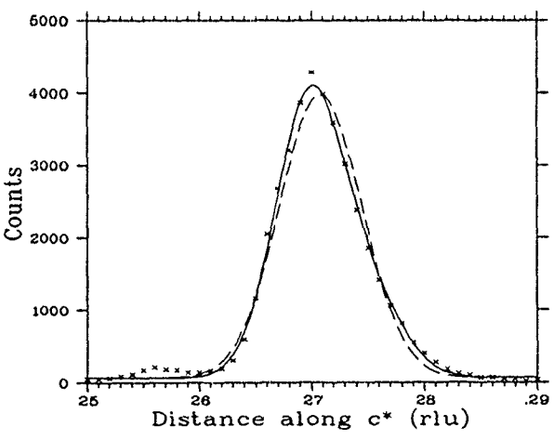

FIG. 4. The dashed line shows a single-Gaussian fit to the (10τ) peak in the two-phase region at 122.3 K. Notice the lopsidedness of the fit. The solid line shows a two-Gaussian fit to the same data. Although the number of free parameters remains the same, the result is a far better fit. At this temperature the peaks are separated by only 0.005 rlu.

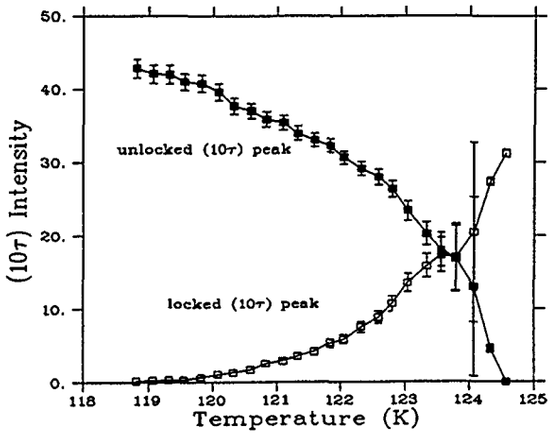

FIG. 5. Intensity of the unlocked (10τ) peak (■) and the intensity of the locked (10τ) peak (□) vs temperature over the two-phase region.

tensities of the commensurate and incommensurate phases are shown in Fig. 5. The intensity of the locked-in phase increases smoothly up to 125 K while that of the incommensurate phase decreases in a similar manner, disappearing rapidly at 125 K. In the region above 123.6 K (where the incommensurate peak is very close to the commensurate value and becoming very weak) the fits to the individual peaks become quite uncertain although, of course, the total is fitted well.

We had some doubt as to whether or not this two-phase region is genuine or is merely a result of an inhomogeneous internal magnetic field in the sample. By measuring the slope of the coexistence curve on the b-axis field phase diagram (Fig. 4 of the paper by Willis *et al.*[13]) near 125 K and 3 T, we found that the field would have to vary by at least 10% over the volume of the sample to give a two-phase region that was 5 K wide. However, the applied field profile varies by less than 2% over the sample volume so this, in itself, cannot account for the effect. Another possibility is that the irregular shape of the sample leads to internal field inhomogeneity. Supposing that it did, and noting that Willis *et al.*[13] show [in their Fig. 2(b)] that the magnetization does not change significantly between 100 and 125 K and that the magnitude of the slope of the coexistence curve at the $\tau=1/4$ rlu lock-in is very similar to that at 125 K and 3 T, the same field inhomogeneity would give the same 5 K distribution in phases at the two different temperatures. This would completely smear out the $\tau=1/4$ lock-in, which is not the case.[9] Thus, internal field inhomogeneity cannot account for the two-phase region. This also demonstrates that the demagnetization factors arising from sample shape are negligible. However, there remains the possibility that this two-phase region is a sample-dependent feature, as has so often plagued experiments in the rare earths. Further experiments to investigate this region, with other samples, are desirable.

In summary, the measurements reported here allow us to identify one of the phases previously observed and reinterpret the b-axis magnetic phase diagram in this region, as a new phase is present in the 120–125 K region at 3 T. There may be a splitting of one of the coexistence curves as seen earlier for the c-axis phase diagram.[5,6]

Magnetic critical neutron scattering from a single crystal of Cr+0.18 at. % Re[1] was observed above its Néel transition (323 K) to an incommensurate spin density wave state. The data were analyzed in terms of the critical susceptibility model that successfully fit analogous data from single crystals of pure chromium and Cr+0.2 at. % V.[2] An additional complication in this case is the fact that a small portion of the sample becomes commensurate antiferromagnetic at a temperature well above 323 K, which causes a commensurate magnetic Bragg peak that partially obscures the critical scattering near 323 K. The "Sato-Maki" [2] form of incommensurate critical susceptibility fits the data reasonably well.[3] The intensity of magnetic critical scattering in Cr+0.18 at. % Re is about a factor 2 stronger than in pure Cr, whereas in Cr+0.2 at. % V it is about the same factor weaker.

Photoinduced disaccommodation of magnetic permeability in yttrium iron garnet (abstract)

I. Matsubara, K. Hisatake, and K. Maeda
Department of Physics, Kanagawa Dental College, Yokosuka, Kanagawa 238, Japan

After illuminating a single crystal of yttrium iron garnet grown by a modified floating zone method at 77 K, the complex permeability was measured from 77 to 300 K under low alternating field. As well as the decreasing of permeability and the appearance of a peak in μ''-T curve, disaccommodation (DA) or the change of permeability with time was found to be induced around 140 and 210 K. As the result of the superposition of disaccommodation, the peak in the μ''-T curve is observed to be divided. These photoinduced magnetic effects cannot be attributed to a single origin, for only photoinduced DA disappears in the process of warming. The origins are discussed and a model is proposed, taking account of the mobility of oxygen vacancy depending on the charge state and the photoexcited electron.

K. Kishio
Department of Industrial Chemistry, University of Tokyo, Bunkyo-ku, Tokyo 113 Japan

$Bi_2Sr_2CaCu_2O_8$ crystals were irradiated with heavy ions (Pb, Xe) to produce columnar defects along the c direction or at 45° with respect to it. We describe the dependence of the critical currents, irreversibility fields, pinning force, and magnetic relaxation rates on the dose and on the type of ions. The irreversible properties of the Pb-irradiated samples are more enhanced than those of the Xe-irradiated sample at low temperatures, and vice versa at high temperatures. At low temperatures the efficiency of the columnar defects is enhanced with the ion dose but, at high temperatures, the maximum dose (2.5×10^{11} ions/cm^2) is less efficient than intermediate doses. The unidirectional nature of the columnar pinning centers serves to demonstrate that the vortices maintain linelike features. For most of the irradiated samples, the pinning force density data are reduced to a single curve below 45 K. The relaxation rates at low temperatures reflect thermal reduction of the effective pinning barriers.

I. INTRODUCTION

$Bi_2Sr_2CaCu_2O_8$ (BSCCO) is characterized by weak flux pinning even relative to other high-temperature superconductors (HTS). This is reflected in its low critical currents and low irreversibility fields,[1] which hinder high-current applications. Therefore, the possibility of enhancing the pinning force is important not only for studying the flux properties, but also as an indication of the possibility of reaching critical currents that will enable high-current applications. BSCCO is also one of the most anisotropic compounds among the known cuprate HTS, due to the weak coupling between the Cu-O layers. The effect of the coupling on the vortex properties is still debated. In particular, it is still unclear in what range of field and temperature the coupling is important and the vortices are linelike, and at what range the coupling can be neglected and the vortices are two dimensional "pancakes".[2] References 3–15 list some of the experimental works dealing with this issue.

Columnar defects are now a common probe for studying flux properties in HTS.[12–20] These defects, induced by heavy-ion irradiation, have several advantages. Columnar defects are very efficient pinning centers; thus their effect indicates how much the pinning force may be artificially enhanced. In addition, these defects are oriented and it is possible to distinguish between linelike vortices and pure two-dimensional pancakes by looking for the dependence of pinning properties on the angle between the applied field and the defects.[13–15] Linelike vortices are most efficiently pinned when they are oriented along the defect, and tilting them away from the defects should decrease pinning. On the other hand, no angular dependence is expected for two-dimensional pancakes, since the density of pinning centers in each Cu-O plane is what matters, and the correlation of pinning centers at different planes is not relevant. Thus, important information concerning the vortices dimensionally may be obtained by studying the angular dependence of the pinning properties.[13–15]

In previous works[13–15] we have demonstrated the unidirectional nature of the columnar defects in BSCCO via the hysteresis loops, $M(H)$. Typical results are shown in Fig. 1. The figure describes the evolution of the unidirectional pinning with temperature via the difference between the hysteresis loops recorded for field in the direction of the columnar defect (+45°) and for the field perpendicular to it (−45°) for sample B3 (see Table I). We find that the magnetization is largest for fields applied along the defects and conclude that this unidirectional pinning indicates the linelike nature of

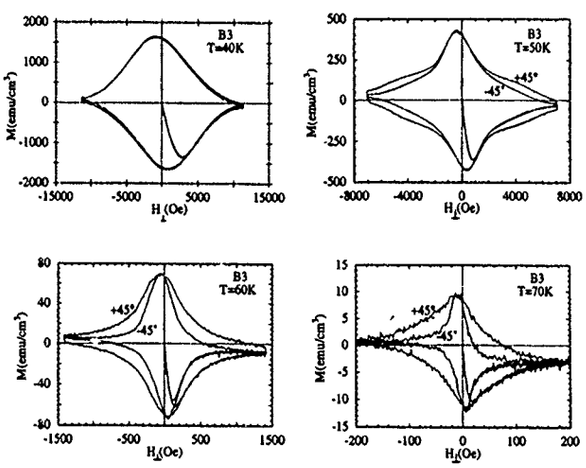

FIG. 1. Magnetization curves for sample B3 with the applied field at ±45° relative to the c direction at 40, 50, 60, and 70 K.

vortices in BSCCO. In this article we pursue these previous works and describe extensive magnetic measurements on BSCCO crystals irradiated with Pb or with Xe ions. We report on (i) the dependence of the critical current and (ii) the dependence of the irreversibility line on the dose and on the type of irradiation; (iii) the scaling properties of the pinning force density; (iv) the angular dependence of J_c and the irreversibility line; and (v) a preliminary study of relaxation of the remanent magnetization.

II. EXPERIMENT

The measurements were performed on BSCCO crystals irradiated with 5.8-GeV Pb ions or 6-GeV Xe ions along the c direction or at 45° with respect to it. Irradiation was carried out at the Grand Accelerateur National d'Ions Lourds (GANIL, Caen, France). The Pb ions produce *continuous* columnar defects along their paths. The Xe ions did not produce columnar defects, but only clouds of clusters dispersed around the ion trajectory. In the case where the diameter of these clouds is smaller than the distance between two neighboring ion trajectories, the Xe ions tracks act as correlated disordered defects.[21] All our measurements were performed on an Oxford Instruments vibrating sample magnetometer (VSM). The sample preparation is described in Ref. 22. The transition temperature $T_c=85$ K of the unirradiated samples is reduced by less than 0.5 K after irradiation. Table I lists the samples under investigation, their dimensions, and the details of ion irradiation.

III. RESULTS AND DISCUSSION

A. Critical currents

The critical currents were estimated from the width of the magnetization curves, using the Bean model[23] for rectangular samples.[24] The main response of the sample magnetization is in the Cu-O planes, i.e., the response due to $H_\perp$ (the component of the field perpendicular to the planes). Therefore, in comparing magnetization curves with the applied field at different angles relative to the c direction, we use $H_\perp$ values. Figure 2(a) shows the critical current J_c as a function of temperature, at a constant field $H_\perp=0.75$ T, applied along the defect, for the BSCCO crystal under investigation. Note that $H_\perp$ is larger than the self-field[25] $H_s\approx J_c d$ (d is the shortest dimension of the sample), in order to avoid uncertainties in determination of J_c. The figure shows that (I) the critical current increases with the dose and (II) the Pb irradiation is more efficient in enhancing J_c than the Xe irradiation. As we show below, these two observations hold only below 50 K.

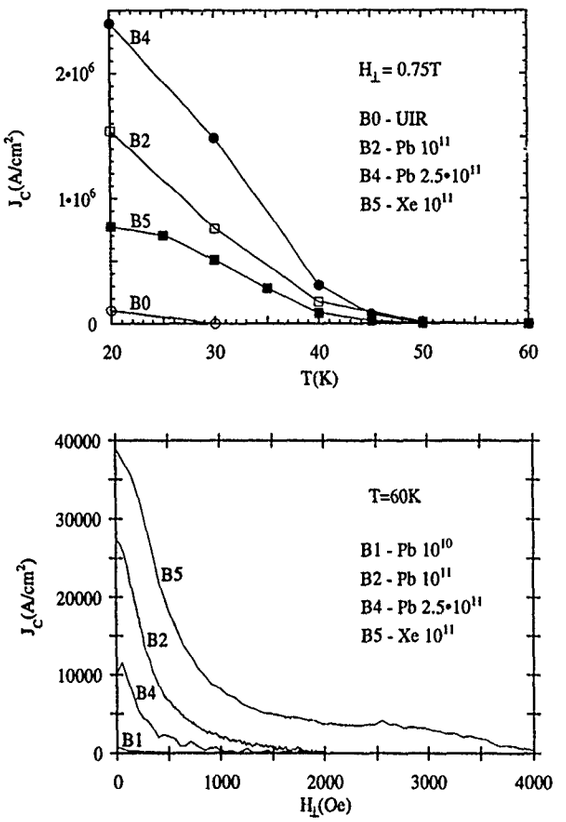

FIG. 2. (a) The critical current density as a function of temperature at $H_\perp=0.75$ T for various samples. (b) The critical current density at $T=60$ K as a function of magnetic field for the irradiated samples.

Figure 2(b) shows the critical current as a function of field, for the isotherm $T=60$ K, for irradiated BSCCO crystals. We note that H_s at 60 K in these samples is not larger than 300 Oe. At this temperature, J_c of sample B4 (Pb-irradiated, 2.5×10^{11} ions/cm^2) is smaller than that of B2 (Pb, 10^{11}). Also, it is apparent that the critical current of sample B5 (Xe-irradiated, 10^{11}) is higher than the critical current of all other irradiated samples. Thus, at approximately 50 K there are two crossover phenomena: first, in the efficiency of the columnar defect, the maximum dose becomes relatively less efficient at high temperatures; second, in the efficiency of the defects created by the Xe irradiation: at low temperatures, columns produced by Pb ions are more efficient in flux trapping than defects produced by Xe ions, whereas at high temperatures the reverse situation is observed. Insight into these phenomena is obtained from the analysis of the irreversibility line and the pinning force density, which follows below.

B. Irreversibility line (IRL)

The irreversibility field was determined from the hysteresis loops with a criterion of $J_c<100$ A/cm^2. Figure 3 shows the irreversibility field as a function of temperature for different doses and types of irradiation. Note that in this figure

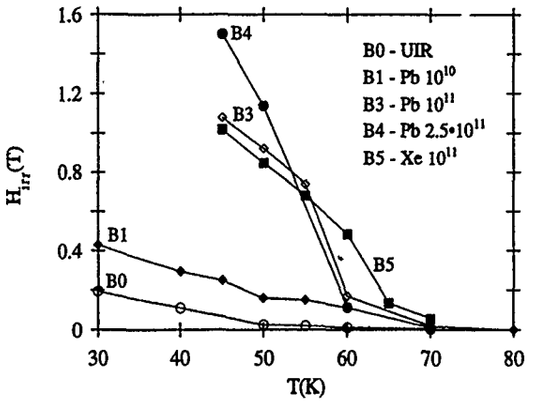

FIG. 3. The irreversible field H_{irr} as a function of temperature for various samples.

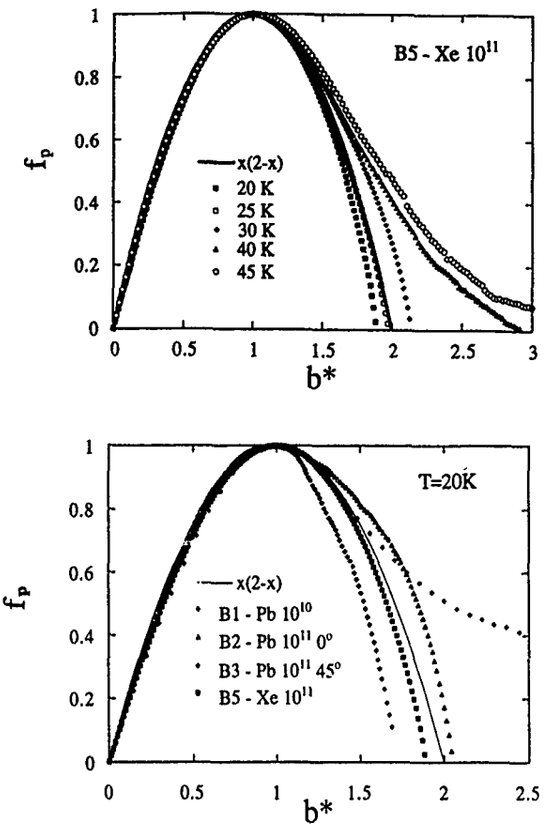

FIG. 4. (a) The rescaled pinning force density $f_p = F_p/F_{p,max}$ as a function of the reduced field $b^* = H/H_{max}$, for sample B5 at various temperatures. The solid line denotes the function $b^*(2-b^*)$. (b) The rescaled pinning force density $f_p = F_p/F_{p,max}$ as a function of the reduced field $b^* = H/H_{max}$, for various irradiated samples at $T = 20$ K. The solid line denotes the function $b^*(2-b^*)$.

we present the IRL of sample B3; the IRL of sample B2 (the same dose but irradiated in the c direction) is almost the same. The irradiation shifts the irreversibility field upwards in a significant way. At low temperatures, the shift is more pronounced for higher doses of irradiation. However, at temperatures above 55 K this is not the case. Between 50 and 60 K there is a crossing of the irreversibility lines of the samples irradiated by Pb ions with doses of 10^{11} and 2.5×10^{11} ions/cm^2 (samples B3 and B4, respectively). This crossover indicates that there is an optimum irradiation dose of Pb ions at high temperatures above which the critical current becomes smaller.

The crossover can probably be related to a transition between two mechanisms of nonlogarithmic creep processes. It was theoretically shown[26] that a creep process in the presence of columnar defects is governed by a nucleation motion of vortex lines. Such a motion can be realized by two different mechanisms. At a low density of columnar defects, when the transverse localization length of a vortex line $L_\perp$ is smaller than d_r, the averaged distance between the columnar defects, the creep process is dominated by the motion of vortex lines to the bulk after being liberated from the columnar defect. At high density of columnar defects, when $L_\perp$ is comparable with d_r, the creep process is dominated by a motion of flux lines via a sequence of hops from one columnar defect to an adjacent one. The increase of columnar defects density results therefore in a suppression of the effective barrier for flux creep and in the enhancement of the relaxation rate. The crossover temperature between the two processes depends on the density of defects and occurs at lower temperatures for the larger dose. This crossover in the flux-creep process, which was identified experimentally[27] in BSCCO crystals with columnar defects, is probably responsible for the crossovers of J_c and of the IRLs between samples B3 and B4.

Another interesting feature apparent from Fig. 3 is the crossing of the IRLs of the Xe-irradiated sample (B5) and those of the Pb-irradiated samples (B3 and B4) at 55 K. At low temperatures the IRL of the Xe-irradiated sample (B5) follows the IRL of the sample irradiated by Pb ions with the same dose (10^{11}, B3). At 55 K, however, the IRLs of the Pb-irradiated samples decrease rapidly whereas the IRLs of the Xe-irradiated sample decrease quite slowly with T. This indicates that the efficiency of columnar defects produced by the Pb ions decreases strongly at high temperatures. Also, the irreversibility lines of all the samples irradiated by Pb ions tend to converge at the high-temperature regime of the irreversibility line. This convergence, first observed by Hardy *et al.*,[28] provides another indication of the rapid decrease, at high temperatures, of the efficiency of the defects produced by the Pb ions. The surprising observation that the IRL of the Xe sample (B5) decreases more moderately than that of the Pb samples suggests that a new pinning mechanism becomes dominant at high temperatures in the Xe-irradiated sample.

The difference between the irradiation by the Pb and Xe ions can provide an explanation for the above observations. Since the Xe ions produce only clouds of dispersed anisotropic defects, while the Pb ions produce continuous defects, we expect that at low temperatures the Pb irradiation provides more efficient defects. At high temperature, however, vortices start to wander inside and between the clouds. Above some threshold temperature, when the mean amplitude of thermal fluctuations becomes larger than the spacing of clusters within clouds, the defects created by the Xe irradiation become equivalent to columnar defects with the diameter of the clouds.[21] The efficiency of these columnar de-

fects at high temperatures is higher than those of the columnar defects created by the Pb ions, since the diameter of the clouds seems to be larger. We suggest, therefore, that the origin of the new pinning mechanism in the Xe-irradiated sample is the columnarlike defects created at high temperatures.

C. Density of the pinning force

Figure 4(a) shows F_p as a function of H (we assume that $H \approx B$) for sample B5, irradiated by Xe ions. The data are presented in the normalized coordinates $f_p = F_p/F_{p,\max}$ vs $b^* = H/H_{\max}$, where $F_{p,\max}$ is the maximal value of F_p, and $H_{\max}$ is the value of H at $F_{p,\max}$. The figure demonstrates that below $H_{\max}$ the data for all isotherms below 45 K can be reduced to a single curve. The scaling of the pinning force density for the irradiated samples at temperatures below 45 K indicates that a single dominant pinning mechanism is involved.[29,30]

The general shape of the curves for $T<45$ K closely resembles the parabola $f_p(b^*)=b^*(2-b^*)$. A similar function (though with H_{c2} as the scaling field) has been analytically derived and used for samples with $\Delta\kappa$ pinning of volume defects.[30] Different functional forms of $f_p(b^*)$ were recently identified in unirradiated and proton-irradiated $YBa_2Cu_3O_7$ (YBCO) crystals.[31,32] The difference in the scaling functions is clearly consistent with the difference in the pinning size (point or cloud) taking place in these systems.

The similarity in the functional form of the curves is lost for large fields at $T>40$ K: the pinning force density does not drop sharply to zero, as is the case for $T<40$ K, but rather decreases slowly so that a "tail" originates at high fields [see Fig. 4(a)]. For even higher temperatures the scaling in the range $H<H_{\max}$ also breaks down.

A similar scaling was also found in the other irradiated crystals (B1, B2, and B3), at low temperatures. This is demonstrated in Fig. 4(b), which shows f_p vs b^* for the samples B1, B2, and B3 together with B5, at $T=20$ K. The scaling in the range $H<H_{\max}$ is clearly evident. The general shape of the curves, except for sample B1, follows the function $f_p(b^*)=b^*(2-b^*)$. At higher temperatures, however, the $f_p(b^*)$ curve develops a tail in the large-field regime, and as the temperature is further increased the scaling in the low-field regime does not hold any more. It is interesting to note that both the unirradiated sample and the sample with the largest dose of irradiation (B4) do not exhibit the scaling discussed above.

The absence of the scaling of the pinning force at temperatures higher than 45 K can possibly be related to the appearance of a tail in the pinning force density curve at high temperatures ($T>45$ K). A tail in the pinning force density was recently observed in irradiated YBCO crystals,[32] and was attributed, using flux creep models, to an increase in the thermal activation. We suggest an alternative explanation, namely that a different pinning mechanism starts to be important for $T>45$ K. This possibility is consistent with the increase of the critical current of the sample irradiated by Xe ions in comparison to the rapid decrease of the J_c of the samples irradiated by Pb ions, at high temperatures [see Fig. 2(b)].

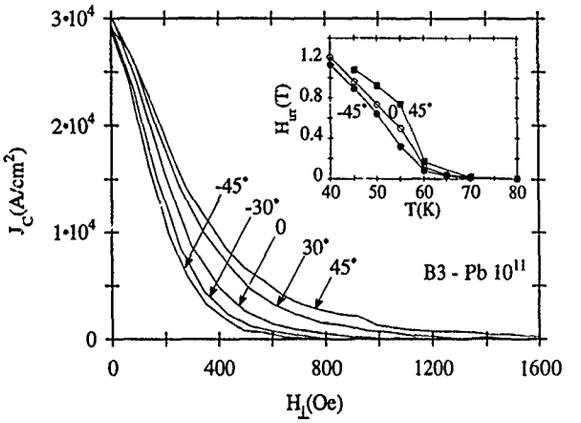

FIG. 5. The critical current density of sample B3, at $T=60$ K, as a function of $H_\perp$ for different field directions. Inset: The irreversible field H_{irr} as a function of temperature for sample B3 for different field directions.

We note that there are several difficulties in our attempt to obtain information from the functional form of $f(b^*)$. First, the scaling holds only up to $H_{\max}$, and deviations from scaling are observed at high fields. Second, the functional form to which we compare $f(b^*)$ was derived for low-temperature superconductors, for which the scaling field is the upper critical field H_{c2}. Further study is therefore needed in order to establish the relevance of the functional form of $f(b^*)$ to the pinning mechanism in HTS.

D. Angular dependence

The angular dependence of J_c is described in Fig. 5, which shows the critical currents of sample B3 for different angles between the field and the columnar defects. The maximum critical current is obtained for the external field in the direction of the defects (45°), thus demonstrating the unidirectional nature of J_c.

Another demonstration of the unidirectional features is provided in the inset of Fig. 5, which shows the dependence of the irreversibility field on the direction of the field relative to the defect. It is clear that the irreversibility field decreases as the angle between the field and the defect increases. This is a clear indication of the presence of coupling between the layers, which yields the possibility of tilting vortices by an external field; without this coupling the component of the field parallel to the planes penetrates freely and no tilting is possible.[14,15] At low temperatures, it might be quite difficult to observe unidirectional pinning.[15] However, a closer look reveals angular dependence also in this temperature regime.

E. Relaxation

In this section we present preliminary results on relaxation measurements for Pb-irradiated samples. In these measurements the sample is cooled in the presence of a field of 1.6 T. The field is then turned off and the relaxation is measured. The results should be treated with caution due to the possible effect of self-fields in this procedure. However, the consistency of results of different shapes implies that the effect of self-fields is not dominant. Moreover, we wish to

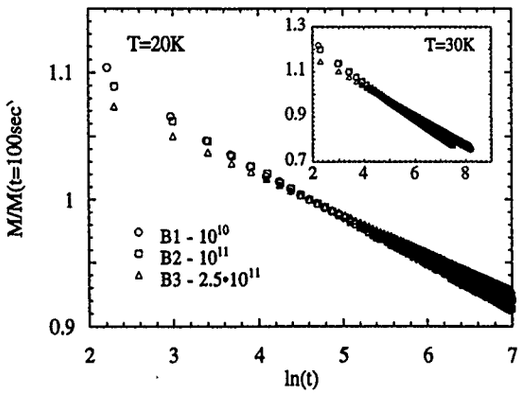

FIG. 6. The magnetic relaxation for the Pb-irradiated samples at $T=20$ K and 30 K (inset). Note: The magnetic moment was divided by its value at $t=100$ sec in order to compare data obtained from different samples.

compare our results to other reports[20] in which relaxation at zero field was used. At low temperatures, the relaxation of the irradiated samples in the experimental time window are logarithmic with time. We thus can extract the effective barrier by using $U=kT/(d \ln M/d \ln t)$ and neglect corrections of the interpolation formula. The effective barriers that are extracted from these relaxation rates show a strong decrease as temperature is increased. In Fig. 6 we present the logarithmic relaxation of the remanent magnetization in irradiated samples for 20 and 30 K (inset). It is apparent that at constant temperature the relaxation rates at the various samples are very similar (see an example in Table I), although there are apparent differences in the magnitude of the magnetization. A similar result of converging effective barriers for samples with different irradiation was obtained by Gerhauser *et al.* at $T=10$ K.[20] The convergence was interpreted as an indication that the intervortex interactions are not important and thus the effective barrier should reflect only the effective barrier for the depinning of a single vortex from the defect.

In our previous works[13–15] we reported on apparent unidirectional pinning deduced from the different hysteresis loops for different field directions with respect to the columnar defects. This unidirectional pinning was more apparent above 50 K. At lower temperatures the hysteresis loops look almost identical (see Fig. 1), i.e., the relative anisotropy in $M(H)$ decreases as temperature is decreased. The reduction in the pinning barrier as temperature increases can explain the difference in the relative anisotropy between high and low temperatures. At low temperatures, when the applied field is not in the direction of the defect, the pinning potential is high enough to overcome the Gibbs free energy, and thus the hysteresis loops overlap for various field directions.[12,15] When the temperature increases the Gibbs energy plays the major role, and unidirectional pinning is observed at all fields.

IV. SUMMARY AND CONCLUSIONS

In this article we have shown that columnar defects created by heavy-ion irradiation can improve the irreversible properties of HTS BSCCO crystals i.e., their J_c, U_{eff}, and IRL. There is an optimum dose of irradiation (approximately 10^{11} ions/cm^2) above which these properties suffer a reduction. Defects produced by Xe ions, although they consist of clouds of clusters, can be treated in the high-temperature range as columnar defects with a diameter defined by the cloud's diameter. We conclude that at the range of temperatures where scaling of the pinning force density holds, a single pinning mechanism (probably $\Delta\kappa$ pinning of volume defects) affects the magnetic behavior. The angular dependence of J_c and IRL leads us to conclude that the vortices in the BSCCO system are linelike vortices. The temperature dependence of U_{eff} can explain the temperature dependence of the relative anisotropy of pinning efficiency of columnar defects.

The electrical resistivity $\rho(T)$ and magnetic susceptibility $\chi(T,H)$ ($1.8 \leq T \leq 350$ K and $0 \leq H \leq 5.5$ T) have been measured on single crystals and epitaxial thin films of $Y_{1-x}Tb_xBa_2Cu_3O_7$. The T_c is 92 K and irrespective of Tb doping up to $x=0.50$. For $T>T_c$, $\rho(T)$ has a linear dependence, i.e., $\rho(T) \approx A+BT$, with the reduced resistivity $\rho(T)/\rho(250\text{ K})$ for $x=0.10$, 0.25, and 0.50, being independent of Tb doping. The results of magnetic susceptibility along with the computation of effective moment of Tb in the presence of crystal electric fields (CEF) tend to suggest that the Tb is mixed valent. The insensitivity of T_c to the Tb doping and the possibility that Tb may be mixed valent are in sharp contrast to the case of Pr and Ce doping which have been shown to be very deleterious to superconductivity. The magnetic susceptibility $\chi(T)$ is extremely anisotropic, and this anisotropy cannot be explained by simple models with CEF effects.

Among the striking features of the high-T_c superconductor $YBa_2Cu_3O_7$ (YBCO) are the insensitivity of the superconducting properties to rare-earth substitutions for Y since many of the rare-earth elements possess magnetic moments, normally leading to conditions deleterious to superconductivity. The exceptions to this behavior are Ce, Pr, and Tb, where Pr forms a nonsuperconducting isostructural compound and Ce and Tb do not form the YBCO structure at all. The valence instability of Ce and Tb in many metallic compounds and oxides is a common occurrence, e.g., CeO_2 and Tb_4O_7. The fact that $CeBa_2Cu_3O_{7-\delta}$ and $TbBa_2Cu_3O_{7-\delta}$ do not form has been attributed to Ce and Tb entering the lattice as a tetravalent or mixed-valent ion and thus driving the system unstable. However, Pr, of which Pr_6O_{11} is the stable oxide and strongly suggestive of unstable valence behavior, does form the $PrBa_2Cu_3O_{7-\delta}$ phase. $PrBa_2Cu_3O_{7-\delta}$, although being crystallographically identical to all the other rare-earth-based superconductors of the series, is an insulator, and substitution of Pr for Y in $Y_{1-x}Pr_xBa_2Cu_3O_{7-\delta}$ suppresses T_c with superconductivity disappearing at $x \approx 0.55$.

The mechanism(s) responsible for the depression of T_c with x has been the subject of considerable interest and controversy. Numerous investigations have been carried out with the objective of developing an understanding of Pr in the $RBa_2Cu_3O_{7-\delta}$ compounds. Most of the discussion of the T_c depression centers on the Pr valence and/or possible magnetic pair breaking due to a $4f$-electron and conduction-hole interaction which is absent in the other rare-earth-doped $YBa_2Cu_3O_{7-\delta}$ systems. Results of these investigations tend to conclude that Pr is slightly mixed valent and hybridizes with the charge carriers within the adjacent CuO_2 planes, and thus depresses T_c by a combination of dynamic hole filling and pair breaking.[1–4] Evidence from electron-energy-loss spectroscopy[5] and x-ray absorption spectroscopy indicates that the valence of Pr is close to 3+, which is consistent with the thermodynamic studies if strong hybridization is also included.

Based on our recent study of electrical resistivities of thin films of $Y_{1-x}Pr_xBa_2Cu_3O_{7-\delta}$ and $Nd_{1-x}Ce_xBa_2Cu_3O_{7-\delta}$,[14] $\rho(T,x)$ behavior of the Ce-doped samples closely follows the behavior seen for the Pr-doped compounds, strongly suggesting that the depression of T_c is due to a common mechanism and that hole filling or $4f$-electron hybridization with CuO planes rather than magnetic pair breaking may be the dominant mechanism (see Fig. 4).

As mentioned above, Tb, like Ce and Pr, is also known to show mixed-valent behavior in many oxide systems and other compounds with two possible magnetic ground states ($J=6$ for Tb^{3+} and $J=\frac{7}{2}$ for Tb^{4+}). As a natural extension of our study of hole filling and pair breaking in these systems, we have focused our attention on Tb-doped $YBa_2Cu_3O_{7-\delta}$ single crystals and thin films. Our earlier study of this system has already revealed some interesting and unexpected phenomena. In this paper, we report our recent results of transport and magnetic measurements with an emphasis on the unusual behavior observed in this Tb-doped system.

The $\rho(T)$ for $Y_{1-x}Tb_xBa_2Cu_3O_{7-\delta}$ films is shown in Fig. 1 for $x=0.1$, 0.25, and 0.50. The substitution of the magnetic Tb for Y surprisingly does not shift T_c (92.5 K) even for x as high as 0.50. However, $\rho(T,x)$ for all x displays a linear-T behavior, i.e., $\rho(T) \approx A+BT$ for $T>T_c$ although the magnitude of the normal-state resistivity increases systematically with Tb concentration x. The superconducting transition for all x is very sharp with the temperature width of the transition being less than 1.2 K. The results of the resistivity experiments presented here are somewhat unexpected in that magnetic susceptibility results for $Y_{1-x}Tb_xBa_2Cu_3O_{7-\delta}$ single crystals to be presented next strongly suggest that Tb may be mixed valent. The resistivity behavior and the apparent insensitivity of T_c to the Tb doping is thus perplexing.

It is interesting to note that the T-linear slope of $\rho(T,x)$ for $T>T_c$ increases rapidly with increasing x, and a fit of $\rho(T,x)$ to $A+BT$ shows that the Tb doping primarily alters

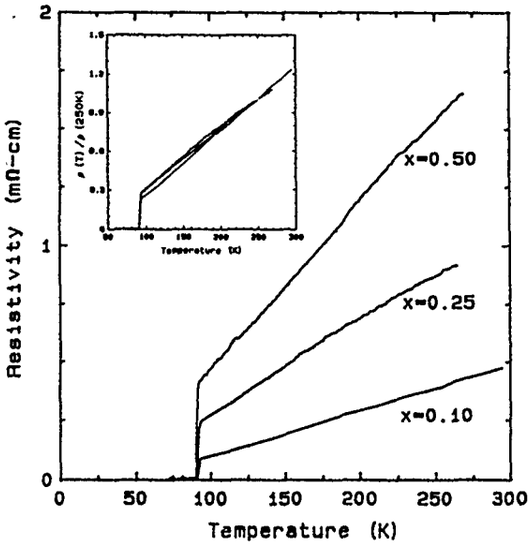

FIG. 1. The resistivity $\rho(T)$ vs temperature of thin films of $Y_{1-x}Tb_xBa_2Cu_3O_{7-\delta}$ for $x=0.10$, 0.25, and 0.50. Inset: The reduced resistivity $\rho(T)/\rho(250\ \mathrm{K})$ vs temperature.

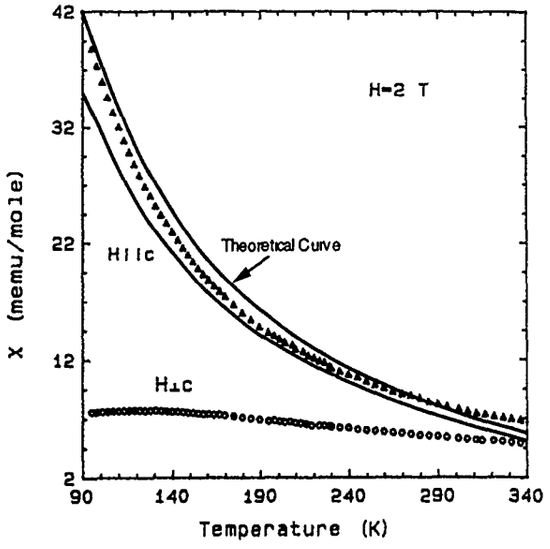

FIG. 3. The magnetic susceptibility $\chi(T)$ vs temperature for the oxygenated single crystal of $Y_{1-x}Tb_xBa_2Cu_3O_{7-\delta}$ with $x\approx0.30$ for $H\|c$ (triangle) and $H\perp c$ (circle) at $H=2.0$ T. The solid lines are the single-ion CEF theoretical predictions assuming a Tb^{4+} in the system for the two directions of the field.

the slope and much more weakly impacts on the $T\rightarrow0$ intercept. This can be seen in a plot of a reduced resistivity $\rho(T)/\rho(250\ \mathrm{K})$ versus temperature for $x=0.10$, 0.25, and 0.50 (see inset in Fig. 1) where an approximately universal curve is seen, reflecting a common reduced slope. This suggests that the scattering mechanism for carrier transport in the CuO_2 planes leading to the linear-T dependence is dependent on Tb doping, and this coupled with the independence of T_c on Tb doping is puzzling, considering many of the models proposed to explain the linear-T dependence of $\rho(T)$ are based on excitations which also mediate the pairing.

Shown in Fig. 2 is magnetic susceptibility $\chi(T)$ (defined as M/H) versus temperature for $2\leqslant T\leqslant100$ K at $H_{\|c}=20$ Oe for a single crystal with $x=0.3$. As can be seen, the onset

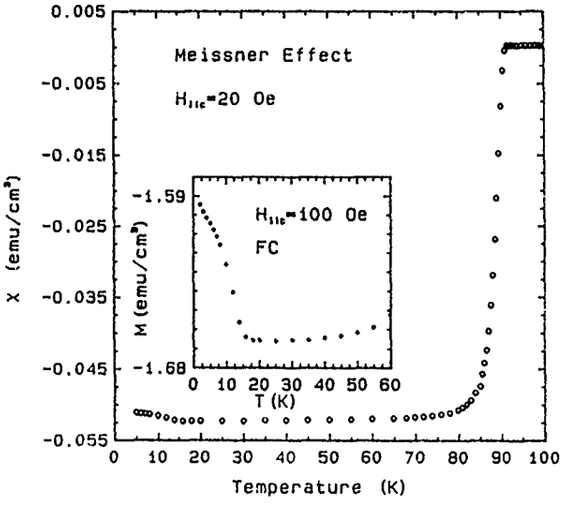

FIG. 2. The magnetic susceptibility $\chi(T)$ vs temperature for an oxygenated single crystal with $x\approx0.30$ at $H_{\|c}=20$ Oe. Inset: Magnetization M vs temperature at $H_{\|c}=100$ Oe.

of T_c is at 90.5 K with a width of T_c less than 2 K, implying a full or nearly full oxygen content in the sample. The value of T_c is in good agreement with the results of electrical resistivity measurements on epitaxial thin films presented above. The flux expulsion (Meissner effect) is 70% (of $1/4\pi$), which was obtained on cooling the sample through T_c in the magnetic field. In addition, it is interesting to note that there is a sharp up-turn that developed at $T\leqslant15$ K in $\chi(T)$ which becomes more evident in higher fields (see the inset in Fig. 1, where a plot of magnetization M versus temperature at $H_{\|c}=100$ Oe is shown). This behavior may suggest magnetic ordering associated with Tb. It is not uncommon for rare-earth ions to be ordered at low temperatures, for instance, $T_N\approx1.5$ K for $NdBa_2Cu_3O_7$ and $T_N\approx2.5$ K for $GdBa_2Cu_3O_7$. However, ordering at such a relatively high temperature is normally not expected for Tb as well as for the majority of rare earths. Yet, it is well known that Pr anomalously orders at $T_N\approx17$ K in $PrBa_2Cu_3O_7$. Other probes, such as low-temperature specific heat, can certainly help to clarify this issue.

Shown in Fig. 3 is $\chi_c(T)$ and $\chi_{ab}(T)$, where $\chi_c(T)$ is for $H\|c$ and $\chi_{ab}(T)$ for $H\perp c$, for the single crystal with $x\approx0.30$ and $T_c=90.5$ K. As can been seen, $\chi(T)$ for this sample is extremely anisotropic with $\chi_{ab}(T)$ nearly T independent and $\chi_c(T)$ displaying a strong Curie-Weiss-like response. $\chi_c(T)$ can be fitted to a modified Curie-Weiss law, i.e., $\chi(T)=\chi_0+C/(T-T^*)$, with $\chi_{c0}=3.7\times10^{-3}$ emu/mol, $\mu_{\mathrm{eff}c}=8.10\mu_B$, and $T_c^*\approx60$ K for $H\|c$. The value of χ_{c0} obtained for $H\|c$ is unusually large in contrast to those reported for $YBa_2Cu_3O_{7-\delta}$.[6] The $\mu_{\mathrm{eff}c}$ is close to a value expected for Tb^{4+}. This value is also consistent with that obtained for the fully oxygenated polycrystalline sample which gives $8.25\mu_B$. The measured value of μ_{eff} is closer to the Hund's-rule value of $7.90\mu_B$ for Tb^{4+} than $9.72\mu_B$ for Tb^{3+}, suggesting a nearly tetravalent Tb in this compound.

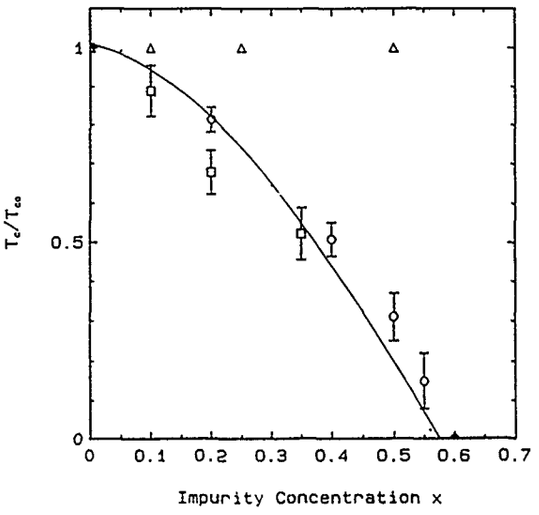

FIG. 4. The superconducting transition temperature T_c with dopant concentration x for $Y_{1-x}Tb_xBa_2Cu_3O_{7-\delta}$ (triangle), $Y_{1-x}Pr_xBa_2Cu_3O_{7-\delta}$ (circles), and $Nd_{1-x}Ce_xBa_2Cu_3O_{7-\delta}$ (squares) (see Ref. 6). The vertical bars indicate the transition width. The solid line is the smoothed variation of T_c vs x for polycrystalline $Y_{1-x}Pr_xBa_2Cu_3O_{7-\delta}$.

An analysis of $\chi(T)$ for the same temperature range used to determine the measured μ_{eff} and using crystal electric field (CEF) parameters extrapolated from measured CEF excitation for $DyBa_2Cu_3O_{7-\delta}$ and $HoBa_2Cu_3O_{7-\delta}$ gives $\mu_{\text{eff}}=9.1\mu_B$ for the effective paramagnetic moment for Tb^{3+}, including CEF effects. Thus, at this time CEF effects seem unable to account for the discrepancy between the measured paramagnetic moment and that expected for a Tb^{3+} ion.

If Tb is tetravalent, or at least mixed valent as suggested by $\chi(T)$, the effects observed in this Tb-doped system are quite unusual and in strong contrast to the case of the Pr- and Ce-doped compounds. For the Pr- and Ce-doped $YBa_2Cu_3O_{7-\delta}$, the $4f$ electrons are extremely deleterious to the superconductivity state (see Fig. 4). The insensitivity of T_c for $Y_{1-x}Tb_xBa_2Cu_3O_{7-\delta}$ would seem to suggest that Tb enters the $YBa_2Cu_3O_{7-\delta}$ as a stable 3+ valent ion with negligible exchange coupling between the $4f$ electrons and charge carriers in the CuO_2 planes. If Tb is trivalent, then the nonformation of an orthorhombic 1:2:3 Tb structure similar to that formed with Y and most of the other rare earths is puzzling. Also, the analysis of $\chi(T)$ data both for the oxygenated polycrystalline and the single-crystal samples leads to a effective paramagnetic moment suggestive of mixed-valent behavior. If we accept the premise that Tb is mixed valent in this system, then why is T_c insensitive to Tb doping? At the present stage we are not able to give a conclusive explanation as to why Tb does not depress T_c, but issues related to how the $4f$ electrons hybridize with other states may provide an answer to this dilemma. Intuitively, the extraordinarily small spatial extent of the $4f$ shell of Tb (compared to those of Pr and Ce) may be the cause, resulting in a hybridization significantly different from that in the other systems, and thus unexpected phenomena.

Indeed, this point becomes more interesting by considering CEF models of Tb^{4+} and Tb^{3+} (see Fig. 3). As can be seen, the theoretical analysis of $\chi(T)$ for the Tb^{4+}-doped system (solid lines in Fig. 3) using CEF parameters extrapolated from measured CEF excitation for $DyBa_2Cu_3O_{7-\delta}$ and $HoBa_2Cu_3O_{7-\delta}$ fails to predict a behavior similar to that observed in the Tb-doped system, and the same analysis of $\chi(T)$ assuming a trivalent Tb in the system (not shown) is also inconsistent with the experimental observation. CEF effects alone, evidently, cannot account for the anomalously large anisotropy in this system, strongly suggesting that additional effects possibly associated with the details of the $4f$-electron hybridization absent in other high-T_c systems and Pr-doped YBCO are required to characterize the actual behavior in the Tb-doped system. It has been thought that in cuprate superconductors the anisotropy of $\chi(T)$ is primarily caused by the anisotropy in the Van Vleck terms, which are a reflection of the anisotropy induced due to the spatial orientation of the Cu d orbitals and driven by CEF effects.[8] If Tb is tetravalent, the hybridization between the $4f$ electrons and charge carriers within the planes would impact heavily on the anisotropy of the Van Vleck contributions.

Relevantly, the other major phenomenon also shown in Fig. 3 is the non-Curie-Weiss behavior for $T>T_c$ when an external field H perpendicular to the c axis is applied. As can been seen, $\chi_{ab}(T)$ is unusually linear for $T>150$ K, and thus significantly different from the Curie-Weiss law. For $T<150$ K, in addition, a well-defined peak or a plateau is repeatedly seen at low fields. In contrast, for $H\|c$, $\chi(T)$ retains normal Curie-Weiss behavior. This behavior is apparently unusual in that in other high-T_c materials at $T>T_c$ the Curie-Weiss law is always well obeyed irrespective of the direction of the applied field H, and that the deviation from the Curie-Weiss law is generally an indication of a nonparamagnetic behavior. It cannot be ruled out that the unusual observation found in $\chi(T)$ may represent the presence of spin fluctuations or weak magnetic correlations in CuO planes due to the unusual $4f$-electron hybridization with some states. Further efforts are required in order to reach a conclusive explanation as to why the magnetic properties of the Tb-doped superconductor behave so unusually.

Magnetic order of Pr ions in related perovskite-type Pr123 compounds

M. Guillaume, P. Fischer, B. Roessli, A. Podlesnyak, J. Schefer, and A. Furrer
Laboratorium für Neutronenstreuung, Eidegenössische Technische Hochschule Zürich und Paul Scherrer Institut, CH-5232 Villigen PSI, Switzerland

The magnetic order of Pr ions in polycrystalline, tetragonal $PrBa_2Cu_3O_{6.2}$ has been studied by neutron-diffraction measurements. The basic ordering consists of an antiferromagnetic arrangement with the propagation vector $\mathbf{k}=[1/2, 1/2, 1/2]$, but the magnetic ordering is imperfect due to finite correlation length $\xi_c=(10\pm1)$ Å along the c axis. The Néel temperature is determined to be $T_N=(12\pm1)$ K, and the magnetic saturation moment of the Pr ions turns out to be $(1.9\pm0.2)\,\mu_B$. The distance Pr-O(2) compared in several related perovskite-type Pr compounds correlates with the Néel temperature in accordance with the superexchange interaction.

I. INTRODUCTION

Neutron-diffraction measurements[1] on the nonsuperconducting $PrBa_2Cu_3O_7$ yield an exceptionally high Néel temperature T_N of 17 K which exceeds the T_N value derived for the isostructural compound $GdBa_2Cu_3O_7$ (Ref. 2) by an order of magnitude, in disagreement with the de Gennes scaling law. The basic ordering of $PrBa_2Cu_3O_7$ (Ref. 1) consists of a simple antiferromagnetic arrangement with the propagation vector $\mathbf{k}=[1/2, 1/2, 1/2]$ and magnetic moment orientation [0,0,1]. The magnetic moment at saturation is $0.74\mu_B$ (Ref. 1), which is small compared to the free-ion value of $gJ=3.2\mu_B$.

For the polycrystalline compound $PrBa_2Cu_3O_6$ susceptibility measurements yield $T_N(\mathrm{Pr})=10.8$ K (Ref. 2) for the ordering of the Pr sublattice, whereas recently for a single crystal of $PrBa_2Cu_3O_6$ Uma *et al.*[3] observed $T_N\approx12$ K. From single-crystal neutron-diffraction studies on $PrBa_2Cu_3O_{6.2}$,[4] the copper ions exhibit long-range magnetic ordering according to $\mathbf{k}=[1/2,1/2,1/2]$ below $T_N(\mathrm{Cu})\approx370$ K. The Cu spins are oriented approximately perpendicular to the c axis, and the temperature dependence of the 1/2, 1/2, 3/2 magnetic peak indicates normal saturation below ~100 K. So far there is no information concerning the magnetic moment and the easy axis of magnetization of the Pr ions.

From recently published neutron-diffraction results[5] of $RBa_2Cu_3O_7$ (R = rare earth) we determined by extrapolation for the interionic distances Cu(2)-Cu(2), Cu(2)-O(3), Pr-O(2) an intermediate valence for Pr in the $PrBa_2Cu_3O_7$ sample of +3.4, whereas for $PrBa_2Cu_3O_6$ we obtained a valence of +3.0. We assume that this extrapolated valence is a structural effect associated with strong hybridization of Pr with the oxygen ligand atoms in the CuO_2 planes. On the other hand, neutron spectroscopy[6] and electron-energy-loss spectroscopy (EELS)[7] measurements show clear evidence for an effective valence of +3. How do these structural changes in the Pr compound from oxygen 7 to the oxygen 6 influence the magnetic ordering? With these motivations we report in the present paper on long-range antiferromagnetic order of Pr ions in $PrBa_2Cu_3O_6$ by neutron diffraction and present an interpretation of the results based on the present knowledge of the crystalline electric field in this system. We observed a correlation in several related perovskite-type Pr compounds between the distance Pr-O(2) and the Néel temperature. Magnetic neutron-diffraction studies on a tetragonal $PrSrBaCu_3O_7$ sample yielded similar results as obtained for the $PrBa_2Cu_3O_7$ compound.

II. EXPERIMENTAL RESULTS

Sample preparation and experimental details have been described elsewhere.[8] For $PrBa_2Cu_3O_{6.2}$ we performed neutron-diffraction measurements at $T=18$ K and $T=1.5$ K, i.e., well above and well below the Néel temperature. In the difference pattern of the two temperatures shown in Fig. 1 we clearly observe a magnetic peak at $2\Theta=18.3°$ which may be indexed in the magnetic unit cell as (1,1,1) with the

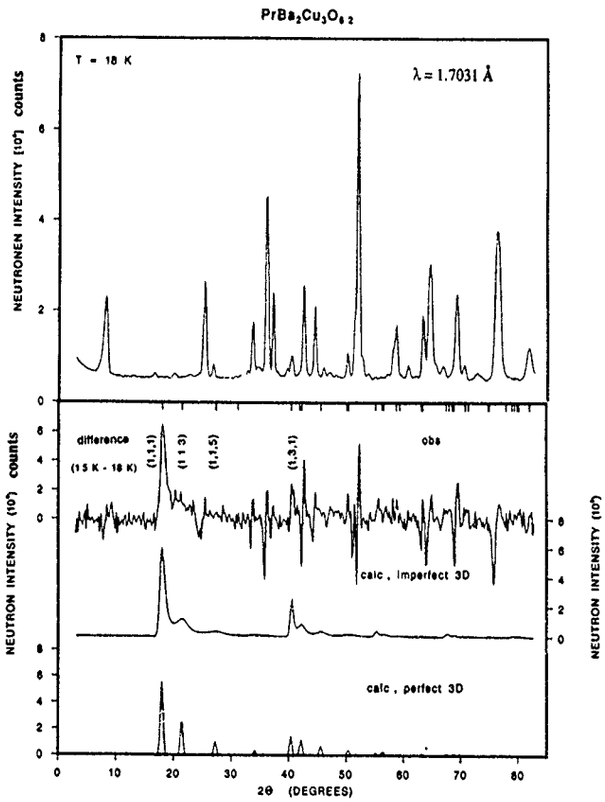

FIG. 1. Upper part: Neutron-diffraction pattern of $PrBa_2Cu_3O_{6.2}$ measured at 18 K. Lower part: Magnetic difference neutron-diffraction pattern (1.5 K–18 K) for $PrBa_2Cu_3O_{6.2}$ (indices h, k, l referring to the magnetic unit cell). The observed intensities are compared with a calculation for both imperfect and perfect 3D ordering.

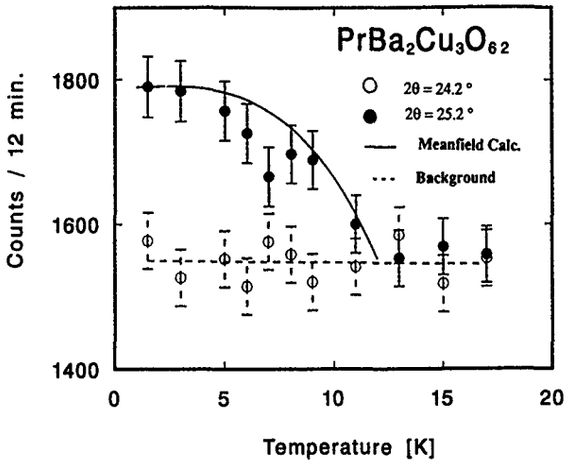

FIG. 2. Temperature dependence of the magnetic neutron intensity of the (1/2, 1/2, 1/2) peak observed for $PrBa_2Cu_3O_{6.2}$ yielding, $T_N=(12\pm1)$ K. The line is the result of a mean-field crystal-field calculation.

propagation vector $\mathbf{k}=[1/2, 1/2, 1/2]$ as in nonsuperconducting $PrBa_2Cu_3O_7$. The neighboring negative and positive differences in the intensities which appear at the nuclear Bragg position are due to the change of the lattice parameters when changing the temperature from $T=18$ K to $T=1.5$ K. Since all three Miller indices are half-integer, the magnetic unit cell is doubled along all basic translations compared to the chemical unit cell, corresponding to antiferromagnetic coupling along all three crystallographic directions. Pronounced line broadening of the magnetic peaks was observed. The widths at half maximum of the magnetic lines depend on the reflection index (h, k, l) and the scattering angle 2Θ. We emphasize that these linewidth anomalies only affect the magnetic peaks.

The measurement of the temperature dependence of the dominant (1/2,1/2,1/2) peak (indices h, k, l referring to nuclear unit cell) yields a Néel temperature $T_N=(12\pm1)$ K, see Fig. 2.

III. DATA ANALYSIS

The unusual line shapes observed in the magnetic neutron diffraction pattern of $PrBa_2Cu_3O_{6.2}$ can be shown to result from finite magnetic correlations along the c axis, equivalent to the occurrence of magnetic intensity for a particular reflection (h, k, l) turns out to be a Lorentzian:

$$I_{hkl}(\mathbf{q}) \propto F(\mathbf{Q})^2 \frac{\Gamma}{\Pi(\Gamma^2+|\tau_{hkl}-\mathbf{Q}|^2)} \delta(q_a)\delta(q_b),$$
$$\mathbf{q}=(q_a,q_b,q_c)=\tau_{hkl}-\mathbf{Q}. \quad (1)$$

$F(\mathbf{Q})$=neutron magnetic form factor, $\mathbf{Q}$=scattering vector.

Figure 1 shows the result of the least-squares refinement of the magnetic difference intensities based on Eq. (1) and the magnetic form factor[9] of Pr^{3+} which excellently reproduces the observed data. From our diffraction results we cannot decide whether the Pr^{3+} magnetic moments are directed parallel or perpendicular to the c axis (both fits yield approximately the same goodness of fit χ^2), and the (average) correlation length along the c axis is $\xi_c=2/\Gamma=(10\pm1)$ Å.

The nuclear and magnetic intensities at 1.5 K yield the best fit for the magnetic moment of Pr: $\mu_{Pr}=(1.9\pm0.2)\mu_B$.

A similar calculation for perfect three-dimensional (3D) long-range magnetic order yields a saturated moment of about $0.8\mu_B$; however, the calculated intensities clearly do not correspond to the measurement as can be seen from Fig. 1.

IV. DISCUSSION

By means of neutron-diffraction investigations we have established for $PrBa_2Cu_3O_{6.2}$ imperfect three-dimensional "long-range" magnetic ordering due to finite c correlation length of 10 Å, with a magnetic moment of saturation at $1.9\mu_B$ of Pr^{3+}.

Compared to $PrBa_2Cu_3O_7$ the rather unusual and unexpected increase of the magnetic moment in $PrBa_2Cu_3O_{6.2}$ can be explained by the drastic change of the low-lying crystal-field levels when going from the O_7 to the O_6 compound. The corresponding crystal-field parameters have been worked out by Nekvasil *et al.*[6] from neutron spectroscopic experiments. A mean-field calculation based on their crystal-field parameters yields saturated magnetic moments of $1.1\mu_B$ and $2.1\mu_B$ for the O_7 and O_6 compounds, respectively, which reasonably compare to the moment values determined by neutron diffraction. The crystal-field interaction for the tetragonal O_6 compound [with vanishing "orthorhombic" crystal-field parameters B_2^2 and B_2^4, Ref. (6)] produces an extremely anisotropic single-ion susceptibility, yielding the c axis as the easy axis of magnetization. The calculated temperature dependence of the magnetic Bragg intensities (which are linearly related to the square of the ordered moment) is also in excellent agreement with the experimental findings, see Fig. 2.

Jostarndt *et al.*[10] showed that the magnon peak position of $PrBa_2Cu_3O_6$ (splitting of Γ_5 doublet ground state due to the anitferromagnetic ordering of Pr ions) as a function of temperature decreases drastically to 0 at around $T=12$ K. This extrapolation yields a Néel temperature of (12±2) K which is in good agreement with our neutron-diffraction result with T_N of 12 K.

The exceptionally high Néel temperatures of the $PrBa_2Cu_3O_x$ compounds is still a matter of debate. It may be related to strong hybridization of the $4f$ electrons with the p orbitals of the ligand oxygen ions in the CuO_2 planes which enhances the superexchange interaction between the Pr ions. Hybridization is presumably also the reason for the unusually large line widths of the crystal-field transitions.[10,11]

The surprising imperfect magnetic ordering in $PrBa_2Cu_3O_{6.2}$ is to some extent similar to the magnetic Dy ordering discovered recently in a single crystal of $DyBa_2Cu_3O_6$ which shows below ~1.5 K "short-range" magnetic order along the c axis and even at 70 mK a finite c-correlation length of about 13 Å together with 2D long-range antiferromagnetic ordering below 0.55 K.[12] The same behavior was recently observed (but not quantitatively analyzed) in $PrBa_2Cu_3NbO_8$,[13] which shows a Néel temperature of 12.6 K similar to $PrBa_2Cu_3O_{6.2}$. The imperfect antiferro-

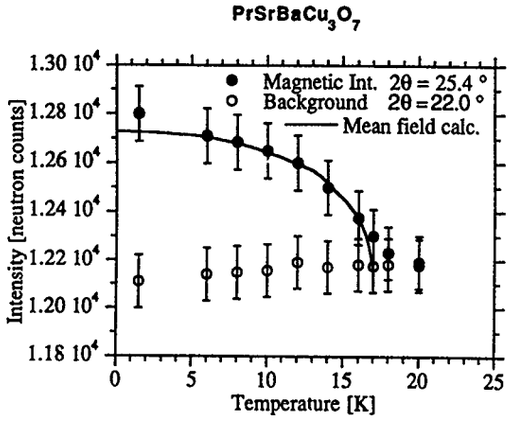

FIG. 3. Temperature dependence of the magnetic neutron intensity of the (1/2, 1/2, 1/2) peak observed for $PrSrBaCu_3O_7$, yielding $T_N=(17\pm1)$ K.

magnetic ordering has a correlation length of about 7 Å along the c axis. Also polycrystalline $HoBa_2Cu_3O_7$ (Ref. 14) exhibits an imperfect three-dimensional magnetic ordering, existing below $T_N=190$ mK due to a finite correlation length $\xi_c=29$ Å along the c axis.

The observed anomalies of perovskite-type Pr compounds are not unique. Similar results were also observed for PrO_2 (Ref. 15) which shows a Néel temperature of 14 K. An even higher Néel temperature $T_N=21$ K was reported for $PrCu_2Si_2$.[16]. The Pr compounds (PrO_2, $PrCu_2Si_2$, $PrBa_2Cu_3O_x$) showed a large value of the linear electronic specific heat capacity coefficient[16,17] which indicates a heavy-fermion-like behavior. Anomalous is furthermore the absence of the spin-Kondo effect in $PrCu_2Si_2$ in contrast to other RCu_2Si_2 (R=rare earth) compounds which clearly show the spin-Kondo effect.[16]

We have also started neutron-diffraction investigations on a $PrSrBaCu_3O_7$ compound which has a tetragonal symmetry. Despite the disorder produced by Sr entering the Ba sites, we still observe a T_N of 17 K, as shown in Fig. 3 , i.e., as high as for the $PrBa_2Cu_3O_7$ compound. From the magnetic difference neutron-diffraction pattern intensities for $T=20$ K subtracted from those at $T=1.5$ K we clearly observed a magnetic peak at (1/2, 1/2, 1/2) which does not show asymmetric line broadening. In $PrSrBaCu_3O_7$ the antiferromagnetic ordering is therefore of longer range than in $PrBa_2Cu_3O_{6.2}$. On the other hand, the low-energy spectrum of the crystalline electric field of $PrSrBaCu_3O_7$ looks similar to the $PrBa_2Cu_3O_7$ compound. We have calculated the temperature dependence of the magnetic moment using the crystal-field parameters worked out by Nekvasil *et al.*[18] for the $PrBa_2Cu_3O_7$ compound. Our result is in good agreement with the experimental findings, see Fig. 3. Thus the substitution of Ba^{3+} by Sr^{2+} which leads to disorder does not change the magnetic ordering of the Pr ions in $PrSrBaCu_3O_7$.

TABLE I. The distance Pr-O(2) Å at $T=10$ K for several Pr compounds, related with the Néel temperature.

	Pr-O(2) (Å)	T_N (K)
$PrBa_2Cu_3O_7$ (Ref. 1)	2.449(5)	17.0±1
$PrSrBaCu_3O_7$	2.439(5)	17.0±1
$PrBa_2Cu_3O_{6.2}$	2.480(4)	12.0±1
$PrBa_2Cu_2NbO_8$ (Ref. 10)	2.487(6)	12.6±1

A comparison of the Néel temperatures of several related Pr perovskite-type compounds, see Table I, indicates a systematic correlation with the variation of the distance Pr-O(2). The higher the T_N values are the smaller Pr-O(2) distances have been determined by neutron diffraction (at $T=10$ K) as expected from the superexchange interaction.

ACKNOWLEDGMENTS

We would like to thank X. Z. Wang, B. Hellebrand, and D. Bauerle from J-Kepler University of Linz for providing us the ceramic sample $PrSrBaCu_3O_7$ for neutron-scattering experiments. Corresponding detailed results will be published later. Financial support by the Swiss National Science Foundation is gratefully acknowledged.

Inelastic neutron scattering has been employed to study the magnetic excitations of Ho^{3+} in a grain-aligned sample of $HoBa_2Cu_3O_7$. The lowest lying branch exhibits dispersion for spin waves propagating in the (a,b) plane, whereas excitations along the c axis remain constant in energy. The data are analyzed in the random phase approximation in terms of the Heisenberg and an anisotropic model, resulting in an enormous spatial anisotropy of the magnetic coupling parameters, which are weakly ferromagnetic, antiferromagnetic, and almost zero for nearest-neighbor Ho^{3+} pairs along the a, b, and c axes, respectively. In addition, we have been able to separate the spin wave excitations in longitudinal and transverse parts.

It is now well known that for nearly all high-T_c compounds $RBa_2Cu_3O_{7-\delta}$ (R denotes rare earth) superconductivity and magnetic ordering of the R ion sublattice coexist at low temperatures. In order to understand the interplay of magnetism and superconductivity in these systems, information on both the electronic ground state of the R^{3+} ions and the coupling mechanism between the R^{3+} ions is highly desirable. While the ground-state wave functions in these systems are well established particularly through neutron spectroscopic investigations of the crystalline-electric-field (CEF) interaction,[1] there is a lack of unambiguous information concerning the nature and size of the magnetic pair interactions. It is usually argued that the large separation of the R^{3+} ions along the c axis gives rise to an essentially two-dimensional character of the magnetic correlations. In fact, there are numerous examples for the two-dimensional magnetic behavior of the R^{3+} ions in the $RBa_2Cu_3O_{7-\delta}$ systems,[2] however, for some compounds a three-dimensional long-range magnetic order was clearly observed in neutron diffraction experiments.[2,3]

Several mechanisms could be involved in the coupling of the R^{3+} ions to form two- or three-dimensional spin structures: Dipolar, Ruderman–Kittel–Kasuya–Yosida (RKKY), and superexchange interactions. Calculations based on dipolar interactions alone result in Néel temperatures which are much lower than the observed ordering temperatures, and there are controversies as to the importance of either RKKY or superexchange interactions. Some qualitative information on the coupling of the R^{3+} ions has been obtained from magnetization and low-temperature specific-heat measurements which indicate large anisotropies of the exchange interaction in the (a,b) plane.[4] A more detailed insight into the coupling mechanism results from studying the spin dynamics through the measurement of the collective magnetic excitations or spin waves which inherently contain information on the nature and size of the magnetic coupling between the R^{3+} ions. Inelastic neutron scattering (INS) provides the most direct access to this property and thereby allows a very direct determination of exchange parameters.

Preliminary INS data of the low-lying magnetic excitations observed in a grain-aligned sample of $HoBa_2Cu_3O_7$ have been published in Ref. 5. Here we present new experimental data taken under improved energy resolution. We have chosen $HoBa_2Cu_3O_x$ for two specific reasons. First, a recent low-temperature neutron diffraction study[6] of $HoBa_2Cu_3O_7$ indicates the existence of three-dimensional magnetic correlations associated with the Ho^{3+} sublattice below $T_N=0.19$ K as well as a three-dimensional or mean-field type behavior of the zero-field magnetization with a critical exponent $\beta=0.4\pm0.1$, so that we may expect the magnetic excitations to exhibit dispersion effects. Second, and most importantly, the CEF level scheme of $HoBa_2Cu_3O_7$ is characterized by a series of low-lying states[1] which can be sufficiently resolved within the small range of energy dispersion anticipated for these systems. In particular, we have studied in great detail the lowest ground-state CEF excitation $\Gamma_3\rightarrow\Gamma_4$ with energy $\Delta\approx0.5$ meV, which has by far the largest dipole transition matrix element and therefore exhibits the largest dispersion effects.

The preparation and characterization of the $HoBa_2Cu_3O_7$ sample is published elsewhere.[5] The INS experiments were performed at the reactor BerII at the Berlin Neutron Scattering Center with use of the triple-axis spectrometer FLEX operating in the neutron energy-loss configuration. The energy of the outgoing neutrons was kept fixed at 3.5 meV. No collimation was used, giving rise to an energy resolution of 0.09 meV at $\Delta E=0$. A beryllium filter was inserted between monochromater and sample to eliminate higher order contamination. The samples were oriented with the [001] axis in the scattering plane and mounted in an "orange ILL-type" helium cryostat to achieve temperatures $T\geq1.5$ K. Constant $\mathbf{Q}$ scans were employed throughout the experiments, where $\mathbf{Q}=2\pi(x/a,y/b,z/c)$ is the scattering vector. Due to the random orientation of the sample in the (a,b) plane, however, we could not distinguish between the com-

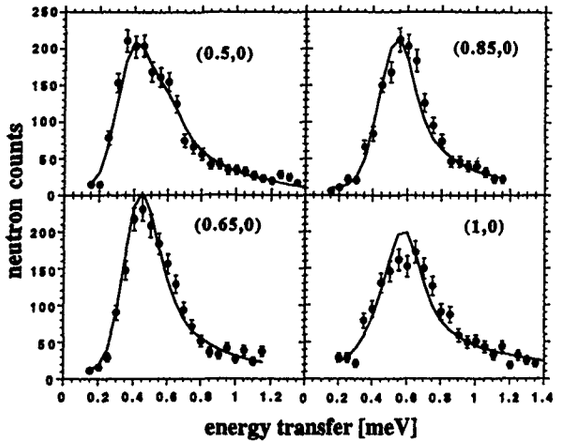

FIG. 1. Normalized and form factor corrected energy spectra of neutrons scattered from grain-aligned $HoBa_2Cu_3O_7$, taken at $T=1.5$ K and constant analyzer energy $E_A=3.5$ meV, for propagation vectors along the $[x',0]$ direction. The lines correspond to the calculated (x,y)-averaged excitation spectra as explained in the text.

ponents of the scattering vector **Q** perpendicular to the z axis, i.e., the actual scattering vector was $\mathbf{Q}=2\pi\,(x'/a,z/c)$ with $x' = \sqrt{x^2+y^2}$ (assuming $a=b$).

We covered a large region of reciprocal space in the (x',z)-plane. For all **Q** the ground-state CEF excitation $\Gamma_3 \rightarrow \Gamma_4$ shows up as a well resolved inelastic line as exemplified in Figs. 1, 2, and 3. Its peak shape is broad and often asymmetric for **Q** perpendicular to the z axis (Fig. 1), whereas for **Q** involving a zero x' component narrow lines are observed (Fig. 2). The energy of maximum peak intensity of this excitation varies typically between 0.4 and 0.6 meV

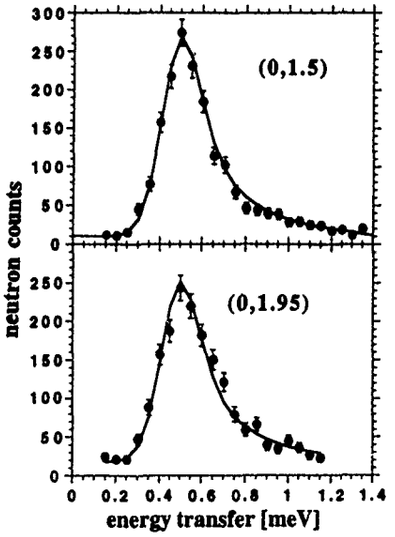

FIG. 2. Normalized and form factor corrected energy spectra of neutrons scattered from grain-aligned $HoBa_2Cu_3O_7$, taken at $T=1.5$ K and constant analyzer energy $E_A=3.5$ meV, for propagation vectors along the $[0,z]$ direction. The lines are the result of the anisotropic line shape fits to the dispersion-free CEF excitations.

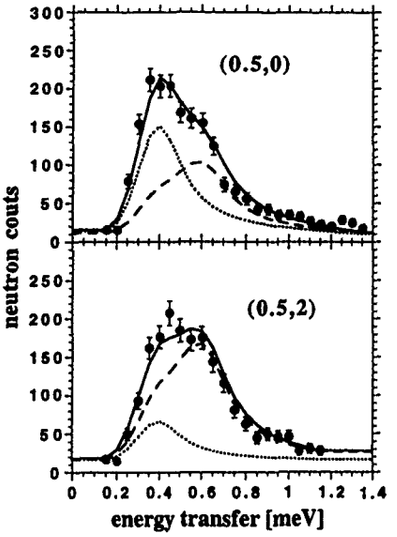

FIG. 3. Normalized and form factor corrected energy spectra of neutrons scattered from grain-aligned $HoBa_2Cu_3O_7$, taken at $T=1.5$ K and constant analyzer energy $E_A=3.5$ meV, for propagation vectors along the $[0.5,z]$ direction. The dotted lines corresponds to the transverse branch of the excitation, the broken lines corresponds to the longitudinal branch of the excitation and the full lines are the result of the total (x,y)-averaged calculation as explained in the text.

when following **Q** along the x' axis, whereas it remains more or less constant upon variation of **Q** along the z axis.

In the random phase approximation the magnetic excitation energies are determined by the poles of the dynamic magnetic susceptibility,[7]

$$\chi(\mathbf{Q},\omega)=\chi_0(\omega)[1-J(\mathbf{Q})\chi_0(\omega)]^{-1}, \tag{1}$$

where $J(\mathbf{Q})$ is the Fourier transform of the exchange coupling and $\chi_0(\omega)$ the single-ion susceptibility. For $x=7$, the calculation becomes particularly simple for an effective two-level system:

$$h\omega(\mathbf{Q})=\left\{\Delta\left[\Delta-2M^2J(\mathbf{Q})\tanh\left(\frac{\Delta}{2k_BT}\right)\right]\right\}^{1/2}. \tag{2}$$

Here, Δ corresponds to the energy separation between the CEF ground state Γ_3 and the first-excited CEF state Γ_4, and $M^2=27$ is the dipole transition matrix element between the two CEF states.[1] For the calculation of $J(\mathbf{Q})$ we took into account Heisenberg-type exchange parameters J_a, J_b, and J_c, coupling the central Ho^{3+} ion pairwise with the Ho^{3+} ions at the nearest-neighbor positions $\pm a$, $\pm b$, and $\pm c$ along the x, y, and z directions, respectively. Our choice of Heisenberg-type exchange is fully supported by the above mentioned behavior of the zero-field magnetization observed by neutron diffraction.[6] From the absence of dispersion along the z axis (Fig. 2) we immediately conclude that $J_c=0\pm0.2$ μeV, as actually expected from the large separation of the Ho^{3+} ions along that axis. The experimental uncertainty associated with J_c results from the standard deviation of the peak positions of Fig. 2 inserted into Eq. (2). Information on J_a and J_b is more difficult to obtain because of the random orientation of the x and y axes in our sample, thus the mag-

netic excitation spectra cannot be analyzed directly according to Eq. (2), but we have to average Eq. (2) in the (x,y) plane, what is explained in detail in Ref. 5. In addition, it is obvious that we have an asymmetric lane shape, as also was seen in the earlier works.[1,8] This asymmetry is explained due to Cu spin fluctuations at the Ho site.[8] However, we have to include this lane shape in our data analysis. The energy spectra of Fig. 1 were least-squares fitted to the model outlined above. The only fitting parameters were an overall scaling factor for the intensity, a constant background level, a half-width parameter for the Gaussian type of the intrinsic broadening of the CEF line, an anisotropic line shape factor and the two model parameters J_a and J_b. Δ was kept fixed at the pure CEF energy (Δ=0.49 meV) determined in a $Y_{0.9}Ho_{0.1}Ba_2Cu_3O_7$ sample.[8] We obtained for $J_a=0.5\pm0.1$ μeV and for $J_b=-1.6\pm0.2$ μeV. Due to the random orientation of the x and y axes another solution is possible by interchanging the parameters J_a and J_b. However, the analysis of a recent low-temperature neutron diffraction study[6] of the magnetic ordering in $HoBa_2Cu_3O_7$ is consistent with our choice of ferromagnetic and antiferromagnetic coupling along the a and b axes, respectively. We derive from our data the molecular-field parameter $J(\mathbf{Q}_0)=2(J_a-J_b-J_c)$ to be $J(\mathbf{Q}_0)=4.2\pm0.6$ μeV, which is in good agreement with the mean-field value $J(\mathbf{Q}_0)=5.2\pm0.5$ μeV calculated from the zero field magnetization.[6]

Our model parameters can reproduce the $\mathbf{Q}$ dependence of the observed energy spectra reasonably well (see Fig. 1). Improvements of the data analysis are possible by going beyond the simple Heisenberg model. For example, the exchange interaction can be generalized to include anisotropies in the coupling of the spin operators $S^\alpha(\alpha=x,y,z)$. As a result the response function is split into transverse and longitudinal components which can be separated in INS experiments through the polarization factor in the neutron cross-section or by use of polarized neutrons, however, our present data would clearly be over interpreted by the application of a full anisotropic model. Nevertheless, with the good energy resolution and many spectra taken with different $\mathbf{Q}$ in reciprocal space we can improve our Heisenberg model. As shown in Fig. 3, the spectra for constant x' values ($x'\neq0$) and different z values should look like exactly the same for the Heisenberg model ($J_c\approx0$), what is obviously not correct.

A step between the full anisotropic model and the Heisenberg model is to express the spin operators $\mathbf{S}$ in $\mathbf{S}^\perp$ and $\mathbf{S}^\parallel$, which results in a transverse and longitudinal component, respectively. Therefore the number of model parameters is increased from two to five ($J_a^\perp$, $J_a^\parallel$, $J_b^\perp$, $J_b^\parallel$, and $M^{\parallel 2}$, $M^2=M^{\parallel 2}+M^{\perp 2}=27$). On the other hand, we are now able to fit all 21 measured energy spectra simultaneously (Fig. 1), as compared two the Heisenberg model, were we can only fit spectra with $\mathbf{Q}=(x',0)$. We obtain the following results:

$$J_a^\parallel=0.0\pm0.4\ \mu\text{eV},\quad M^{\parallel 2}=7.8\pm0.6,$$

$$J_a^\perp=-6.9\pm0.7\ \mu\text{eV},\quad M^{\perp 2}=19.2\pm0.4,$$

$$J_b^\parallel=3.3\pm0.8\ \mu\text{eV},$$

$$J_b^\perp=-2.6\pm0.3\ \mu\text{eV}.$$

Again we find a good agreement between the exchange parameter determined from the dimer excitation,[8] where they can extract only the transverse exchange parameters ($J_a^\perp=-J_b^\perp=2.6\pm0.3$ μeV).

We have been able to prove directly the essentially two-dimensional nature of the magnetic coupling between the Ho^{3+} ions in $HoBa_2Cu_3O_7$. The coupling of the Ho spins for $x=7$ turns out to be extremely anisotropic in the (a,b) plane, i.e., there is a strong antiferromagnetic coupling along the b axis and a smaller ferromagnetic coupling along the a axis. This is in close analogy to the results obtained by fitting the specific-heat anomaly due to magnetic ordering of other $RBa_2Cu_3O_7$ compounds.[4] However, our results are considerably more detailed with respect to the size and the nature of the exchange interaction in the (a,b) plane. In addition, we have been able to separate the spin wave excitations in longitudinal and transverse parts. We get for the transverse component a ferromagnetic and a antiferromagnetic coupling in the a and b direction, respectively, whereas we get for the longitudinal component no and a strong antiferromagnetic coupling in the a and b direction, respectively. The strong magnetic anisotropy in the (a,b) plane can be reproduced neither by dipolar nor by RKKY interactions, thus the coupling of the Ho^{3+} ions is presumably dominated by nearest-neighbor superexchange interactions mediated by the $O(2)$ and $O(3)$ ions as oxygen bridges, which—at the same time—also take part in the superconducting processes. The charge distribution at the plane oxygen sites is therefore one of the most crucial quantities towards a detailed understanding of the relevant physical properties of the $RBa_2Cu_3O_7$ compounds.

Combined electronic-nuclear magnetic ordering of the Ho^{3+} ions and magnetic stacking faults in $HoBa_2Cu_3O_x$ (x=7.0,6.8,6.3)

B. Roessli, P. Fischer, U. Staub, M. Zolliker, and A. Furrer
Laboratorium für Neutronenstreuung, Eidgenössische Technische Hochschule Zürich and Paul Scherrer Institut, CH-5232 Villigen PSI, Switzerland

Magnetic ordering of $HoBa_2Cu_3O_x$ (x=7.0,6.8,6.3) was investigated by means of neutron diffraction. Long-range antiferromagnetism is found for x=7.0 below T_N=190 mK and for x=6.8 below T_N=100 mK corresponding to propagation vector $\mathbf{K}$=[0,1/2,1/2] with magnetic moment directions parallel to the a axis. The observed temperature dependence of the magnetic order parameter is in excellent agreement with mean-field calculations taking into account crystal field, exchange, and hyperfine interactions. No magnetic superlattice reflections were detected for x=6.3. A highly unusual ordering behavior is observed in $HoBa_2Cu_3O_x$ (x=7.0,6.8) where the three-dimensional magnetic ordering is imperfect, due to finite correlation length ξ_c=29 and 129 Å, respectively, along the c axis.

I. INTRODUCTION

Long-range antiferromagnetic rare-earth ordering has been determined in $RBa_2Cu_3O_7$ by means of neutron diffraction for R=Pr, Nd, Gd, Dy, Er, and Yb.[1] However, the magnetic ordering of the $HoBa_2Cu_3O_x$ system with singlet-crystal-field ground state[2] and presumably combined nuclear (^{165}Ho)-electronic ordering below $T_N \approx 170$ mK (Ref. 3) could not be solved unambiguously.[4,5] First neutron-diffraction experiments[4] on $HoBa_2Cu_3O_{6.8}$ revealed a single magnetic peak at temperatures below T_N=140 mK in agreement with heat-capacity measurements;[3] however, the detailed nature of the antiferromagnetic correlations could not be established. On the other hand, μSR measurements on $HoBa_2Cu_3O_7$ (Ref. 5) claimed the existence of 3D antiferromagnetic order below $T_N \approx 5$ K, corresponding to $\mathbf{K}$=[1/2,1/2,1/2] and alignment of the magnetic moments of Ho along the a axis. Below 100 mK the μSR data indicated $\mathbf{K}$=[0,1/2,1/2], easy axis of magnetization [0,0,1], and an ordered Ho moment of $\sim 2.6\ \mu_B$. Therefore new systematic neutron-diffraction measurements were performed on $HoBa_2Cu_3O_x$ (x=7.0, 6.8, and 6.3). First results for x=7.0 have been published in Ref. 6.

II. EXPERIMENTAL

The $HoBa_2Cu_3O_x$ (x=7.0,6.8,6.3) samples were prepared by standard sintering techniques. From resistivity measurements the critical temperatures were found to be T_c=93, 53, and 0 K for x=7.0, 6.8, and 6.3, respectively. The same samples have previously been used to determine the crystal-field interaction by means of inelastic neutron scattering.[7] The present experiments were performed on the multicounter diffractometer DMC[8] at the reactor Saphir of the Paul Scherrer Institut at Würenlingen (Switzerland) operating in the high-intensity mode [vertically focusing Ge(311) monochromator, collimations −/−/12', wavelength 1.7036 Å]. The single-phase quality of the polycrystalline samples was confirmed and the structure parameters were determined by neutron diffraction at 10 K in the high-resolution mode. In particular, the oxygen concentrations x=7.00±0.02, 6.77±0.02, and 6.25±0.02 resulted for the three samples. For the low-temperature experiments the specimens were mounted inside a bottom loading ^{4}He/^{3}He dilution refrigerator attaining 7 mK. To achieve good thermal contact ^{4}He was condensed into the sample voids. The raw data were corrected for absorption according to the measured transmission.

III. RESULTS

The magnetic structures were determined at T=7 mK. In order to visualize the peaks due to magnetic ordering of Ho^{3+} ions we calculated the difference patterns for T=7 mK and $T > T_N$. Figures 1 and 2 show the results obtained for x=7.0 and 6.8, respectively. The magnetic peaks can be indexed with increasing scattering angle 2θ as (0,1/2,1/2), (0,1/2,3/2), (0,1/2,5/2), (1,1/2,1/2), etc., with reference to the chemical cell. Combined with intensity calculations the corresponding antiferromagnetic structure of $HoBa_2Cu_3O_x$ (x=7.0, 6.8) is unambiguously described by the propagation vector $\mathbf{K}$=[0,1/2,1/2], i.e., the magnetic cell is doubled along the b and c directions compared to the chemical one, and the Ho^{3+} magnetic sublattice consists of antiferromagnetic (a,c) layers stacked according to antitranslation [0,1,0] as schematically displayed as insert in Fig. 1. This antiferromagnetic structure is in agreement with the anisotropic exchange parameters determined recently by inelastic neutron scattering experiments on grain-aligned powers of $HoBa_2Cu_3O_x$.[9] The sequence of magnetic peaks observed for x=6.8 is the same as for x=7.0.

In the refinement of the magnetic diffraction patterns we took into account nuclear (^{165}Ho) polarization effects. The magnetic part of the cross section for neutron diffraction from magnetic samples with polarized nuclei and unpolarized neutrons is given by[6]

$$\frac{\sigma}{4\pi} = A^2 M_\perp^2 + 2A b_N I \mathbf{M}_\perp \cdot \mathbf{P} + b_N^2 I^2 P^2, \quad (1)$$

where $A = 0.2696 \times 10^{-12}$ cm is the electronic magnetic scattering length. $\mathbf{M}_\perp \equiv \mathbf{M}\perp(\mathbf{Q}) = \mathbf{M}(\mathbf{Q}) - [\hat{\mathbf{Q}}\cdot\mathbf{M}(\mathbf{Q})]\hat{\mathbf{Q}}$ with $\mathbf{M}(\mathbf{Q}) = g_J f(\mathbf{Q})\mathbf{J}$ is the component of the magnetization perpendicular to the scattering vector $\mathbf{Q}$ and $\mathbf{J}$ the total angular momentum vector. $f(\mathbf{Q})$ is the electronic form factor and $\mathbf{P}$ the polarization vector of the nuclei. b_N is the scattering

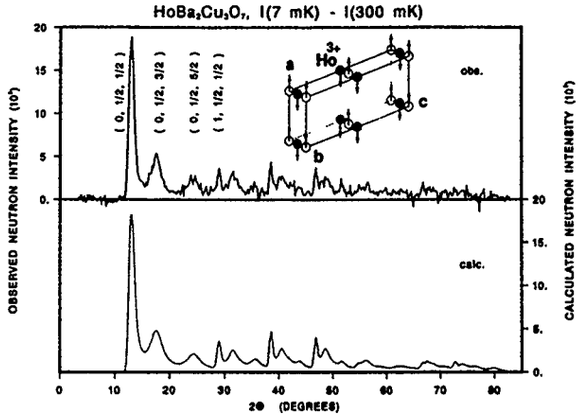

FIG. 1. Observed and calculated magnetic neutron-diffraction difference pattern I (7 mK)$-I$ (300 mK) of $HoBa_2Cu_3O_7$. The calculated line corresponds to the model explained in the text. Inset: Magnetic sublattice of $HoBa_2Cu_3O_7$. The magnetic moments are oriented parallel to the a axis. The statistics correspond to about three days measurements.

length of a thermal neutron by a nuclear spin I.[15] The least-squares refinements of the observed magnetic diffraction patterns were carried out by means of a modified version of the program MINREF[10] including instrumental resolution and using Eq. (1). The electronic form factor of Ho^{3+} was used in the relativistic dipole approximation.[11]

The unusual line shapes observed in the magnetic neutron diffraction pattern of $HoBa_2Cu_3O_7$ (and to a lesser extent in $HoBa_2Cu_3O_{6.8}$) can be shown to result from finite magnetic correlations along the c axis which is equivalent to the occurrence of magnetic stacking faults along that direction. In that case, the shape of the magnetic intensity for a particular reflection (h,k,l) can be described by a Lorentzian:[12]

$$I_{hkl}(\mathbf{q}) \propto \frac{\Gamma}{\pi(\Gamma^2+|\tau_{hkl}-\mathbf{Q}|^2)}\ \delta(q_a)\delta(q_b) \qquad (2)$$

with $\mathbf{q}=(q_a,q_b,q_c)=\tau_{hkl}-\mathbf{Q}$.

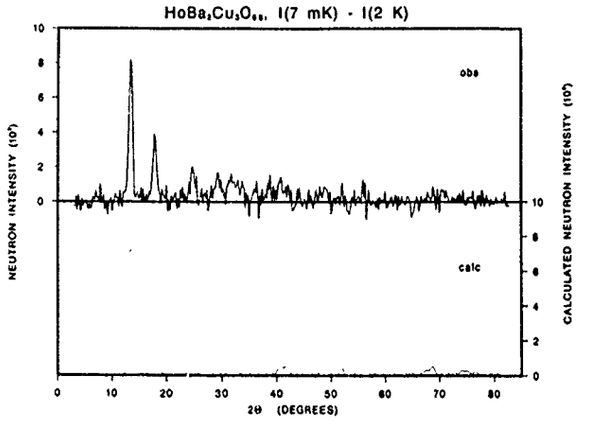

FIG. 2. Observed and calculated magnetic neutron-diffraction difference pattern I (7 mK)$-I$(2 K) of $HoBa_2Cu_3O_{6.8}$. The magnetic structure is the same as for $HoBa_2Cu_3O_7$. The statistics correspond to about three days measurements.

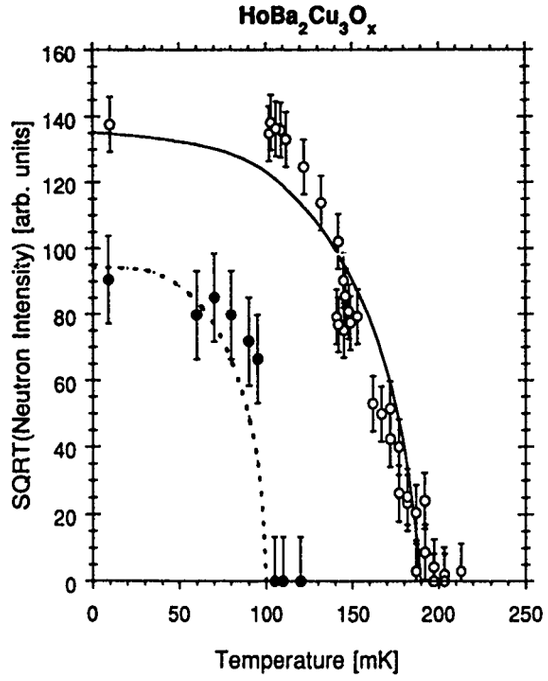

FIG. 3. The open (full) points represent the observed and the (dotted) line the calculated square root of the magnetic neutron intensity for the (0,1/2,1/2) peak of $HoBa_2Cu_3O_x$, x=7.0 with T_N=190 mK (x=6.8 with T_N=100 mK).

Figure 1 shows the results of the least-squares refinement based on Eqs. (1) and (2) (and using the Laue theorem for diffraction in polycrystalline samples), which excellently reproduces the data observed for $HoBa_2Cu_3O_{7.0}$. The Ho^{3+} magnetic moments are directed parallel to the a axis, and the (average) correlation length along the c axis is $\xi_c=2/\Gamma=(29\pm4)$ Å. By scaling the magnetic diffraction pattern with the nuclear reflections we obtain an electronic zero-field moment $\mu=2.8(3)\ \mu_B$ at T=7 mK. A least-squares refinement of the $HoBa_2Cu_3O_{6.8}$ data yields $\mu=1.7(2)\ \mu_B$ and $\xi_c=(129\pm10)$ Å at T=7 mK (see Fig. 2).

Figure 3 shows the temperature dependence of the observed neutron intensities for the (0,1/2,1/2) magnetic reflection. For a mean-field analysis of these data we base our calculations on a Hamiltonian which includes crystal field, exchange, and hyperfine interactions:

$$H=V_c-\lambda\langle J_x\rangle J_x+aJ_xI_x. \qquad (3)$$

V_c is the crystal-field operator, λ the molecular field parameter, a the hyperfine coupling constant, and x the easy axis of magnetization. The crystal field as determined by neutron spectroscopy[2,7] yields Γ_3 and Γ_4 singlets as ground and first excited states, respectively, with energy separation Δ. As the remaining crystal-field states lie far above Δ, we can restrict our calculations to an effective two-level system. H is then diagonalized in the subspace spanned by the vectors $\{|\Gamma_3,m_I\rangle,|\Gamma_4,m_I\rangle;m_I=-I,\ldots,I;\ I=7/2\}$. At finite temperature the induced electronic and nuclear polarizations are given by[13]

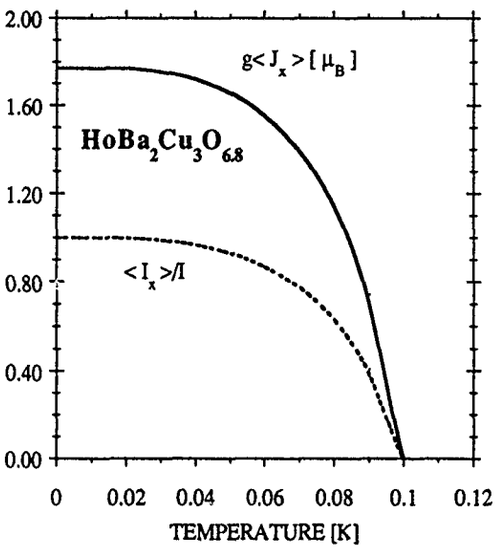

FIG. 4. The lines are the calculated electronic magnetization $\mu(T)$ and the (reduced) polarization of the nuclei $P=\langle I_x\rangle/I$, respectively, for $HoBa_2Cu_3O_{6.8}$, as explained in the text. The same calculations were carried out for $HoBa_2Cu_3O_7$ and are published in Ref. 6.

$$\langle J_x\rangle=\sum_{m_I} z^{m_I} sh\left(\frac{\Delta_{m_I}}{kT}\right)\Big/\sum_{m_I} ch\left(\frac{\Delta_{m_I}}{kT}\right),$$
$$\langle I_x\rangle/I=\sum_{m_I} m_I ch\left(\frac{\Delta_{m_I}}{kT}\right)\Big/\sum_{m_I} ch\left(\frac{\Delta_{m_I}}{kT}\right). \tag{4}$$

Δ_{m_I} is the energy separating two eigenstates of Eq. (3) with same nuclear spin states m_I, and z^{m_I} is the solution of the self-consistent equation for the induced electronic moment of the new quantum states at $T=0$ K:

$$z^{m_I}=|w|\,\frac{x\langle J_x\rangle+m_I\alpha}{\sqrt{1+(x\langle J_x\rangle+m_I\alpha)^2}},$$
$$\alpha=-2|w|\,\frac{a}{\Delta},\quad x=\frac{2|w|}{\Delta}\,\lambda, \tag{5}$$

with $|w|=|\langle\Gamma_4|J_x|\Gamma_3\rangle|$. The hyperfine coupling constant has been determined by electron paramagnetic resonance (EPR) measurements[14] to be $a=39$ mK, and the value of $|w|$ and Δ are known from neutron spectroscopic experiments on $HoBa_2Cu_3O_x$.[2,7] The only adjustable parameter is then the molecular-field constant λ which we have chosen such as to correctly predict the Néel temperature T_N. For both $x=7.0$ and $x=6.8$ we find $\lambda=65$ mK. Figure 4 shows the results of our calculations based on Eqs. (4) and (5), with the model parameters summarized in Table I. At $T=7$ mK the calculated electronic moments turn out to be $\mu=1.77\mu_B$ and $\mu=2.68\mu_B$ for $x=6.8$ and 7.0, respectively, in excellent agreement with the derived values from the diffraction data (see text and Table I). For $x=6.3$ the calculation (assuming $\lambda=65$ mK as for $x=6.8$ and $x=7.0$) yields $T_N=60$ mK and $\mu=0.4\mu_B$ at saturation. This value is too small to give significant contributions to the magnetic diffraction pattern, in agreement with the observed diffraction data for $HoBa_2Cu_3O_{6.3}$. Similar calculations carried out including the full crystal-field level scheme gave essentially identical results as obtained from the effective two-level model, Eqs. (4) and (5,

The Raman spectrum of two-dimensional spin-$\frac{1}{2}$ Heisenberg antiferromagnets is calculated by exactly diagonalizing clusters of up to 26 sites. The obtained spectra are compared to experimental results for various high-T_c precursors, such as La_2CuO_4 and $YBa_2Cu_3O_{6.2}$. In spite of good agreement in the position of the main excitation in the B_{1g} channel, i.e, the two-magnon peak around 0.4 eV, an additional mechanism has to be invoked to account for the broad and asymmetric shape of the overall spectrum. Here, we consider the phonon-magnon interaction which, in a quasistatic approximation, renormalizes the Heisenberg exchange integral. This mechanism is motivated in part by recent experimental observations that the Raman linewidth broadens with increasing temperature. Our results are in good agreement with Raman scattering experiments performed by various groups; in particular, the calculations reproduce the broad line shape of the two-magnon peak, the asymmetry about its maximum, the existence of spectral weight at high energies, and the observation of nominally forbidden A_{1g} scattering.

Raman scattering is a powerful technique for the study of electronic excitations in strongly correlated systems. Recently, much attention has been given to the anomalous magnetic scattering with a very broad and asymmetric line shape observed in the Raman spectra of high-T_c precursors, such as La_2CuO_4, and $YBa_2Cu_3O_{6.2}$ at around 3230 and 3080 cm^{-1}, respectively.[1] The selection rules associated with this peak are also anomalous. While the spin-pair excitations scatter predominantly in the allowed B_{1g} channel, there is also a significant contribution in the nominally forbidden A_{1g} configuration.[1]

Previous theoretical studies[2-4] of Raman scattering in the nearest-neighbor spin-$\frac{1}{2}$ Heisenberg model on a two-dimensional square lattice have shown good agreement with experiments in the position of the two-magnon peak, but they have failed to account for the enhanced width observed in the spectra. Several schemes have been proposed to resolve this problem. Initially, it was believed that strong quantum fluctuations were responsible for the broadening.[3] However, recent studies of spin-pair excitations in a spin-1 insulator, $NiPS_3$, show a relative width comparable to that of two-dimensional cuprates.[5] This leads us to question the view that the observed anomaly is due to large quantum fluctuations intrinsic to spin-$\frac{1}{2}$ systems. Instead, we propose that a magnon-phonon coupling is responsible for the experimentally observed large widths. We remark that the measured widths are 3–4 times larger than the ones predicted within the spin-wave theory using the Dyson-Maleev transformation, even when processes involving up to four magnons are taken into account.[4]

The isotropic Heisenberg Hamiltonian is given by

$$H_0 = J \sum_{\langle ij \rangle} \mathbf{S}_i \cdot \mathbf{S}_j , \tag{1}$$

where the notation is standard, and only nearest-neighbor interaction is assumed. For the cuprates, the exchange integral is $J \simeq 1450$ K$\simeq 0.12$ eV.

In our study, we obtained the ground state $|\phi_0\rangle$ of H_0 using a Lanczos algorithm on finite two-dimensional square clusters ($N=16$, 18, 20, and 26) with periodic boundary conditions. We studied zero-temperature spectra associated with the scattering Hamiltonian[1-4]

$$H_{\text{Raman}} = \sum_{\langle ij \rangle} (\mathbf{E}_{\text{inc}} \cdot \hat{\sigma}_{ij})(\mathbf{E}_{\text{sc}} \cdot \hat{\sigma}_{ij}) \mathbf{S}_i \cdot \mathbf{S}_j , \tag{2}$$

where $\mathbf{E}_{\text{inc,sc}}$ corresponds to the electric field of the incident and scattered photons, and $\hat{\sigma}_{ij}$ is the unit vector connecting sites i and j. We concentrated on the case of polarizations perpendicular to each other, $\mathbf{E}_{\text{inc}} \propto \hat{\mathbf{x}} + \hat{\mathbf{y}}$ and $\mathbf{E}_{\text{sc}} \propto \hat{\mathbf{x}} - \hat{\mathbf{y}}$, giving B_{1g} scattering.

The spectrum of the scattering operator can be written as

$$I(\omega) = \sum_n |\langle \phi_n | H_{\text{Raman}} | \phi_0 \rangle|^2 \delta(\omega - (E_n - E_0)) , \tag{3}$$

where ϕ_n denotes the eigenvectors of the Heisenberg Hamiltonian with energy E_n. In practice, the dynamical spectrum $I(\omega)$ is extracted from a continued-fraction expansion of the quantity

$$I(\omega) = -\frac{1}{\pi} \, \text{Im} \langle \phi_0 | H_{\text{Raman}} \frac{1}{\omega + E_0 + i\epsilon - H_0} H_{\text{Raman}} | \phi_0 \rangle , \tag{4}$$

where ϵ is a small real number introduced in the calculation to shift the poles of Eq. (4) into the complex plane.

Our results for B_{1g} scattering are shown in Figs. 1 and 2. The experimentally observed two-magnon excitation lies around $3J$, which is in good agreement with the location of the main peak in the exactly diagonalized 16-site square lat-

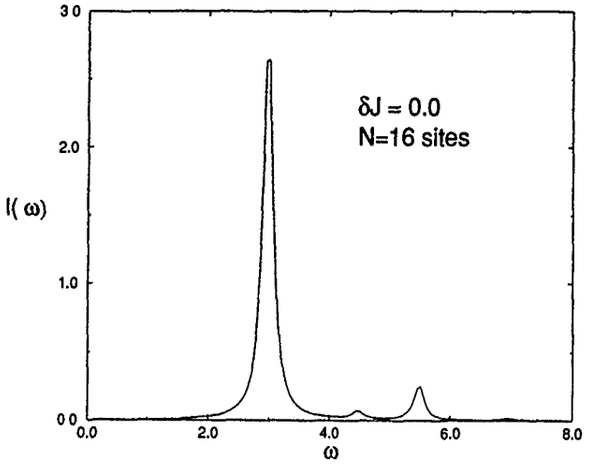

FIG. 1. B_{1g} Raman spectrum in the 4×4 lattice for the pure Heisenberg model. The peaks have been given a finite width $\epsilon=0.1J$, and ω is given in units of J.

tice shown in Fig. 1. The position of this peak can be understood in terms of the Ising model, which corresponds to the limit of the anisotropic Heisenberg Hamiltonian where no quantum fluctuations are present. In its ground state, the Ising spins align antiferromagnetically for $J>0$. Within this model and for a two-dimensional (2D) square lattice, it is well known that the incoming light creates a local spin-pair flip at an energy $3J$ higher than the ground-state energy. This argument remains valid even in the presence of quantum fluctuations. Our results indicate that the two-magnon excitation is at $2.957J$, $3.4260J$, and $3.0370J$ for the 16-, 20-, and 26-site square lattices, respectively. We believe that the somewhat large shift for the 20-site cluster is due to an artifact inherent to the symmetry of the cluster.

While there is good agreement with experiments in regard to the two-magnon peak position, the calculated widths are too small. Thus, it seems necessary to invoke an additional process to account for the observed wide and asymmetric line shape. Here, we propose that the important interaction is between the magnon pair and phonons. The phonons distort the lattice and renormalize the spin-spin exchange interaction in H_0. This mechanism relates to that proposed by Halley[6] to account for two-magnon infrared absorption in, e.g., MnF_2. The calculations in Fig. 2 correspond to the Raman spectra of a disordered lattice, or alternatively, to the quenched phonon approximation. This approximation is valid for the cuprates because there is a clear separation of energies between the fast modes (magnons) and the slow modes (phonons). For instance, in $YBa_2Cu_3O_6$ the characteristic Debye frequency is about 340 cm^{-1} while the two-magnon excitation is $\approx$3080 cm^{-1}. The Born-Oppenheimer approximation focuses on the fast modes and freezes the slow ones.

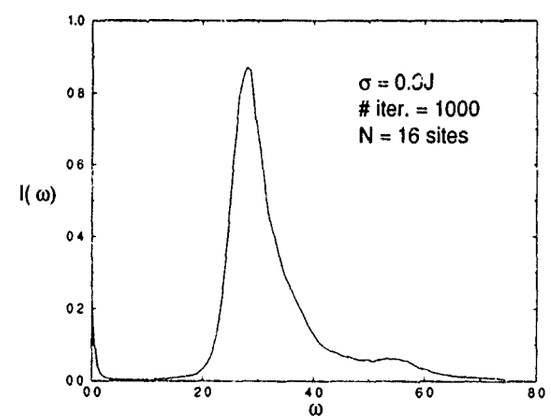

FIG. 2. B_{1g} Raman spectrum for the Heisenberg model on a 4×4 lattice in the presence of randomness in the exchange integral; this represents the effect of the spin-pair–phonon interaction; ω is given in units of J.

In our approach, we consider quantum fluctuations and, more important, finite temperatures, which distort the lattice. In turn, these lattice distortions induce changes, δJ_{ij}, in the exchange integral J of the perfect undistorted lattice. Here, δJ_{ij} represents the instantaneous value of $\mathbf{Q}\cdot\nabla_{\mathbf{Q}}J_{ij}(\mathbf{R})$, where $\mathbf{R}$ denotes the equilibrium position of the ion carrying the spin, and $\mathbf{Q}$ is the deviation from the equilibrium. In the quenched disorder approximation, we obtain the effective Hamiltonian

$$H_i=\sum_{\langle ij\rangle}(J+\delta J_{ij})\mathbf{S}_i\cdot\mathbf{S}_j, \tag{5}$$

where $|\delta J_{ij}|<J$ is a random variable reflecting the motion of the ions. Owing to this motion, the translational invariance of the original Heisenberg Hamiltonian [Eq. (1)] breaks down. This corresponds to taking a snapshot of the lattice, i.e., to a Born-Oppenheimer-type approximation which focuses on the fast (high-energy) modes and freezes the slow (low-energy) phonon modes.

In our study, the random couplings δJ_{ij} were drawn from a Gaussian distribution

$$P(\delta J_{ij})=\frac{1}{\sqrt{2\pi}\sigma}\exp[-(\delta J_{ij})^2/2\sigma^2].$$

For a typical optical phonon frequency ($\approx$340 cm^{-1} for $YBa_2Cu_3O_6$), we expect $\sigma\simeq 0.3J$.[7] $I(\omega)$ was obtained as the quenched average over $m\simeq 1000$ realizations of the randomly distorted lattice. The quenched average of an operator $\hat{O}$ is defined by

$$\langle\langle\hat{O}\rangle\rangle=\frac{1}{m}\sum_{j=1}^{m}\langle\phi_0(j)|\hat{O}|\phi_0(j)\rangle, \tag{6}$$

where $\phi_0(j)$ is the ground state of the jth realization of the disordered system.

In Fig. 2, we show the Raman spectrum for the 16-site square lattice in the presence of random exchange couplings drawn from a Gaussian distribution with $\sigma\simeq 0.3J$, which we found to agree best with experimental spectra.[1]

We find that the three main features observed in the experiments,[1] namely, the broad line shape of the two-magnon peak, the asymmetry about its maximum, and the existence of spectral weight up to $\omega\sim 8J$ are well reproduced. Beyond the two-magnon peak, there is a continuum of phonon-multimagnon excitations. The small feature

around $\omega \sim 5.5J$ is tentatively assigned to a four-magnon excitation. We are currently investigating this point. In addition, the calculated A_{1g} component (not shown), which becomes allowed due to disorder, also shows good agreement with experiments.

Finally, we would like to stress that not every kind of disorder gives rise to the observed broadening of the spectrum. For instance, disorder by points defects or twinning planes will not produce such an effect. Also, it is observed in experiments that the Raman linewidth broadens with increasing temperature.[8] This is a strong indication of a phonon mechanism for the broadening.

In summary, we find strong evidence of phonon-induced broadening of the two-magnon Ramam scattering peak by treating the low-energy phonons as a static random distortion of the lattice. Our results are in good agreement with experimental spectra.

[7] For conventional transition metal oxides and halide magnets, the dependence of the superexchange integral J on the spin-spin separation r is approximately given by $J(r) \sim r^{-10}$. This decay law can be extracted from experiments probing the pressure dependence of J; see, e.g., M. J. Massey *et al.*, Phys. Rev. B **41**, 8776 (1990). However, for the cuprates the exact value of the decay exponent is still not agreed upon. For instance, recent results of M. Aronson *et al.*, Phys. Rev. B **44**, 4657 (1991), predict an exponent of about -6.4 ± 0.8. Nevertheless, *any* of these values for the decay exponent gives a very strong dependence of J on the spin-spin separation, and our estimate for σ is not significantly affected by them.

Vortex flux creep and magnetic hysteresis in a type-II superconductor (abstract)

M. K. Hasan, S. J. Park, and J. S. Kouvel[a)]
Physics Department, University of Illinois, Chicago, Illinois 60680

Upon reversal of the external magnetic field H during any hysteretic cycling of a type-II superconductor in its vortex state, the rate at which the magnetic flux density B varies with H is typically seen to start from zero and then change gradually. Measurements have now been made of the time dependence of B (the vortex flux creep) at many fixed-H points on several hysteresis loops of a grain-oriented $YBa_2Cu_3O_7$ sample at 4.2 K (with **H** and **B** along the c axis), and it is observed that the size of the logarithmic dB/dt drops abruptly to zero, before proceeding to change in sign, whenever H is reversed. This curious similarity between the hysteretic behavior of dB/dt at fixed H and that of the nearly instantaneously measured dB/dH can be understood qualitatively in terms of the vortex pinning. As rotational magnetization measurements have recently shown,[1] the unpinning and repinning of moving vortices is manifested macroscopically as a frictional process. Thus, the reversal of vortex motion involves the reversal of frictional forces, during which the vortex population in the superconducting sample (which is proportional to B) does not change with time or field.

Interactions with the Dy^{3+} sublattice observed in high resistance ultrathin $DyBa_2Cu_3O_{7-x}$ films (abstract)

K. M. Beauchamp, G. C. Spalding, W. H. Huber, and A. M. Goldman
University of Minnesota, Minneapolis, Minnesota 55455

A low-temperature anomalous magnetoresistance has previously been reported in disordered ultrathin $DyBa_2Cu_3O_{7-x}$ films. This unusual behavior was associated with interactions between the charge carriers and a magnetic lattice. Here, new results are presented showing a peak in the temperature dependence of the resistivity near the Dy^{3+} Néel temperature. A calculation is included which shows that the peak in $R(T)$ is consistent with spin disorder scattering from the Dy^{3+} ions as they order antiferromagnetically. These observations lend support to the suggestion, based on neutron scattering studies, that the Dy^{3+} interactions are not strictly dipolar and that the electrons may contribute to the magnetic ordering of the Dy^{3+} sublattice.

Probing of the pairing state of HTSCs utilizing *a-b* plane magnetization anisotropy (abstract)

J. Buan, N. E. Israeloff, C. C. Huang, and A. M. Goldman
Center for Science and Application of Superconductivity and School of Physics and Astronomy, University of Minnesota, Minneapolis, Minnesota 55455

J. Z. Liu and R. N. Shelton
Department of Physics, University of California, Davis, California 95616

We have performed measurements of the a-b plane longitudinal and transverse magnetization anisotropy on an untwinned, high quality single crystal of $LuBa_2Cu_3O_{7-x}$ in magnetic fields below H_{c1} as a function of temperature, from 2 K to the transition temperature and the angle between the field and a fixed direction in the a-b plane. When the superconducting order parameter has nodes on the Fermi surface, such as the case of the spin-singlet $d_{x^2-y^2}$ order parameter, nonlinear effects associated with low-energy quasiparticles should become important.[1] It was pointed out by Yip and Sauls that these effects will be most important at low temperatures. They should be observable in a measurement of the anisotropy of the magnetization or the magnetic torque. The magnetization is predicted to develop an anisotropic component transverse to the applied field. Anisotropic transverse magnetization with $d_{x^2-y^2}$ symmetry is not seen in the temperature regime 5 to 25 K. Our results set stringent limits on the anisotropy of the transverse magnetization in this range. Within the resolution of our experiment no evidence for d-wave pairing is observed.

Supported in part by the Materials Research Group Program of the NSF under Grant No. NSF/DMR-8908094.

Theory of two-dimensional antiferromagnets with a nearly critical ground state (abstract)

Andrey V. Chubukov[a] and Subir Sachdev
Departments of Physics and Applied Physics, P. O. Box 2157, Yale University, New Haven, Connecticut 06520

We present the general theory of clean, two-dimensional, quantum Heisenberg antiferromagnets which are close to the zero-temperature quantum transition between ground states with and without long-range Néel order. For Néel-ordered states, "nearly-critical" means that the ground state spin stiffness, ρ_s, satisfies $\rho_s \ll J$, where J is the nearest-neighbor exchange constant, while "nearly-critical" quantum-disordered ground states have an energy gap, Δ, towards excitations with spin-1, which satisfies $\Delta \ll J$. The allowed temperatures, T, are also smaller than J, but *no* restrictions are placed on the values of $k_B T/\rho_s$ or $k_B T/\Delta$. Under these circumstances, we show that the wave vector /frequency-dependent uniform and staggered spin susceptibilities, and the specific heat, are completely universal functions of just three thermodynamic parameters. On the ordered side, these three parameters are ρ_s, the $T=0$ spin-wave velocity c, and the ground state staggered moment N_0. Explicit results for the universal scaling functions are obtained by a $1/N$ expansion on the $O(N)$ quantum nonlinear sigma model. These calculations lead to a variety of testable predictions for neutron scattering, NMR, and magnetization measurements. Our results are in good agreement with a number of numerical simulations and experiments on undoped and lightly doped $La_{2-\delta}Sr_{\delta}CuO_4$.

Behlen Laboratory of Physics and Center for Materials Research and Analysis, University of Nebraska, Lincoln, Nebraska 68588-0111

MnBiAl films are of considerable current interest for possible magneto-optical applications because of their perpendicular anisotropy, large polar Kerr rotation, reduced grain size, and structural stability. We report here experimental and theoretical studies of the effect of Al alloying on the electronic structure and magneto-optical properties of MnBi. Our measured spectral dependencies of the polar Kerr rotation in the two systems are similar. We carried out relativistic self-consistent spin-polarized electronic structure calculations on MnBi and MnBiAl, and the calculated densities of states are in good agreement with available x-ray photoemission spectroscopy data for both materials. The spin magnetic moment of Mn increases and the overall orbital moment decreases with the addition of Al to MnBi. The latter effect implies the lowering of spin-orbit interactions upon alloying MnBi with Al, and the two effects together suggest that the spectral dependencies of the Kerr rotation should be similar, as is observed experimentally.

MnBi has been known for several decades as a material with a large Kerr rotation. Recently, efforts have been made to improve its magneto-optical properties by alloying with other metals such as Al.[1–4] The electronic structure of MnBi has been calculated by Coehoorn and deGroot,[5] and a cluster study on the electronic and magnetic properties of MnBi and MnBiAl has been reported.[6] We report here theoretical and experimental studies of the electronic structure and magneto-optical properties of MnBi and MnBiAl.

MnBi crystal is hexagonal with four atoms per unit cell and the space group symmetry is $P6_3/mmc$ with sites a and c occupied. MnBiAl also has the same structure, and the distance between the hexagonal planes remains essentially unchanged upon alloying MnBi with Al. Unfortunately, little information is available on the change in the a lattice constant with the addition of Al. Also, the sites occupied by the Al atoms are unknown, but the interstitial sites in the hexagonal NiAs structure are thought to be the most likely candidates. In the present calculations we assume MnBiAl to be an ordered structure with all the interstitial (d) sites occupied by Al atoms. We had to make the a lattice constant of MnBiAl 15% larger than that of MnBi to stabilize the electronic structure calculations.

The relativistic self-consistent spin-polarized electronic structure calculations are based on the linear muffin-tin orbitals method (LMTO) in the local density approximation.[7] MnBi and MnBiAl have four and six atoms per unit cell, respectively. With s, p, and d as basis functions, the relativistic Hamiltonian gives 72×72 and 108×108 matrices for MnBi and MnBiAl, respectively.

The results for total and partial spin-polarized densities of states (DOS) for MnBi are shown in Fig. 1. The Mn $3d$ states dominate the spectrum with a peak around 3 eV below the Fermi level in the occupied states. The magneto-optical properties of MnBi are primarily determined by transitions between Mn d and Bi p states. The present results are similar to those of Coehoorn and deGroot[5] based on the augmented spherical wave method.

The MnBiAl DOS, plotted in Fig. 2, are qualitatively similar to those of MnBi. The differences in the two spectra arise because of the additional hybridization mainly between the s-p states of Bi and Al in MnBiAl. The calculated DOS for the two systems are in good agreement with the x-ray photoemission spectroscopy data of Wang *et al.*[2]

The calculated magnetic moments in MnBi and MnBiAl are listed in Table I. The Mn moment in MnBiAl is about 5% larger than that in MnBi, whereas the induced moment on Bi goes down. This is due to the reduced hybridization between Mn and Bi states, which results from the hybridization of the Bi and Al states mentioned in the preceding paragraph.

The Kerr rotation in the two systems is primarily due to the magnetism of Mn and the spin-orbit interactions of Bi.[8]

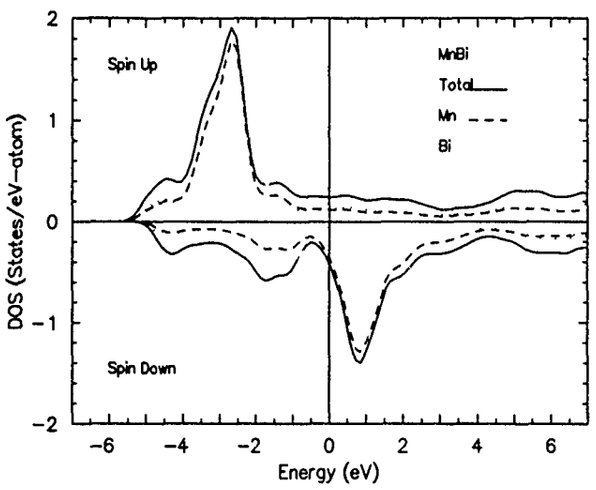

FIG. 1. Total and partial spin-polarized densities of states of MnBi.

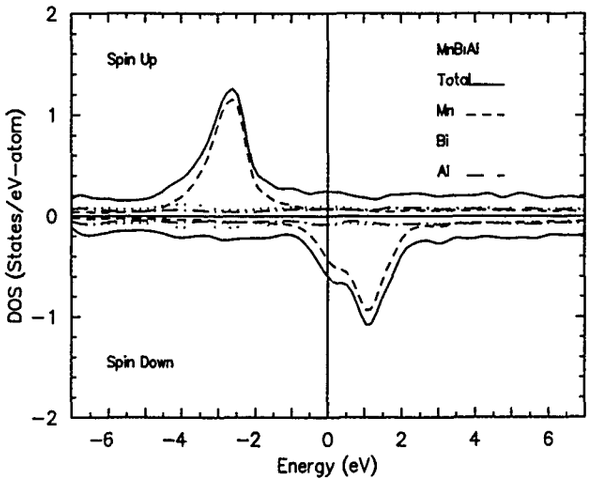

FIG. 2. Total and partial spin-polarized densities of states of MnBiAl.

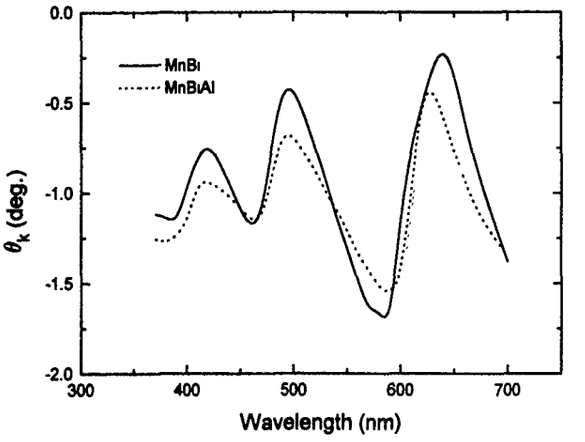

FIG. 3. Measured polar Kerr rotation as a function of the wavelength in MnBi and MnBiAl. The oscillations in the rotation are due to optical interference effects in the SiO_x overcoat. The nominal compositions were $Mn_1Bi_{0.8}$ and $Mn_1Bi_{0.8}Al_{0.4}$.

We have seen above that the addition of Al to MnBi enhances the Mn magnetic moment. To study the effect of Al on spin-orbit interactions, we have calculated the orbital moments in the two systems, which are given by

$$l_z = \sum_{\sigma l m_l} n^{\sigma}_{m_l} m_l ,$$

where m_l is the magnetic quantum number corresponding to the orbital quantum number l and $n^{\sigma}_{m_l}$ is the occupied number density for spin σ.[9] The calculated values of the orbital moment (in μ_B) for MnBi and MnBiAl are 0.129 and 0.057 per unit cell, respectively. Thus the addition of Al to MnBi lowers the spin-orbit interactions due to the hybridization of Al and Bi states.

The present calculations are based on 33.3 at. % Al in MnBiAl, while the experimental results are for Al concentrations of typically 15 at. %. Thus the increase in the magnetic moment of Mn and the decrease in spin-orbit interactions for the experimental concentrations of Al in MnBi are expected to be small. Since the changes in the magnetic moments and spin-orbit interactions due to aluminization of MnBi have opposite effects on the Kerr rotation, we expect Kerr spectra of MnBi and MnBiAl to be quantitatively similar.

TABLE I. Magnetic moments (in μ_B) for different sites in MnBi and MnBiAl.

	MnBi		MnBiAl
	Present calculations	Ref. 5	Present calculations
Mn	3.78	3.61	4.08
Bi	−0.20	−0.09	−0.01
Al			−0.02

Our experimental results for the Kerr rotation as a function of wavelength are plotted in Fig. 3. The oscillations in the data are due to multiple reflections from the ~150 nm thick SiO_x overcoat. Taking the average values of these oscillations, we note that the Kerr rotations for MnBi and MnBiAl are similar, in agreement with our theoretical predictions. Our experimental results are also in agreement with those of Di *et al.*[4] The experimental results of Wang *et al.*[1,2] are somewhat similar to the above data except for a low value of 0.7° for MnBi at 633 nm.

In conclusion, the electronic structure calculations predict that the Kerr rotations in MnBi and MnBiAl should be similar, which is in agreement with the experimental data.

Low-temperature characterization of the magnetic properties of MnBiAl thin films

K. W. Wierman, J. X. Shen, R. D. Kirby, and D. J. Sellmyer
Behlen Laboratory of Physics and Center for Materials Research and Analysis, University of Nebraska, Lincoln, Nebraska 68588-0111

The magnetic properties of thin-film samples of $MnBi_{0.8}Al_x$ with aluminum concentrations of $x=0.0$, 0.4, 0.6, and 0.8 were systematically studied over a temperature range of 20 to 300 K. The as-deposited films are amorphous and nonmagnetic, but highly textured polycrystalline films that are ferromagnetic are formed by annealing at 350 °C. Our measurements show that the coercivity of such films rapidly decreases, then approaches a constant value (4 kOe for $x=0.4$) with increasing annealing time. Magnetic measurements show that both anisotropy and coercivity decrease with decreasing temperature. Unlike bulk MnBi, our $MnBi_{0.8}Al_x$ thin films do not have a spin reorientation transition at low temperatures. This may be due to impediment of the lattice contraction by the Al atoms doped into the interstitial sites of the MnBi lattice.

INTRODUCTION

MnBiAl has been proposed as a possible magneto-optical storage candidate due to its large Kerr rotation and perpendicular magnetic anisotropy. Wang reported that (Al,Si) doping increased the Kerr rotation, improved the thermal stability, and reduced the polycrystalline grain size.[1] Roberts[2] carried out neutron diffraction studies on bulk MnBi and found that the c axis contracted by more than 1% as the temperature was lowered from 300 to 5 K. Recent work by Guo *et al.*[3] on bulk MnBi showed that the uniaxial anisotropy constant decreases substantially with decreasing temperature, and the lattice contraction may be a major contributing factor to this decrease. It is also of interest to ascertain what role aluminum doping plays in determining the anisotropy energy and its temperature dependence.

EXPERIMENT

$MnBi_{0.8}Al_x$ thin films with nominal Al contents $x=0.0$, 0.4, 0.6, and 0.8 were made by sequential evaporation of Bi, Mn, and Al from a tungsten boat onto a room-temperature glass substrate. The base pressure of the vacuum chamber was 3×10^{-7} Torr, and the film thickness was typically 80 nm. After evaporation, the thin films were covered with a 150-nm-thick SiO_x protective layer. Samples were annealed in vacuum for 4 h at 350 °C. X-ray diffraction measurements show large intensities for the (002) and (004) MnBi peaks, indicating that the annealed films have the NiAs-type hexagonal structure with the c axis highly oriented along the film normal. The c-axis lattice parameter of $MnBi_{0.8}Al_{0.8}$ (6.06 Å) is the same as that of $MnBi_{0.8}$ (6.07 Å) within measurement error, similar results were obtained for $x=0.4$, 0.6. In the measurements reported here, the temperature dependencies of the perpendicular anisotropy constant K_u, coercive force H_c, and remnant magnetization were determined from hysteresis loops generated by an alternating-gradient force magnetometer (AGFM). Kerr rotation versus total annealing time measurements were made using an apparatus described elsewhere.[4]

RESULTS AND DISCUSSION

Figure 1 shows the perpendicular and parallel hysteresis loops as measured with the AGFM for $MnBi_{0.8}Al_{0.4}$ at three different temperatures. These loops clearly show that perpendicular anisotropy is maintained down to low temperatures for $x=0.4$, and similar loops were obtained for the $x=0.0$, 0.6, and 0.8 samples. No evidence of the spin reorientation transition reported for bulk MnBi is found in these measurements.[5]

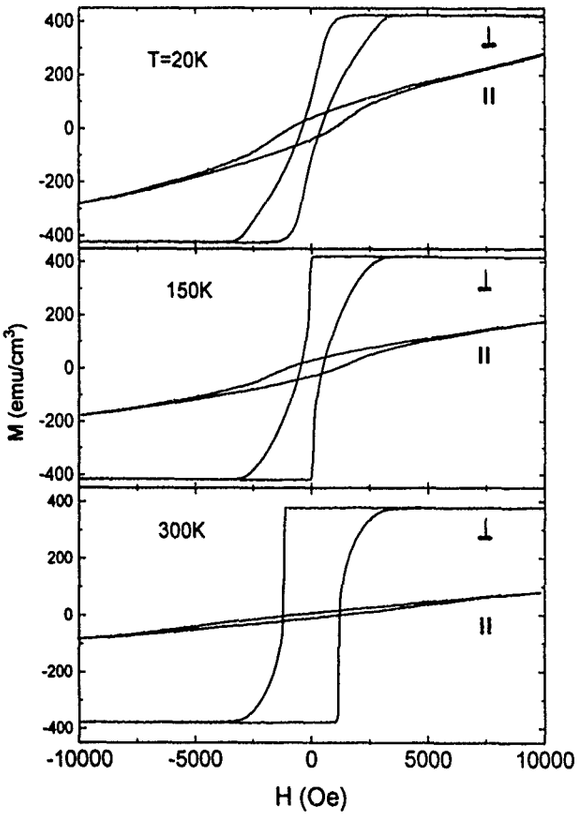

FIG. 1. Parallel and perpendicular magnetization loops for $MnBi_{0.8}Al_{0.4}$. The parallel and perpendicular loops are indicated.

 0021-8979/94/75(10)/6348/3/$6.00 © 1994 American Institute of Physics

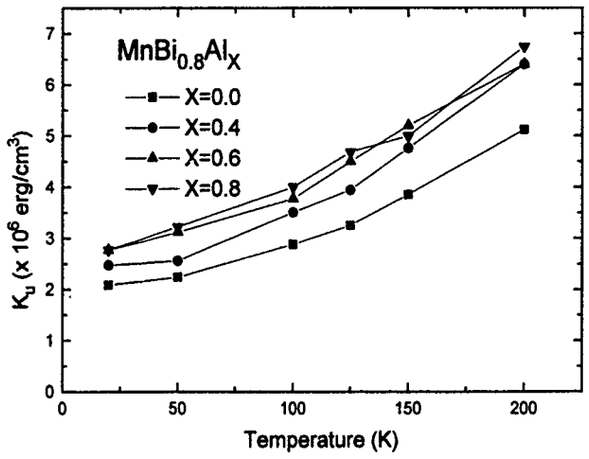

FIG. 2. Temperature dependence of the anisotropy constant K_u of $MnBi_{0.8}Al_{0.4}$ for four different sample compositions.

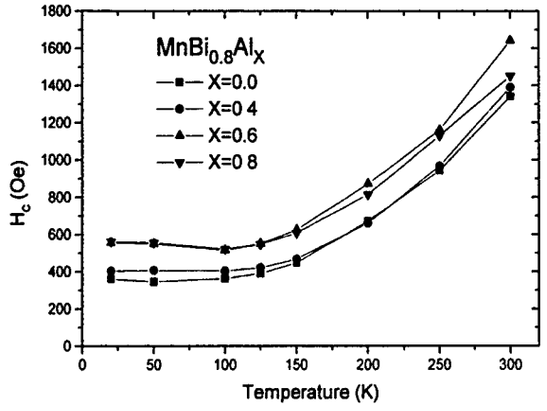

FIG. 4. Coercivity of $MnBi_{0.8}Al_{0.4}$ vs temperature for four different sample compositions.

The area between the perpendicular and parallel hysteresis loops was used to determine the magnetic anisotropy constant K_u, and Fig. 2 shows the temperature dependence of K_u for $x=0.0$, 0.4, 0.6, and 0.8. It can be seen that for each sample K_u increases with increasing temperature, as was found for bulk MnBi,[3,5] with the $x=0.8$ sample showing the largest increase. K_u could not be reliably determined for temperatures above 200 K because of the limited magnetic field available on the AGFM. Assuming the decrease in K_u with decreasing temperature is due to contraction of the c axis, then Al doping appears to hinder this contraction. This would be consistent with the Al atoms residing at the interstitial sites as opposed to in the grain boundaries.

Figure 3 plots the ratio of the remnant magnetization to the saturation magnetization (M_r/M_s) as a function temperature. The sharp drop in this ratio as T goes below 150 K is likely associated with the rapid reduction in K_u as the temperature is lowered. However, even at 50 K the anisotropy field ($2K_u/M_s$) is still a factor of two to three larger than the demagnetizing field ($H_d=4\pi M_s$), suggesting that the rapid drop in the remnant magnetization near 150 K is due to domain formation. It should also be noted that Al doping seems to only moderately improve loop squareness.

Figure 4 shows the coercivity as a function of temperature for all four samples. It should be noted that the $x=0.8$ sample has a slightly smaller coercivity than the $x=0.6$ at 300 K, even though it has a larger value of K_u. This suggests that physical properties other than the anisotropy field, such as crystalline microstructure and small variations in composition, are important in determining the magnitude of the coercivity.

Figure 5 shows the coercivities of $MnBi_{0.8}$ and $MnBi_{0.8}Al_x$ as a function of annealing time at 350 °C. The initial rapid decreases in the coercivities are consistent with crystallization of small particles, followed by growth of the particles. After annealing for about 6 h, no additional reductions in the coercivities are observed, suggesting that the crystallization process is completed and the particle sizes have reached their maximum values. The magnitude of the Kerr rotation (not shown) shows a behavior consistent with this interpretation. It rises rapidly from zero as a function of annealing time, finally saturating after 6 h of annealing. The

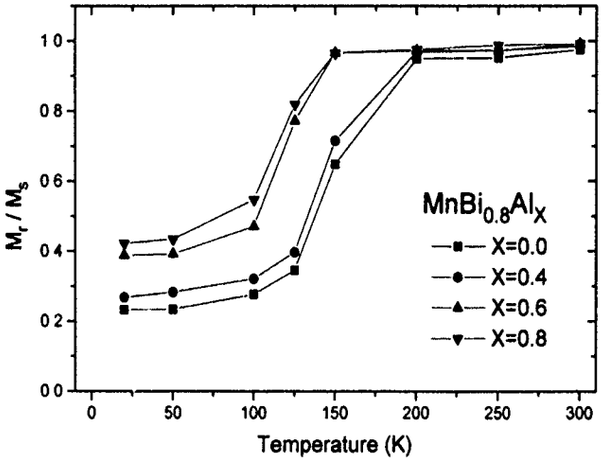

FIG. 3. Temperature dependence of the remnant magnetization M_r for four different sample compositions.

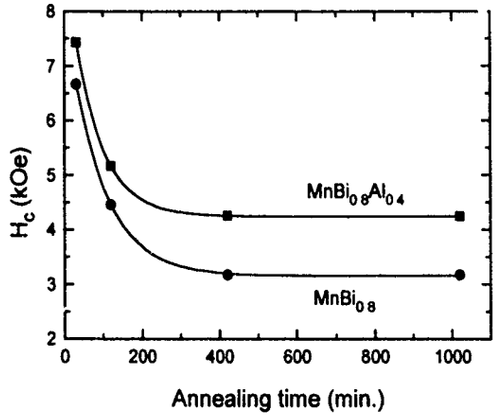

FIG. 5. Coercivity vs annealing time for $MnBi_{0.8}Al_{0.4}$ and $MnBi_{0.8}$.

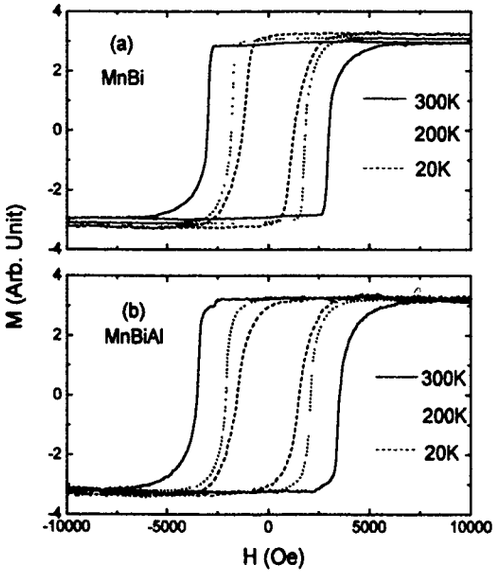

FIG. 6. Hysteresis loops obtained with an AGFM for (a) $MnBi_{0.8}$ and (b) $MnBi_{0.8}Al_{0.4}$ after 45 h of annealing at 350 °C.

Al-doped sample has a larger coercivity for all annealing times, which may be a reflection of the smaller grain sizes expected with Al doping.[1]

Figure 6 shows the temperature dependencies of the hysteresis loops for $MnBi_{0.8}$ and $MnBi_{0.8}Al_{0.4}$ after 45 h of annealing. Notice that both samples have nearly 100% remnant magnetization, even at the lowest temperature of 20 K. These results show that annealing conditions can have a larger effect on the remnant magnetization than does Al doping. The similar results here for $MnBi_{0.8}$ and $MnBi_{0.8}Al_{0.4}$ may be a consequence of diffusion of Si from the SiO_x overcoat into the bulk of the sample, as has been suggested by Wang.[1]

In summary, we have studied the magnetic properties of $MnBi_{0.8}Al_x$ for four different compositions over the temperature range 20 to 300 K. The values of the uniaxial anisotropy constant K_u were found to increase with Al content at room temperature and below. Our measurements showed no evidence of the low-temperature spin-reorientation transition previously observed in bulk MnBi. Coercivity measurements versus annealing time were obtained showing the sensitivity of the magnetic properties to annealing conditions. Further x-ray diffraction and electron microscopy studies are needed to determine the positions of the Al atoms and further to determine the effects that annealing conditions have on the crystal structure and microstructure. These studies are under way.

The functions of Al in MnBiAlSi magneto-optical films

D. Huang, X. W. Zhang, C. P. Luo, H. S. Yang, and Y. J. Wang
State Key Laboratory of Magnetism, Institute of Physics, Chinese Academy of Sciences, Beijing 100080, China

This article reports the effect of Al doping into MnBiSi films on the structure and magneto-optical properties of the parent. Under suitable Al doping, the x-ray diffraction peaks of (002) and (004) move to a larger 2Θ value related to that of MnBiSi. Moreover, two satellite peaks appear beside the main (002) and (004) peaks of MnBiAlSi. Such structural distortion due to Al doping results in an increased Kerr rotation angle, an effective perpendicular anisotropy constant K_u, as well as improvement of the thermal stability of MnBiSi.

I. INTRODUCTION

Since 1973 great attention has been paid to the amorphous rare-earth (RE)–transition-metal alloy film because of its large magneto-optical (MO) recording density.[1–3] These materials are used in practical MO disk products on the market today. However, a number of basic deficiencies remain, which include domain stability, thermal stability, and corrosion resistance. Moreover, these materials have small Kerr rotation angle and poor figure of merit around 400 nm. Apparently, RE–TM alloys must be replaced by a new medium because the short-wavelength recording is the trend for the MO disk since realization of the 420-nm recording will make it possible to increase the area density by a factor of 4.[4]

Nowadays, finding a new recording medium suitable for short-wavelength MO recording is of great interest. Several candidates such as Pt/Co multilayers and doped garnet are competing as the second generation recording medium. Pt/Co multilayers especially have a good figure of merit at about 400 nm (Ref. 5) as compared to the amorphous film.

Much of the earlier work on MO media was about MnBi (Ref. 6) since it satisfies some requirements of MO media such as large Θ_K, perpendicular anisotropy, and rectangular hysteresis loop. The major factor that obstructs the progress of MnBi as an available MO medium is that it has two crystal phases with the transition temperature close to its Curie temperature and thermomagnetic writing will result in thermal instability. In 1988, Wang reported on the (Al,Si)-doped MnBi film.[7,8] With the doping of Al and Si, the phase transition of MnBi is successfully suppressed. Meanwhile, the Θ_K is greatly increased to 2.04° at 6328 Å, 1.6° at 0.4 μm. Comparatively, at 0.4 μm, it is about three times as large as that of Pt/Co multilayers and six to seven times of TbFeCo. As a result, (Al,Si)-doped MnBi film becomes a promising candidate.[9]

In this article, using the data from the homogeneous saturated samples, we have systematically studied the effect of Al doping, concerning the MO properties, crystal structure, and temperature dependence of some material parameters.

II. EXPERIMENTAL PROCEDURE

As our previous reports showed,[7,8] $Mn_{1.0}Bi_{0.7}Al_{0.3}$ (named MnBiAlSi) and $Mn_{1.0}Bi_{1.0}$ (MnBiSi) films were prepared by thermal evaporating pure metals Bi, Al, and Mn, respectively, on glass substrate from multiple Ta boats. The area of substrate is 8×8 mm^2. Silicon oxide film as a protective layer was then deposited on these samples. The base pressure of the vacuum system is about 5×10^{-6} Torr.

The composition of the films was controlled by a quartz crystal monitor during evaporation, Bi, Al, Mn, and SiO were approximately 50, 9, 30, and 150 nm, respectively. The as-deposited films were annealed at about 600 K for 6 h in a vacuum of 1×10^{-6} Torr for alloying.

Magnetic domain structure was examined by using a polarization microscope (PM) in polar reflective mode. The polar Θ_K spectra and hysteresis loop were obtained by using modulation method through glass substrates. The crystalline structure was detected by a x-ray diffractometer (XRD). Torque was also employed to measure the effective perpendicular anisotropy constant K_u at different temperature. The annealing experiment was designed to study the thermal stability.

III. RESULTS AND DISCUSSION

The typical magnetic domain images of MnBiAlSi film are given in Fig. 1, in which Fig. 1(a) is taken just after annealing. Figures 1(b) and 1(c) are taken after the sample was magnetized under 6 kOe along the vertical direction, corresponding to both the remanence states with positive and negative M_r. It reveals that the samples are uniformly saturated. The domain picture of MnBiSi is similar to Fig. 1.

Figures 2(a) and 2(b) are the x-ray diffraction profile of MnBiAlSi and MnBiSi films. The extremely strong (002)

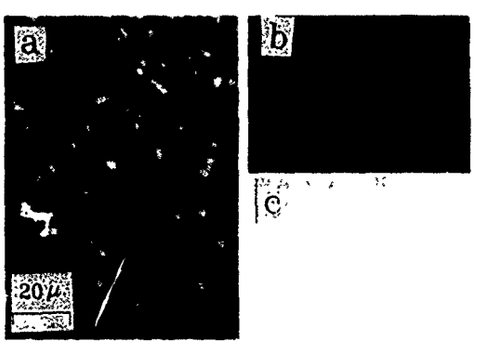

FIG. 1. Magnetic domain images of a MnBiAlSi film, in which (a) is taken just after annealing and (b) and (c) are taken after the domain images are saturated along the vertical with the opposite contrast.

 0021-8979/94/75(10)/6351/3/$6.00 © 1994 American Institute of Physics

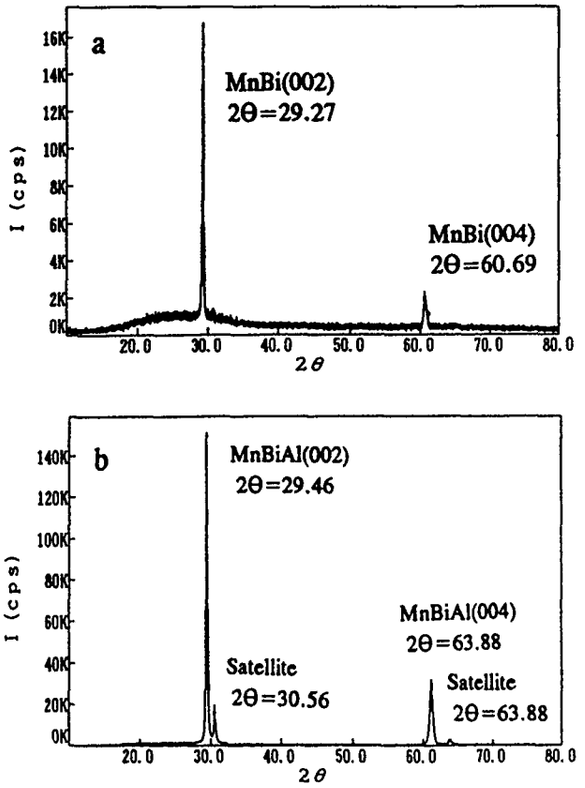

FIG. 2. X-ray diffraction profiles.

and (004) peaks are their common feature. It means that the perfect (002) texture with the c axis normal to the film plane is formed. Meanwhile, the c-axis orientation is also fine, which can be confirmed by $\delta\Theta \approx 1.9°$ from the Θ–2Θ curve (rocking curve) of the MnBiAlSi sample.

The other structural feature for Al doping into MnBiSi is that two new small satellite peaks appear beside the (002) and (004) peaks of MnBiAlSi on the x-ray profile, and they belong to the same crystal face family. These two peaks are surely not from any peak of Mn, Bi, or MnBi crystalline. They are effect of Al doping and may be of an unknown second new phase, at present. Below we can see that this second phase is stable in structure during the repeatedly heating-quenching circles.

Moreover, it is also found that the index d of MnBiAlSi between the two nearest hexagonal base planes is slightly reduced, from 6.10 Å (MnBiSi) to 6.04 Å (MnBiAlSi). This is evidence of Al in corporation in the MnBi structure.

It is well known that the Al-doped MnBi film has much larger Θ_K than MnBi film.[7,8] Figure 3 is the Kerr rotation spectra of MnBiAlSi and MnBiSi for our new homogeneous saturated samples. The reflectivity spectra of MnBiAlSi is also shown. Besides the different Θ_K value, we can see that the spectra of MnBiAlSi has an apparent peak structure around 6300 Å, but the peak of MnBiSi is poorly defined. In order to make it clearer, we show the curves in the insert where just the shape of both Kerr spectra are compared. Since the magneto-optical MO effect comes from the transition of the polarized electron,[10,11] the difference between the spectra suggests that Al doping modulates the structure of the electronic state of MnBi near the Fermi level.

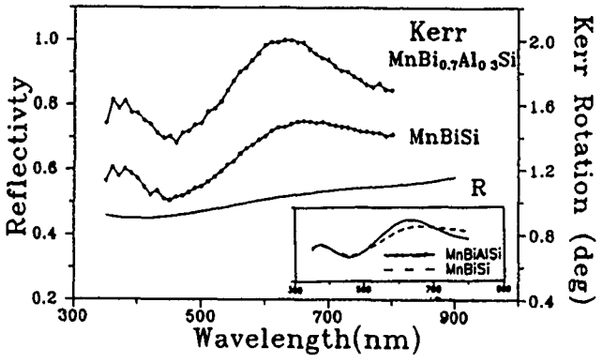

FIG. 3. Kerr rotation and reflectivity spectra. In the insert the shape of Kerr spectra for both samples are compared.

From the hysteresis loops measured by surface magneto-optical Kerr effect (SMOKE) at 6328 Å, as indicated in Fig. 4, we can see that the coercivity increases from about 1.4 kOe of MnBiSi to 2.3 kOe of MnBiAlSi. Also, the rectangular shape is highly improved with the doping of Al atoms. These will make the MnBiAlSi more suitable for MO recording.

At room temperature, K_u of MnBiAlSi is 2.5×10^6 erg/cm^3 and $K_u=1.2\times10^6$ erg/cm^3 for MnBiSi. The temperature dependence of the normalized anisotropy constant $K_u(T)/K_u$ (300 K) is given in Fig. 5 for MnBiAlSi and MnBiSi, respectively, for the range 80 to 300 K. From it, we can see that when the temperature varies from 300 down to 80 K, K_u of MnBiSi decreases by 80% from 2.5×10^6 to 0.5×10^6 erg/cm^3, similar to the previous report on MnBi alloy film.[12] Comparatively, K_u of MnBiAlSi has only a little change on the whole temperature.

As a magneto-optical recording medium, the thermal stability is very significant. Consequently, the experiment of about 750 K annealing on MnBiAlSi and MnBiSi were done, which approaches to the temperature of MnBi phase transition. The annealing procedure is that the samples were annealed in vacuum about 1×10^{-6} Torr for different durations from 10 to 3000 min at 750 K and then were cooled down to room temperature at the rate of -1.6 K/s. Figure 6 shows the Θ_K value versus the annealing time. It is clear that with the

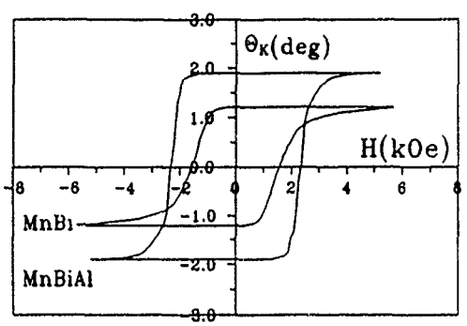

FIG. 4. Kerr hysteresis loops.

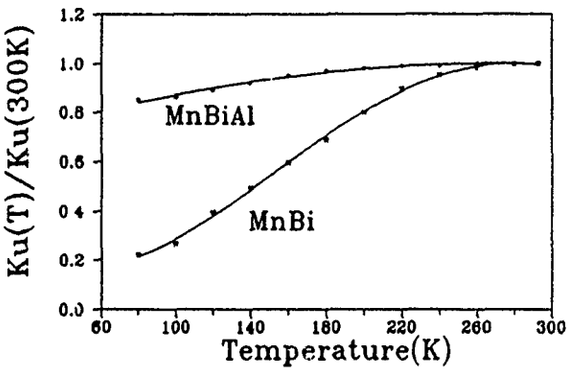

FIG. 5. Temperature dependence of anisotropy constant.

increase of annealing time, Θ_K of MnBiSi decreases continuously from 1.5° to 1.06°, while Θ_K of MnBiAlSi is almost unchanged.

As mentioned above, the Al doping into MnBiSi greatly improves the MO properties and stability, and this improvement maybe resulted from the structure change.

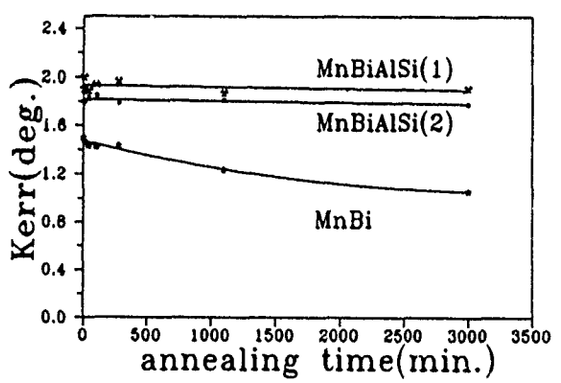

FIG. 6. Effect of thermal annealing on the value of Θ_K.

In the close-packed hexagonal structure of MnBi, there are a total of 14 Mn atoms on two neighboring hcp basal planes and three Bi atoms located at the intermediate between the hcp basal planes in a crystal unit cell. There are three interstitial sites that are identical to the site of three Bi atoms.[13]

In a solid solution if a large atom like Bi is replaced by a small atom like Al, the lattice constant decreases. The change or distortion of the crystal structure must carry out the change of the properties. We know that MO effect of MnBi mainly comes from the interband transition. Its large Θ_K value comes from Mn $3d$ electrons, which are strongly hybridized with Bi $6p$ electrons.[14] We consider that the doped Al atoms will surely affect the hybrid states, and consequently will produce the better MO properties including the larger Kerr rotation. The entrance of Al atoms into the lattice of MnBi including the Bi sites and the interstitial sites also affect the bonding between the nearest Mn atoms. The suppression of the phase transition could be related to the improvement of the bonding.

We report on the magnetic and magneto-optical properties of the intermetallic alloys $Mn_5(Ge_{1-x}M_x)_3$, where M=Sn, Pb. Generally, these alloys were ordered ferromagnetically at $T \geq 300$ K for $x<0.3$. The structure of $Mn_5(Ge_{1-x}Sn_x)_3$ remains in the hexagonal $Mn_5Si_3(hP16)$ phase up to $x=0.25$ and then changes to Ni_2In $(hP6)$ as x approaches 1. The magnetization and Curie temperature of these alloys is largest for small x and reach a minimum value near $x=0.5$. The room temperature Polar Kerr rotation, however, increases from $-0.06°$ at $x=0$ to maximum value of $-0.12°$ at $x=0.1$ before decreasing toward zero for $x>0.3$. The $Mn_5(Ge_{1-x}Pb_x)_3$ samples show a Mn_5Si_3 structure with ferromagnetic behavior for $x \leq 0.3$, and varying structure with rapidly decreasing magnetization above $x=0.3$. The magnetic behavior observed was complex for $x \geq 0.3$. The Kerr rotation of the Pb-doped alloys in the ferromagnetic region monotonically decreases from $-0.06°$ to zero at $x \approx 0.3$.

I. INTRODUCTION

Current research of materials for use as magneto-optic storage media focuses on ferromagnetic materials that have strong uniaxial anisotropy and Curie temperatures in the range of 30–200 °C.[1,2] The intermetallic compound Mn_5Ge_3 is ferromagnetic with a Curie temperature in the range of 27–47 °C. Favorable optical properties such as high optical absorption and large Kerr rotation might be expected largely due to the metallic character of the alloy and the high density of ferromagnetically aligned Mn^{2+} and Mn^{3+} ions present.[3] Panissod and his coworkers[4] have studied the $Mn_5(Ge_{1-x}Si_x)_3$ ferroantiferromagnetic transition as x changes from 0 to 1. They reported that Si can be substituted for Ge in Mn_5Ge_3 over the whole range of x and that these alloys are isostructural $(D8_8)$. The transition is from ferromagnetic for $x<0.85$ to antiferromagnetic for $x>0.85$. The aim of this work is to study the effects of heavy-element alloying on the magnetic properties and magnitude of the Kerr rotation (Θ_K). We report on the preparation and properties of the compounds $Mn_5(Ge_{1-x}M_x)_3$ with M=Sn, Pb.

II. EXPERIMENTS

Samples were prepared from 99.995 at. % pure Mn, 99.99 at. % pure Ge, and 99.9999 at. % pure Sn or 99.999 at. % pure Pb. Stoichiometric amounts were alloyed by arc melting in an argon atmosphere. In order to obtain homogeneous alloys, each sample was melted four to five times. Mass losses during melting totaled about 2% for $Mn_5(Ge_{1-x}Sn_x)_3$ and about 3% for $Mn_5(Ge_{1-x}Pb_x)_3$. The samples were then annealed in vacuum at 700 °C for 10 days.

The structure of the samples was analyzed by x-ray diffractometry. Their magnetization and coercivity were measured using an alternating gradient force magnetometer (AGFM) and superconducting quantum interference device (SQUID). The Curie temperatures were measured by both a high-temperature Faraday balance magnetometer and AGFM at $H=500$ Oe. The Polar Kerr rotation was determined by a home-made apparatus[5] at room temperature and fields up to 8 kOe.

III. RESULTS AND DISCUSSION

A. Crystallographic data

Figure 1 shows x-ray diffraction measurements on representatives of the $Mn_5(Ge_{1-x}Sn_x)_3$ samples. $Mn_5(Ge_{0.90}Sn_{0.10})_3$ [Fig. 1(a)] is found to have a $Mn_5Si_3(hP16)$ type structure, as does $Mn_5(Ge_{0.70}Sn_{0.30})_3$ [Fig. 1(b)] but with a $Ni_2In(hP6)$ structure phase also beginning to appear. The $Mn_5(Ge_{0.30}Sn_{0.70})_3$ sample [Fig. 1(c)] shows the $Ni_2In(hP6)$ structure. Only small amounts of Mn oxides show up in the x-ray spectra. It has also been found by others that Mn_5Ge_3 has a Mn_5Si_3 structure[3] and Mn_5Sn_3 has a Ni_2In structure.[6] When Sn is substituted for Ge in Mn_5Ge_3 [i.e., $Mn_5(Ge_{1-x}Sn_x)_3$] it can be expected that for small x the compounds will maintain the Mn_5Si_3 structure and that for large x the compounds should form the Ni_2In structure. In the middle range these structures could be mixed and show various lattice distortions. Since the Sn atomic diameter is larger than that of Ge, when Sn is substituted for Ge in Mn_5Ge_3 the lattice parameter of the crystal changes. Table I gives the variations in the lattice parameters measured in our samples.

Figure 2 shows x-ray diffraction measurements on some of the $Mn_5(Ge_{1-x}Pb_x)_3$ samples. We find that, as expected, $Mn_5(Ge_{0.95}Pb_{0.05})_3$ [Fig. 2(a)] has the $Mn_5Si_3(hP16)$ structure. This structure type becomes unstable at $x>0.3$. $Mn_5(Ge_{0.50}Pb_{0.50})_3$ [Fig. 2(b)] shows the Ni_3Sn $(hp8)$ type structure, which is predominant for this composition. $Mn_5(Ge_{0.30}Pb_{0.70})_3$ [Fig. 2(c)] mainly shows the Ni_3Sn $(hp8)$ type structure but broad peak is found at a position expected from a pure tetragonal Mn phase. We also note that for x larger than 0.5 the desired compounds were difficult to form. This was especially noted for Mn_5Pb_3, which often resulted

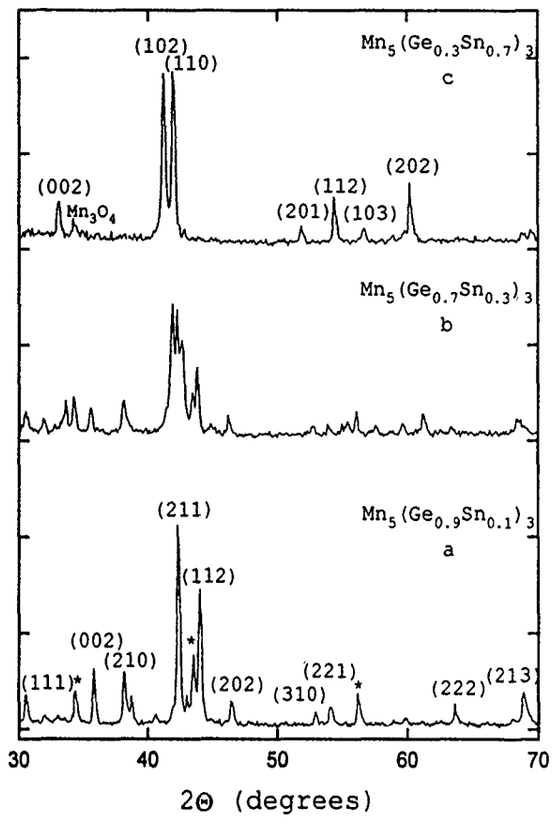

FIG. 1. X-ray diffraction patterns for several compositions of $Mn_5(Ge_{1-x}Sn_x)_3$: (a) $x=0.1$ with the Mn_5Ge_3 ($hP16$ Mn_5Si_3) spectrum labeled. The asterisks denote weak peaks attributed to Mn_2Ge ($hP6$ Ni_2In). (b) $x=0.3$. The spectrum shows peaks for both Mn_5Ge_3 ($hP16$ Mn_5Si_3) and Mn_2Ge ($hP6$ Ni_2In), with the former being dominant. (c) $x=0.7$ with peaks for $Mn_{1.77}Sn$ ($hP5.54$ Ni_2In) labeled.

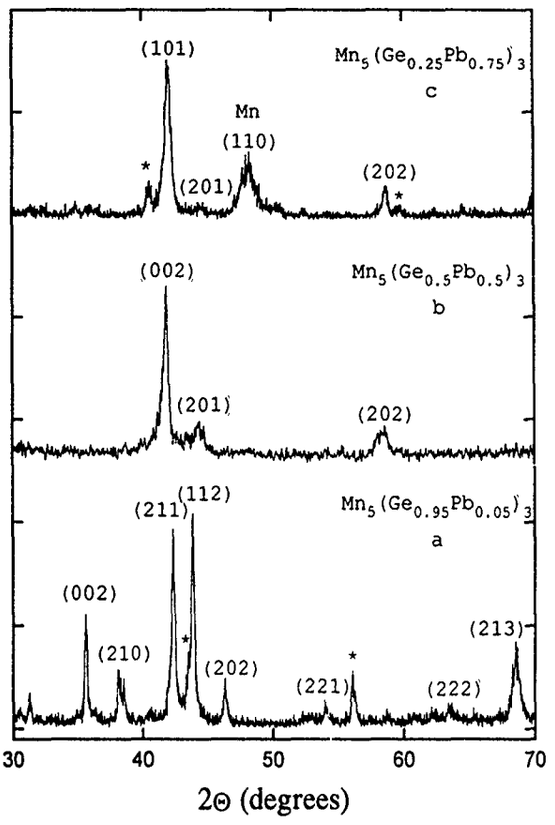

FIG. 2. X-ray diffraction patterns for several compositions of $Mn_5(Ge_{1-x}Pb_x)_3$: (a) $x=0.95$ with labels corresponding to the Mn_5Ge_3 ($hP16$ Mn_5Si_3) spectrum. The asterisks denote weak peaks attributed to Mn_2Ge ($hP6$ Ni_2In). (b) $x=0.5$. The labels correspond to the Mn_3Ge ($hP8$ Ni_3Sn) spectrum. (c) $x=0.7$ with the labeled peaks belonging to the Mn_2Ge ($hP6$ Ni_2In) structure.

in a fcc Pb structure with the main peak from the β-Mn spectrum also present. Mn has a smaller atomic diameter than Pb so it is expected that Mn_5Pb_3 in a fcc phase have a smaller lattice parameter than the pure fcc Pb lattice. These effects of alloy substitutions are confirmed by our experimental results. As shown in Table I, we found that the cubic lattice parameter a changes from 4.962 Å for the pure Pb crystal to 4.955 Å for the Mn_5Pb_3 alloy.

TABLE I. Structural lattice parameters for the relevant compositions of $Mn_5(Ge_{1-x}M_x)_3$ for M=Sn, Pb, and the average magnetic moment per Mn atom at $T=5$ K. Data are only shown for samples from which it could be clearly calculated.

Composition	Lattice parameter		Average moment per Mn atom (μ_B)
	a	c	
Mn_5Ge3	7.193	5.069	2.52
$Mn_5(Ge_{0.95}Sn_{0.05})_3$	7.196	4.990	2.52
$Mn_5(Ge_{0.90}Sn_{0.10})_3$	7.176	5.061	2.23
$Mn_5(Ge_{0.85}Sn_{0.15})_3$	7.116	4.978	2.23
$Mn_5(Ge_{0.80}Sn_{0.20})_3$	7.172	5.036	2.13
Mn_5Ge_3	7.193	5.069	2.52
$Mn_5(Ge_{0.95}Pb_{0.05})_3$	7.179	5.048	1.42
$Mn_5(Ge_{0.90}Pb_{0.10})_3$	7.164	5.055	2.16
$Mn_5(Ge_{0.85}Pb_{0.15})_3$	7.168	5.039	2.10
$Mn_5(Ge_{0.80}Pb_{0.20})_3$	6.755	5.212	1.23
Mn_5Pb_3	4.955	4.955	0.01
Pb	4.963	4.963	0.00

B. Magnetic properties

Figure 3(a) shows the compositional dependence of the magnetization measured at $T=5$ K and a maximum field of 50 kOe with a SQUID magnetometer. The Curie temperatures for the compounds studied are shown in Fig. 3(b). All of the $Mn_5(Ge_{1-x}Sn_x)_3$ alloys made have a ferromagnetic transition and for $x\leq 0.3$ they are ferromagnetic at room temperature. The magnetization at $T=5$ K first generally decreases with increasing x, and then shows a slow increase above $x=0.5$. The coercivity however is maximized for $x=0.5$, reaching 1.2 kOe at $T=5$ K. The Curie temperature initially remains nearly constant, then decreases with increasing x beyond $x=0.3$, reaching a minimum at $x=0.5$, after which it increases again as x goes to 1.0.

It can be seen in Table I that as x increases, both the lattice parameter a and the average moment per Mn atom generally decrease. This is understandable since the hybridization of Mn $3d$ electronic states normally increases as the interatomic separation becomes smaller as given by the quantum theory.

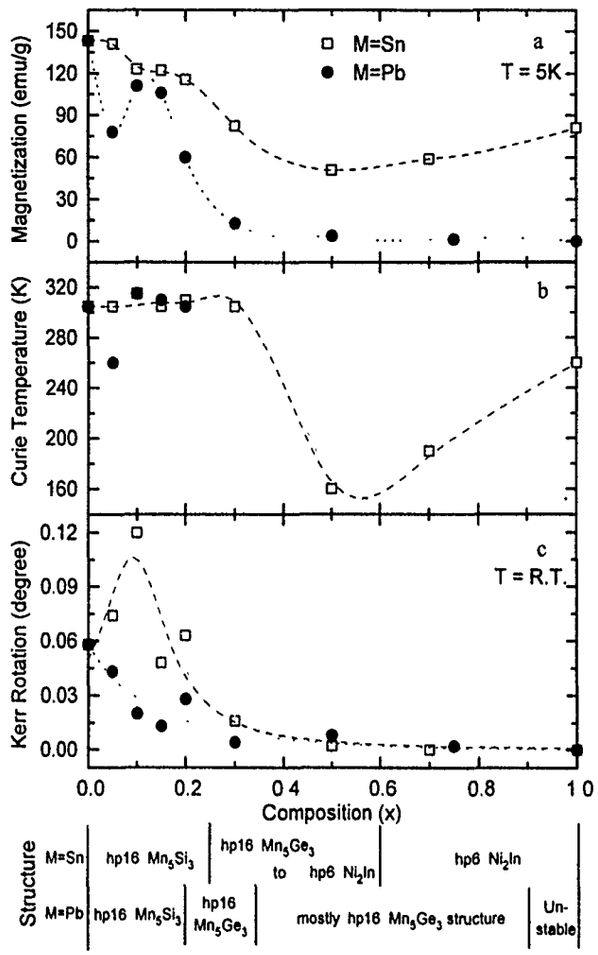

FIG. 3. Magnetic properties verses composition for $Mn_5(Ge_{1-x}M_x)_3$, M=Sn, Pb: (a) SQUID measurements of magnetization at $T=5$ K and $H=50$ kOe. (b) Curie temperature measurements from Faraday balance magnetometer and M vs H loops with fields up to 500 Oe. (c) Kerr rotation measurements at room temperature and fields up to 8 kOe. The curves are only meant to serve as a reference to the general trends noted. The various structure regions for each sample set are also shown for reference.

The $Mn_5(Ge_{1-x}Pb_x)_3$ alloys are ferromagnetic at room temperature only for $x \leq 0.2$. The magnetization and Curie temperature show a minimum at $x=0.05$, for reasons that are not presently clear. When $x>0.1$ both of these properties decrease as x increases. The explanation is the same as given for the $Mn_5(Ge_{1-x}Sn_x)_3$ alloys concerning the hybridization of the Mn $3d$ states. When $x>0.3$ the Pb substituted alloys show a complex magnetic behavior. For example, the $Mn_5(Ge_{0.25}Pb_{0.75})_3$ sample measured at $T=5$ K and up to $H=50$ kOe has a small (about 1.5 emu/g) magnetization which is unsaturated, and a coercivity of about 11 kOe, while at room temperature it still has a coercivity of about 2 kOe.

C. Magneto-optic properties

Figure 3(c) shows the relationship of the magnitude of the Polar Kerr rotation to the composition, measured at room temperature in fields up to 8 kOe. The sign of the rotation is negative for all of the samples studied. For $Mn_5(Ge_{1-x}Pb_x)_3$, the Kerr rotation monotonically decreases from the value for the parent alloy Mn_5Ge_3 with increasing x. In agreement with the magnetization at room temperature with an applied field of 8 kOe the Kerr rotation of the Sn substituted compounds increased slightly for $x<0.15$. The peak value of $\theta_K=0.12°$ at $x=0.1$ is enhanced above what would be expected from a direct relationship between θ_K and M. Beyond this peak the Kerr rotation drops off, going to zero rapidly outside the single phase region at $x=0.25$. The Kerr rotation values below $x=0.4$ for both cases was measured very near the Curie temperature in both series of samples which would adversely affect the magnitude of the rotation due to decreased magnetic magnetizations. However, the Polar Kerr rotation is an intrinsic quantity that depends on factors such as composition, crystal structure, and electronic structure. It is interesting that there is an enhanced maximum in Θ_K for the Sn case that apparently occurs within a single phase region. Presumably this reflects subtle changes in the electronic structure. This indicates the need for at least a spin-polarized calculation on the parent Mn_5Ge_3 compound.

IV. CONCLUSION

The magnetic and magneto-optical properties strongly depend on the alloy structure. Our $Mn_5(Ge_{1-x}Pb_x)_3$ samples showed the Mn_5Si_3 structure and were ferromagnetic for $x \leq 0.3$, exhibiting complex magnetic behavior for $x>0.3$. All of the $Mn_5(Ge_{1-x}Sn_x)_3$ alloys were also ferromagnetic, but the low-temperature magnetization showed a minimum value at $x=0.5$. Only the substitution of Sn for Ge in Mn_5Ge_3 allowed the alloy to both keep the Mn_5Si_3 structure and increase the Kerr rotation.

In general the presence of heavy elements is necessary for large spin-orbit interactions, which can aid in producing a large Kerr effect; in the case of these compounds there is a compensating effect on alloying with Sn or Pb that reduces the strength of the magnetic coupling, as evidenced by a reduction in M_s and T_c. Thus, in these compounds, any tendency for Kerr-effect enhancement is overwhelmed by the destruction of the ordered magnetic state.

Magnetic and optical characteristics of bilayered films composed of Tb-Fe-Co layer with overlayers of Co-Cr, Ni-Fe, Ta, and C

Kibong Song and Masahiko Naoe
Department of Physical Electronics, Tokyo Institute of Technology, 2-12-1, O-okayama, Meguro-ku, Tokyo 152, Japan

Amorphous Tb-Fe-Co single layers and Tb-Fe-Co/M (M: Ta, C, $Co_{82}Cr_{18}$, $Ni_{81}Fe_{19}$) bilayers have been prepared by using a facing targets sputtering apparatus. The Tb-Fe-Co films deposited by Kr sputtering exhibited internal stress as low as 1×10^9 dyn/cm^2 even at a pressure as low as 0.2 mTorr. The Tb-Fe-Co/Ta bilayers showed a Kerr rotation angle as large as 0.85° at the thickness of Tb-Fe-Co layer of about 30 nm. The direction of magnetic moments in Tb-Fe-Co layers were arranged antiparallel by a soft magnetic $Ni_{81}Fe_{19}$ overlayer.

I. INTRODUCTION

Amorphous Tb-Fe-Co layers have been prepared in working gas such as Ne, Ar, Kr, and Xe by using a facing targets sputtering (FTS) apparatus.[1] The interfacial effects in the Tb-Fe-Co/M bilayers with various overlayer M have also been investigated. The four kinds of materials used as overlayer were paramagnetic Ta with metallic reflectivity, diamagnetic C with nonmetallic absorbability, and ferromagnetic $Co_{82}Cr_{18}$, and $Ni_{81}Fe_{19}$. The overlayers seemed to be very interesting for enhancing the Kerr effect because $_{73}$Ta possesses a magnetic susceptibility χ_m as high as 154 while $_{75}$Pt has a χ_m of 190 in Co/Pt multilayers for magneto-optical media. It is well known that $Co_{82}Cr_{18}$ films are semihard magnetic and exhibited large perpendicular magnetic anisotropy energy,[2] and that $Ni_{81}Fe_{19}$ films are very soft magnetic, exhibited very high permeability and low coercivity and revealed apparent in-plane orientation of magnetic moment.[3]

II. EXPERIMENTS

Specimen films of amorphous Tb-Fe-Co single layers and Tb-Fe-Co/M bilayers were deposited on glass slide substrates by using a FTS apparatus, as described in a previous article.[1] The sputtering chamber was provided with two pairs of rectangular facing targets and rotatable substrate holder, so that the bilayers could be deposited successively without breaking the vacuum. The size of the target plates was 160 $\times$100 mm^2.

The residual gas pressure was less than 4×10^{-7} Torr before sputtering. The Tb-Fe-Co layers with thickness t_{MO} of 100 nm were deposited at the working gas pressure of 0.1~10 mTorr, and Tb-Fe-Co/M bilayers were deposited at the Ar pressure of 0.5 mTorr. Internal stress of specimen films was measured by the bending-beam method reviewed by Blackburn and Campbell.[4] Magnetic properties were measured by using a vibrating sample magnetometer (VSM). The Kerr rotation angle θ_K and the coercivity H_c were determined on the Kerr hysteresis loops observed from the substrate side at the wavelength of 633 nm.

III. RESULT AND DISCUSSION

Figure 1 shows the dependence of the deposition rate R_d of Tb-Fe-Co films on the atomic weight w_A and radius r_A of the working gas at the pressure of 0.5 mTorr. This dependence indicated that Ar and Kr should be best for R_d among all working gases at the pressure of 0.5 mTorr.

Figure 2 shows the dependence of the absolute value of compressive internal stress $|\sigma_I|$ in Tb-Fe-Co films with thickness of 100 nm on the working gas pressure P_{wg}. The films deposited at lower P_{wg} of lighter gases such as Ne and Ar exhibited larger $|\sigma_I|$ because of the larger number and higher energy of recoiled Ne and Ar atoms.[5] On the contrary, the films deposited at lower P_{wg} of Kr exhibited smaller $|\sigma_I|$ because of the smaller number and lower energy of recoiled Kr atoms. So, the adatoms with high kinetic energy at lower P_{wg} of Kr may cause to form a uniform and poreless film and it resulted to the reduction of $|\sigma_I|$. However, the films deposited at higher P_{wg} of Kr exhibited larger $|\sigma_I|$ because of the energy loss due to collision of sputtered atoms with heavy Kr atoms. The heaviest and largest Xe gas could scatter the sputtered atoms severely and caused larger $|\sigma_I|$ over all the range of P_{wg} in this study.

The minimum value of $|\sigma_I|$ was obtained by Kr sputtering at P_{wg} of 0.2 mTorr; however, the deposition of bilayers at P_{wg} of 0.5 mTorr seemed to be acceptable for the stability and ability of the power supply. The films deposited at this P_{wg} of Ar and Kr gases exhibited almost the same $|\sigma_I|$. Therefore, Ar was used as the working gas for depositing bilayers in this study.

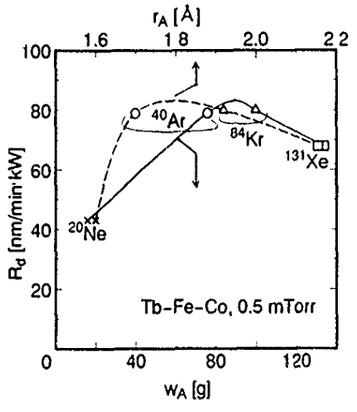

FIG. 1. Dependence of deposition rate R_d of Tb-Fe-Co layers on the atomic weight w_A and radius r_A of the working gas.

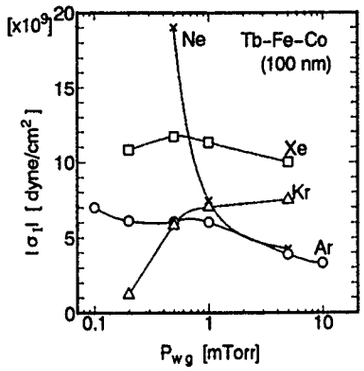

FIG. 2. Dependence of the absolute value of compressive internal stress $|\sigma_I|$ on working gas pressure P_{wg} in Tb-Fe-Co layers with a thickness of 100 nm.

Figure 3 shows the dependence of $|\sigma_I|$ in Tb-Fe-Co/M bilayers on the thickness of magneto-optical Tb-Fe-Co layers t_{MO} for a 100 nm thickness of M layers t_M. The materials of the M layer used as an overlayer were paramagnetic, metallic, and reflective Ta, diamagnetic, nonmetallic, and absorbable C, and ferromagnetic $Co_{82}Cr_{18}$ and $Ni_{81}Fe_{19}$. Bilayers with an overlayer of Ta, C, and $Co_{82}Cr_{18}$ exhibited large $|\sigma_I|$ at small t_{MO}, and it decreased with increasing t_{MO} while bilayers with a $Ni_{81}Fe_{19}$ overlayer exhibited extremely small $|\sigma_I|$.

Figure 4 shows the magnetic hysteresis loops of (a) Tb-Fe-Co (30 nm), Tb-Fe-Co (30 nm)/Ta (100 nm), Tb-Fe-Co (30 nm)/C (100 nm); (b) $Co_{82}Cr_{18}$ (100 nm); (c) Tb-Fe-Co (30 nm)/$Co_{82}Cr_{18}$ (100 nm); (d) $Ni_{81}Fe_{19}$ (100 nm); and (e) Tb-Fe-Co (30 nm)/$Ni_{81}Fe_{19}$ (100 nm), where (⊥) and the solid line represent the hysteresis loop observed for fields applied in the direction perpendicular to layer plane, and (∥) and the dashed line represent the in-plane loop. The loop shapes of the Tb-Fe-Co single layers and bilayers with paramagnetic Ta and diamagnetic C overlayers were almost the same.

The Tb-Fe-Co/$Co_{82}Cr_{18}$ bilayer showed a shared rectangular perpendicular hysteresis loop with the coercivity H_c almost same as that of the Tb-Fe-Co single layer, where the

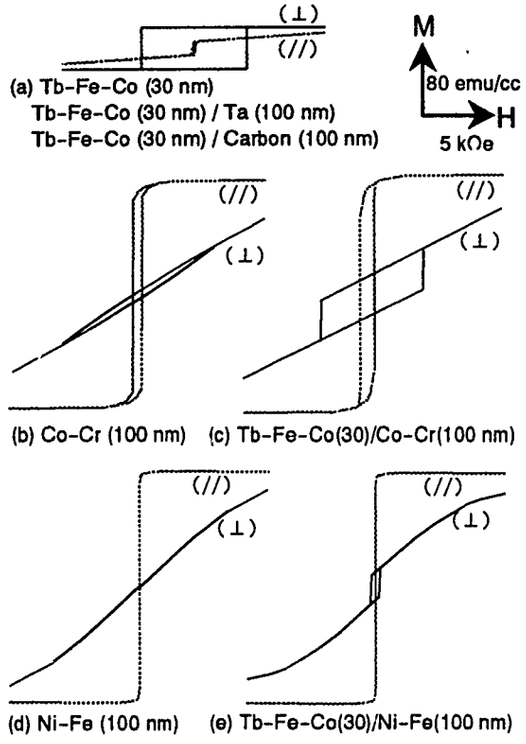

FIG. 4. Magnetic hysteresis loops of Tb-Fe-Co (30 nm)/M bilayers measured in directions normal (⊥) and parallel (∥) to the layer.

side of the loop was slightly sloped, and the in-plane hysteresis loop with higher H_c than those of $Co_{82}Cr_{18}$ and Tb-Fe-Co layers.

The Tb-Fe-Co/$Ni_{81}Fe_{19}$ bilayer showed a shaped perpendicular hysteresis loop the same as that of the Tb-Fe-Co/$Co_{82}Cr_{18}$ bilayer, but H_c was much lower than that of the Tb-Fe-Co single layer, owing to the large in-plane magnetization of the $Ni_{81}Fe_{19}$ layer. The arrangement of magnetic moment in Tb-Fe-Co layers was almost antiparallel. The in-plane hysteresis loop looked almost the same as that of the $Ni_{81}Fe_{19}$ single layer.

Figure 5 shows the dependence of Kerr rotation angle θ_K

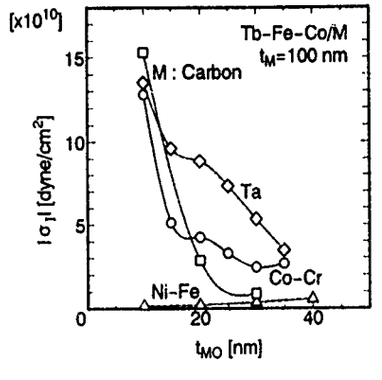

FIG. 3. Dependence of $|\sigma_I|$ on t_{MO} for Tb-Fe-Co/M bilayers, where M is Ta, C, $Co_{82}Cr_{18}$, and $Ni_{81}Fe_{19}$ layers with thickness of 100 nm.

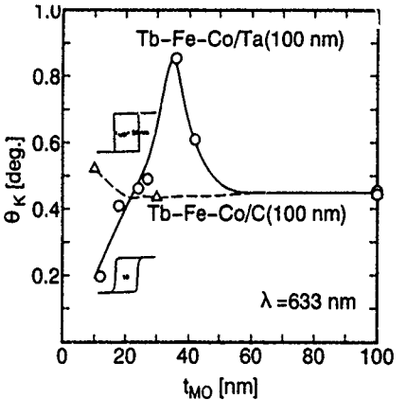

FIG. 5. Dependence of θ_K on t_{MO} and Kerr hysteresis loops for Tb-Fe-Co/M (M: 100 nm Ta and C) bilayers at a wavelength λ of 633 nm.

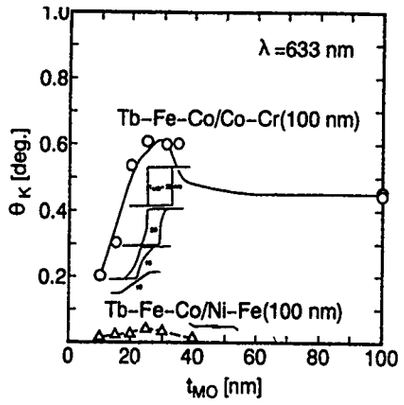

FIG. 6. Dependence of θ_K on t_{MO} and Kerr hysteresis loops for Tb-Fe-Co/M (M: 100 nm $Co_{82}Cr_{18}$, and $Ni_{81}Fe_{19}$) bilayers at λ of 633 nm.

strate side at λ of 633 nm. θ_K of these bilayers took a maximum of 0.6° and 0.04° at t_{MO} of about 30 nm. The Kerr hysteresis loops of bilayers with semihard magnetic $Co_{82}Cr_{18}$ overlayers with t_{MO} more than 25 nm revealed rectangular loop shape. The loop shape became similar to that of $Co_{82}Cr_{18}$ layers with decrease of t_{MO}.

On the contrary, the shape of Kerr hysteresis loops of bilayers with soft magnetic $Ni_{81}Fe_{19}$ overlayers was different. The shared rectangular loop was reduced about a factor of 10, by means of the antiparallel arrangement of magnetic moments in Tb-Fe-Co layers. About 90% of the magnetic moments were arranged antiparallel by means of large in-plane magnetic moments of $Ni_{81}Fe_{19}$ layers. If the domain size of this bilayer is larger than the wavelength of the recording light, then this bilayer could be useful for very stable magneto-optical media, by means of a horseshoelike magnetic path.

IV. CONCLUSIONS

Amorphous Tb-Fe-Co single layers and Tb-Fe-Co/M (M: Tb, C, $Co_{82}Cr_{18}$, $Ni_{81}Fe_{19}$) bilayers have been prepared by using a facing targets sputtering apparatus. Results are as follows: (i) Tb-Fe-Co films deposited with Kr sputtering revealed internal stress as low as 1×10^9 dyn/cm^2 even at a Kr pressure as low as 0.2 mTorr; (ii) Tb-Fe-Co/Ta bilayers exhibited a Kerr rotation angle θ_K as large as 0.85° at a thickness of Tb-Fe-Co layer of about 30 nm; (iii) the direction of magnetic moments in Tb-Fe-Co layers were arranged antiparallel by a soft magnetic $Ni_{81}Fe_{19}$ overlayer.

Change of magneto-optical Kerr rotation due to interlayer thickness in magnetically coupled films with noble-metal wedge

T. Katayama, Y. Suzuki,[a] M. Hayashi,[b] and W. Geerts
Electrotechnical Laboratory, Umezono, Tsukuba, Ibaraki 305, Japan

An intensity oscillation of the saturation polar Kerr rotation ϕ_K due to interlayer thickness d was observed in Fe(5 Å)/Au(d Å)/Fe(5 Å)(100) and Fe(6 Å)/Au(d Å)/Fe(6 Å)(100) sandwiched films. The periods of the oscillation are about 7–8 and 5–6 monolayers of Au thickness, respectively. The oscillation of ϕ_K can be observed only in the photon energy range 2.5–3.8 eV for Fe(6 Å)/Au(d Å)Fe(6 Å). These phenomena are considered to be closely related to a formation of spin-polarized quantum-well states of the minority Δ_1 band in the Au layer sandwiched with two Fe barrier layers. The ϕ_K peak positions and oscillation period do not correspond exactly to those of the change in the in-plane saturation field H_s.

I. INTRODUCTION

Special attention has been focused on 3d-metal/noble-metal multilayers because they have a novel potential as materials for magneto-optical recording and giant magnetoresistance.[1-2] In general, it has been expected that ultrathin films show a different electronic structure from that of bulk materials.[3] The magneto-optical effect is very sensitive to changes of the electronic structure of the material. Bennett *et al.* reported a Kerr rotation oscillation with Cu interlayer thickness d in Fe/Cu(d Å)/Fe sandwiched films.[4] Since their measurements were performed at only one wavelength, it provided little information about the electronic structures.

Recently, we have found a new magneto-optical transition due to the formation of quantum-well states in the ultrathin film of Fe deposited on a Au(100) surface.[5] The new peak appears in the Fe layer thickness range between 2 and 10 Å and shifts from about 3 to 4.3 eV with increasing Fe layer thickness. We have also found an intensity oscillation of the saturation magneto-optical polar Kerr rotation ϕ_K due to the interlayer thickness d in Fe/Au(d Å)/Fe snadwiched films.[6] This can be explained by the formation of quantum-well states (QWS) in the noble-metal layer. This is in agreement with the results as found by Ortega *et al.*[7,8] In this article we present the results for Fe sandwiched Au samples and report on the behavior of polar Kerr rotation ϕ_K and saturation field H_s as a function of the film thickness.

II. EXPERIMENTAL PROCEDURES

All the sandwiched films with Au wedge-shaped interlayers were deposited by molecular-beam-epitaxy (MBE) method using two electron-gun sources for Fe and Au and a Knudsen cell for Ag. The MBE chamber was maintained in the range of 10^{-10} Torr during deposition. In order to make a good layer-by-layer growth of the Fe layer, Au seed layers of 4 or 10 Å were deposited for the Fe/Au/Fe(100) films. On the top of the multilayer, a 20-Å-thick Au cap layer was deposited to prevent oxidation (see Fig. 1). The wedge-shaped Au layers were formed by means of a moving shutter method.

The thicknesses of Fe and Au films were measured and controlled by a quartz thickness monitor (IC-6000) combined with a shutter system. The growth modes and flatness of the films were monitored by observation of the high-energy electron diffraction (RHEED) patterns. ϕ_K and Kerr ellipticity η_K spectra were measured *ex situ* with a Kerr spectrometer using a piezo birefringent modulator in the photon energy range from 1.55 to 6.2 eV at RT. The incident angle of light was about 10° normal to the sample plane. The in-plane saturation field H_s was measured by the longitudinal magneto-optical Kerr effect (MOKE) method.

III. RESULTS

In Fig. 2 the ϕ_K and η_K spectra of the Fe(5 Å)/Au(23 Å)/Fe(5 Å) film are shown. A negative large ϕ_K peak is observed at about 3.8 eV. This peak is due to the plasma resonance in the Ag buffer layer. The Au interlayer thickness d dependence of ϕ_K at each energy was derived from the measured ϕ_K data.

Figure 3 shows the d dependence of ϕ_K/d_{Fe} at 3.5 eV in Fe(5 Å)/Au(d Å)/Fe(5 Å) film. ϕ_K/d_{Fe} in vertical axis shows a ϕ_K value per Fe(1 Å), normalized by the total Fe thickness (10 Å) The dashed line is a guiding base line for the eye. As shown in the figure, the large negative ϕ_K peaks are observed at around $d=4$, 20, and 36 Å and its oscillation period is

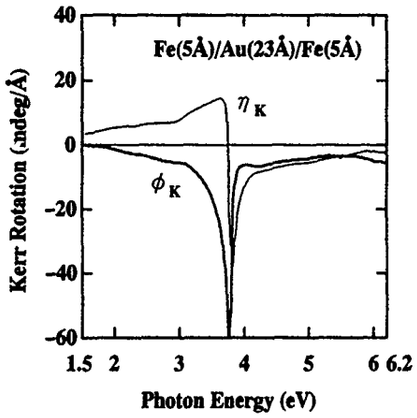

FIG. 2. The spectra of magneto-optical Kerr rotation ϕ_K and Kerr ellipticity η_K in the Fe(5 Å)/Au(23 Å)/Fe(5 Å) sandwiched film.

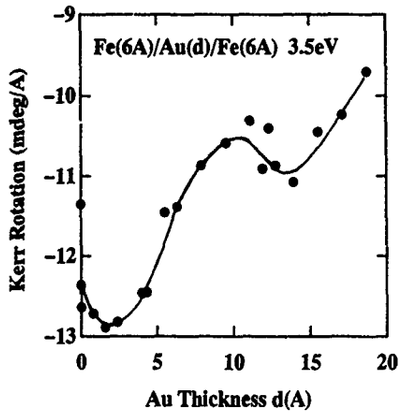

FIG. 4. The Au interlayer thickness d dependence of ϕ_K at 3.5 eV in the Fe(6 Å)/Au(d Å)/Fe(6 Å) sandwiched film.

about 7–8 monolayers (ML). In Fig. 4, the d dependence of ϕ_K at 3.5 eV in the Fe(6 Å)/Au(d Å)/Fe(6 Å) film is shown. An oscillation of ϕ_K is also observed and its period is about 5–6 ML. The ϕ_K oscillations could be only observed in the photon energy range 2.5–3.8 eV.

The oscillation period Λ in Fig. 3 is clearly larger than that of Fig. 4. As to the difference of Λ, it is found that the Λ are about 7–8 ML for Fe(3 Å)/Au(d Å)/Fe(3 Å) and 5–6 ML for Fe(9 Å)/Au(d Å)/Fe(9 Å) films, respectively. So, it is considered that the Λ changes at near Fe=5 Å from about 7–8 to 5–6 ML with increasing Fe thickness. This suggests that the period Λ is probably influenced considerably by a perfection of Fe barrier layer made with a band gap in D_1.

Figures 5(a) and 5(b) show the d dependence of H_s in two kinds of Fe/Au(d Å)/Fe films. The behaviors of H_s in two figures are quite similar; that is, two large H_s peaks are observed around 21 and 26 Å and a small one is near 39 Å. The distance of the two peaks is about 2 ML which is thought to correspond to short oscillation of the oscillatory magnetic coupling.

IV. DISCUSSIONS

As mentioned above, an oscillation of ϕ_K as a function of d is observed in the Fe/Au(d Å)/Fe sandwiched films at various energies. Their oscillation amplitude and period Λ are very sensitive to the measuring energy. Ortega *et al.* found a quantum-well state (QWS) in ultrathin noble-metal layers such as Ag, Au, and Cu grown on Fe and Co by using an inverse photoemission spectroscopy (IPES) method.[7,8] When the energy was fixed, for example at Fermi energy E_F, th IPES intensities oscillated with a period of about 8 ML.[7,8]

In Fig. 6 a schematic drawing of the bulk band structures of bcc Fe and fcc Au near E_F along the film normal is shown.[9,10] Due to presence of an energy gap between upper and lower branches of the Δ_1 minority band in Fe (shown by dotted curves), discrete QWS are formed only in the minority-spin state of the Δ_1 band of Au. The majority-spin state band in the Au is not influenced.

The QWS with different integers should cross the E_F one after another along the Δ_1 band energy dispersion with increasing Au thickness. Therefore, if the spin-polarized

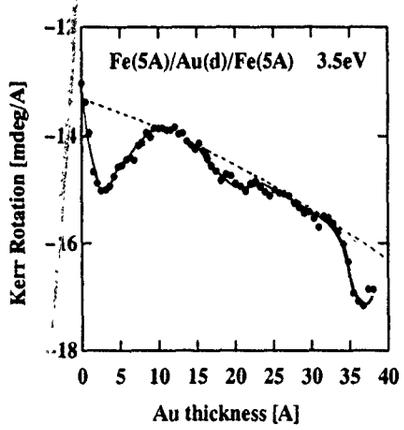

FIG. 3. The Au interlayer thickness d dependence of ϕ_K at 3.5 eV in the Fe(5 Å)/Au(d Å)/Fe(5 Å) sandwiched film. The vertical axis shows a ϕ_K per Fe 1 Å (ϕ_K/d_{Fe}), normalized by the total Fe thickness (10 Å).

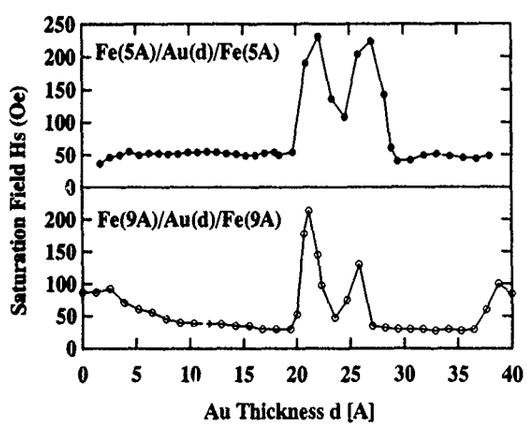

FIG. 5. The Au interlayer thickness d dependence of the in-plane saturation field H_s in (a) Fe(5 Å)/Au(d Å)/Fe(5 Å) and (b) Fe(9 Å)/Au(d Å)/Fe(9 Å) sandwiched films.

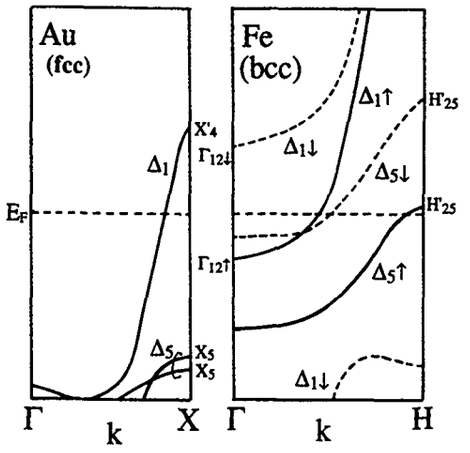

FIG. 6. A schematic drawing of the band structure of bulk bcc Fe and Au near the Fermi energy along the film normal.

QWS in noble metals behave as a final state of optical transition, a new magneto-optical (MO) transition will occur and MO intensities will oscillate periodically as QWS cross the E_F. It is considered that an optical transition from the minority-spin Δ_5 band to the Δ_1 spin-polarized QWS in the Au is a possible mechanism of the new MO transition. Assuming such a QWS model, the most reasonable energy range, in which the MO transitions occur, is above the plasma edge of the Au. However, as mentioned in a previous article,[6] since the energy range in which the ϕ_K oscillation has been observed is rather wide (Ag case), another mechanism might be responsible for the MO effect.

Concerning the relation between IPES oscillation Λ_Q, Ortega *et al.*[11] have reported that Λ_Q at E_F is in good agreement with Λ_H in the Co/Cu(d Å)/Co system, but, as shown here, the H_s peak positions and its period Λ_H did not correspond exactly to that of ϕ_K in Fe/Au(d Å)/Fe films. It is considered that behaviors of the ϕ_K oscillations as a function of d are more complicated than that of H_s because ϕ_K phenomena are related to the electronic structures above E_F. Detailed studies are necessary on the relation between the oscillations of H_s and ϕ_K.

V. CONCLUSION

We reported on ϕ_K spectra and its oscillation due to d in Fe/Au(d Å)/Fe sandwiched films. As a result, the ϕ_K oscillation as a function of d was observed between about 2.5 and 3.8 eV for Fe/Au(d Å)/Fe sandwiched films. The oscillation periods are about 8 ML for less than 5 Å of Fe and 6 ML for more than 6 Å of Fe barriers. The oscillation is thought to be closely related with the formation of QWS in the Δ_1 minority-spin band in Au layers. The ϕ_K peak positions and period, however, did not correspond to that of the oscillatory magnetic coupling.

Chemical modification of magneto-optic garnet film properties

Roger F. Belt, John B. Ings, and Jonathan B. Whitlock
Airtron Division Litton Systems, 200 E. Hanover Avenue, Morris Plains, New Jersey 07950

Single-crystal magneto-optic garnet films of composition $(BiTm)_3(FeGa)_5O_{12}$ have applications to spatial light modulators, optical isolators, and magnetic-field sensors. These as-grown films have a coercivity under 1 Oe and can support cm-size stable domains. It has been found that chemical treatments with oxidizing or reducing gases can reversibly modify the magnetic properties. Treatments are performed at 400–700 °C for fixed times. Reducing treatments dilate the x-ray lattice constant up to 0.1%, introduce Fe^{2+} monitored by increased optical absorption at 1.00–1.06 μm and decrease Faraday rotation about 5% over the visible spectrum. Oxidation can partially or totally reverse these parameters. Magnetic measurements on the bulk film show that coercivity can be finely controlled, square hysteresis loops attained, and domain-wall mobility changed. At the same time the initial perpendicular anisotropy H_k of 8–12 kOe is decreased while the saturation magnetization ($4\pi M_s$) of 100–150 G is affected to a minor degree. For magneto-optic imaging of defects, the resolution, contrast, and device operation are assisted favorably. Magnetic measurements are presented as a function of specific chemical treatment. The data suggest that an oxygen vacancy mechanism is operative at the film surface layers.

I. INTRODUCTION

Single-crystal magneto-optic bismuth garnet films have applications to modulators, optical isolators, microwave devices, and sensors. The high perfection of these films normally leads to a low (<0.5 Oe) as-grown coercivity H_c. Various physical methods have been used to introduce controlled numbers, sizes, and distributions of defects.[1,2] These irreversible modifications serve to increase coercivity, generate a nearly square hysteresis loop, and offer favorable effects in switching devices. In this article we examine chemical treatments in reducing atmospheres such as H_2 to attain reversible results over large areas in 3-in.-diam films.

Small changes of 1–5 Oe in dynamic H_c were measured by Metselaar and Huyberts in YIG single crystals and polycrystals.[3] The likely defects were oxygen vacancies. Lotgering investigated permeability μ changes in Co- or Si-doped YIG polycrystals and developed a model of domain-wall pinning by anisotropic ions.[4] Dixon and Kurtzig reported changes in $4\pi M_s$ with H_2 treatments of bubble films.[5] Milani and Paroli studied specifically the H_2 diffusion in bulk YIG and films but only reported the optical properties.[6] A later paper by Balestrino, Lagomarsima, and Tucciarone described x-ray lattice constant expansions and contractions with H_2-annealed YIG films.[7] A more recent effort by Kappelt *et al.* measured optical anisotropy changes in epigrown films with alternating H_2 and O_2 treatments.[8] Since a comprehensive study of magnetization changes in our films was lacking, we concentrated on this aspect. Our investigations were motivated also by the fact that the chosen film compositions were capable of supporting large stable magnetic domains instead of the normal stripes.[9] These films are valuable for magneto-optic imaging of fields generated around defects by eddy currents.[10]

II. EXPERIMENT

The film compositions used in our experiments were prepared by liquid-phase epitaxy and described thoroughly[11] along with various physical properties[2] in the as-grown condition. In order to simplify any measurements, a single 3 μm layer of film on (111) GGG was used. This was obtained normally by growth on a wafer which touched the melt surface. These films were identical to those grown by total immersion and deposited on both sides of the substrate. X-ray data were obtained with a Picker diffractometer by examining (888) order reflections and measuring lattice constants with Cu $K\alpha_1$ radiation. Anisotropy fields were measured by a magneto-optic transverse susceptibility measurement on a complete wafer.[12] The magnetization, coercivity, and hysteresis curves were recorded on a Princeton Measurements Corp. Micro Mag 2900 alternating gradient magnetometer. Samples for this purpose were 15-20 mm^2 rectangles cut from large wafers. Data were collected with magnetic fields up to 10 kOe both perpendicular and parallel to the film plane. The former showed open loops while the latter showed only a line.

Optical absorption α of our films was measured on a Cary model 14 spectrophotometer. An evaluation of the Fe^{2+} absorption was obtained by measuring α at 1.03 μm on untreated and treated films of identical thicknesses. The relationship of Fe^{2+} and optical absorption has been discussed previously.[13,14] An estimate of OH absorption was determined by measurements at 2.81 μm with a Nicolet model 20DXB Fourier transform infrared (FTIR) spectrometer. The Faraday rotation was measured with a polarizing microscope using a coil to generate a saturation magnetic field normal to the film plane.

Full wafer samples or portions thereof were treated in reducing atmospheres with forming gas (85% N_2-15% H_2) and in oxidizing atmospheres by means of an oxygen ozone mixture (99 O_2-1 O_3).[15] The samples were placed in a Thermco tube furnace for specified temperatures and times. Flow rates of gas were adjusted to maintain sample temperature and insure uniform treatment over the film area. Visually the samples showed no appearance of added defects in the film when examined under a microscope.

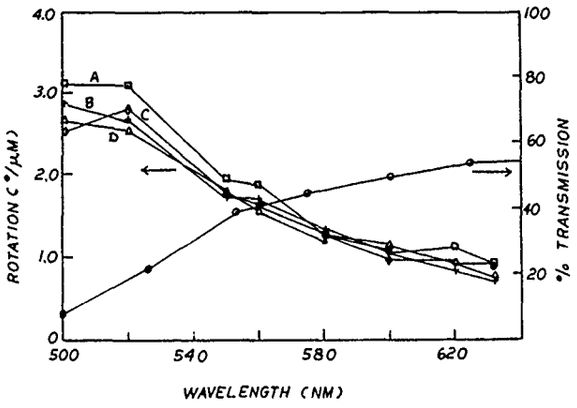

FIG. 1. Faraday rotation and transmission as a function of wavelength. A is a starting film, B, C, and D were H_2 treated for 6 min at 470 °C and then annealed in O_2-O_3 gas mixture for 4, 9, and 14 min, respectively at 580 °C.

III. RESULTS

A. X-ray lattice constants

A brief treatment of our films in forming gas (for example, 10 min at 470 °C) shows some remarkable results. The entire film increases in the (111) determined x-ray lattice constant, a_f. For our films which are originally in compression, i.e., with $a_s < a_f$ where a_s is the substrate lattice constant of 12.383 Å and a_f=12.390–12.400 Å, the amount of the increase is always about 0.008 Å or nearly 0.1%. These data are consistent with the observations of Balestrino and co-workers in YIG.[7] However, we did not observe the high-angle 2θ wings or the final contraction possibly due to our thinner films and/or shorter treatments at lower temperatures. The increased film lattice constant places the film under increasing compression and can create an easy axis of magnetization parallel to the film plane under certain conditions. In one sense, the lattice dilation with H_2 treatments is analogous to ion implantations of H^+, He^{2+}, Ne^+, and others; however, important distinctions are discussed later because the ion implants are not reversible.

If a H_2-treated film is now reacted in the O_2-O_3 gas, the x-ray lattice constant contracts until the value of the as-grown film is nearly reached. Small oscillations about this value are possible to the extent of about ±0.0005 Å; however, the film always remains in compression. The process of reduction oxidation is reversible because alternate treatments increase or decrease the (111) spacings, respectively. In fact, the magnetic film can be "fine tuned" by this process to yield a desirable lattice constant.

B. Optical absorption and Faraday rotation

The Faraday rotation dispersions for the as-grown and H_2-treated films are shown in Fig. 1. The Faraday rotation exhibits a slight decrease of 5%–10% in magnitude over the visible wavelength region for H_2-treated films. The largest decrease is in the 500–560 nm range. This happens to be near the optical transition commonly assigned to tetrahedral Fe^{3+}. It is also interesting that the sign of the Faraday rotation changes as one performs the hydrogen treatment on an as-grown film. This indicates that the Bi^{3+}-Fe^{3+} interaction, which is responsible for Faraday rotation, has been changed drastically.

The optical absorption in the visible range showed no discernible changes with reducing treatments even though the films were slightly darker. However, an accurate measurement of absorption coefficients in the 1.00–1.06 μm range showed that increases of α by factors of 5–10 were observed in the hydrogen treated films. These data are in agreement with the observations of Milani and Paroli[6] who attributed this absorption to the presence of Fe^{2+}. Dillon and Hansen showed the same results earlier.[13,14] We have also examined carefully the infrared absorption at 3560 cm^{-1} and can confirm the presence of OH vibrations. However, the amount of our absorption is markedly less than Milani and Paroli report[6] even when up to five layers (about 15 μm thickness) are examined. We do not observe at all the broad band at 2800 cm^{-1}.

C. Magnetic characterization

Our 3 μm as-grown films are reproducible in their original magnetic properties. The saturation magnetization, $4\pi M_s$ is always 100–150 G while the anisotropy field H_k is always greater than 8 kOe, and orients the magnetization perpendicular to the film plane. The characteristic stripe domains are absent and one sees only 1–2 cm^2 domains with rather few walls between crossed polarizers. The coercivity of the film is initially less than 0.5 Oe as verified by magnetometer measurements on many 5–25 mm^2 samples cut from 3-in.-diam wafers or by domain-wall movement through the entire wafer. The magnetization $4\pi M_s$, likewise undergoes small changes with chemical treatments. In oxygen at temperatures up to 1050 °C, $4\pi M_s$ decreases by about 20–50 Oe, probably due to some d-a site interchange of the Ga^{3+} ions.

Magnetic parameters are summarized in Table I. Treatment of an as-grown film in either air or oxygen at 600 °C has only a slight affect on the magnetic properties even if the treatment persists for several hours. Generally, a slight increase in coercivity H_c is observed. Significantly higher anneal temperatures (1100 °C) can lead to the formation of defects which increase coercivity through a domain-wall pinning mechanism. However, the anneal treatments discussed here do not generally result in pinning defects.

Treatment in forming gas at 450–500 °C for short periods of time (10 min), can also increase the coercivity, as measured by noting the onset and completion of domain-wall motion as the field is varied; however, the increase is not caused by macroscopic pinning defects. As a result of the significant coercivity increase, we are not able to reliable measure H_k with our apparatus. However, upon subsequent reoxidation at 600 °C, the coercivity decreases and H_k values significantly below those of the as-grown film are obtained, probably due to strain relaxation.

The most interesting changes occur in the coercivity when measured on the magnetometer. Under subsequent oxidation up to 1050 °C, H_c increases gradually while upon reduction and reoxidation the coercivity decreases. By successive treatments in O_2 and H_2, an appropriate and repro-

TABLE I. Magnetic film properties.

Sample state	Anisotropy field H_k (kOe)	Magnetization $4\pi M_s$ (G)	Coercivity H_c (Oe)
As grown	8–12	100–150	0.5–5.0
O_2 treated 600 °C	8–12	100–150	1–5
H_2 treated 450–500 °C	···	100	20–120
Reoxidized 600 °C	3.5–8	80–150	0.5–1.0

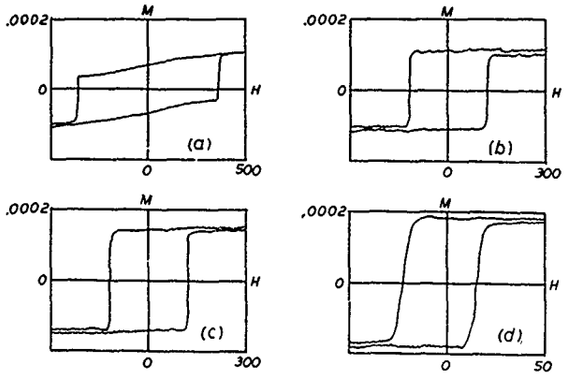

FIG. 2. Hysteresis curves of samples from Fig. 1. All curves were recorded with the field H normal to the sample plane. H is given in Oe and M in emu.

ducible value of H_c can be obtained. Not only does H_c change but the whole dynamics of switching process becomes more favorable, i.e., domain-wall movement is easier, faster, and more uniform over the entire film. An example of the changes incurred in the hysteresis curves with H_2 treatments is illustrated in Fig. 2. Starting with a sample having a coercivity of 300 Oe as shown in (a), samples (b), (c), and (d) were treated first in H_2 at 470 °C for six minutes and then in O_2-O_3 for 4, 9, and 14 min at 580 °C and rerun. The final coercivity at (d) is only 20 Oe. If (d) is retreated in O_2 at higher temperature or longer time, the coercivity will increase. Note also that the H_2 pretreated samples have square loops essentially, may be slightly asymmetric about $H=0$, and have limited "tails." The tails are due to residual domains and not to oblique orientation since high fields up to 10 kOe normal to the film plane eliminated them.

IV. DISCUSSION

Increases of the x-ray lattice constant in our films can be attributed to several possible reductions in the valence state (increase of ionic radius) of the original ions with H_2 treatment. For example, $Bi^{3+} \rightarrow Bi$, $Fe^{3+} \rightarrow Fe^{2+}$, or $Pb^{4+} \rightarrow Pb^{2+} \rightarrow Pb$, or $Pt^{4+} \rightarrow Pt$, where the Pb is introduced by growth from a PbO flux and Pt from the crucible. Unfortunately, the x-ray method is not specific and one or more of these reactions can take place simultaneously. The optical evidence is more direct in that it shows the Fe^{2+} absorption and Faraday rotation are 5–10 times more and 10%–20% less, respectively. If we consider that the Pb^{2+} impurity amounts to less than 1.0 mol % of the film's composition,[16] we can see that these observed optical changes are more likely to be associated with Bi^{3+} and Fe^{3+} rather than Pb^{2+} valence changes.

Recent attempts to calculate quantitatively the Faraday rotation or ellipticity have met with some success.[17,18] These calculations were based on diamagnetic and paramagnetic transitions of the charge transfer type from $2p$ orbitals on O^{2-} to $3d$ orbitals in Fe^{3+}. Sign changes and magnitudes in BiYIG were accounted for only by adding paramagnetic terms. The sign changes generally occur at fixed ranges of Bi concentrations and fixed photon energies. Our results confirm this for $x=0.8$ bismuth levels in our films. Furthermore, our H_2 or O_2 treatments immediately affect the sign of the rotation possibly via the O_2 $2p$ orbitals. A larger question remains on whether we see bulk or surface effects. We are attempting to unravel this by polar Kerr-effect measurements and other data on films thinned by controlled surface removal.

Circular magnetic x-ray dichroism in rare-earth magnets

Xindong Wang, V. P. Antropov, B. N. Harmon, J. C. Lang, and A. I. Goldman
Ames Lab—USDOE and Department of Physics and Astronomy, Iowa State University, Ames, Iowa 50011

With the availability of dedicated high-intensity synchrotron radiation sources, circular magnetic x-ray dichroism (CMXD) is developing as a technique for the investigation of magnetic properties. CMXD is defined as the difference in absorption between right and left circularly polarized beams at an absorption edge and provides information about the local (element and angular momentum specific) spin and orbital magnetic moments. Both theoretical and experimental work on the CMXD spectra of rare-earth magnets is presented. The nature of the feature below the absorption edge in the rare-earth CMXD spectra for the L_2 and L_3 edges is discussed.

Circular magnetic x-ray dichroism is defined as the difference between the absorption coefficients for left- and right circularly polarized x-ray beams in a magnetized sample. With the advent of more intense synchrotron radiation sources, circular magnetic x-ray dichroism has increasingly been used as a probe of the magnetic properties of various crystalline and multilayer systems.[1-5] In the past few years, various theoretical models have been proposed for the interpretation of these spectra both qualitatively and quantitatively.[6-8] For example, sum rules derived by Thole *et al.*[9] and Carra *et al.*,[10] which relate the integrated CMXD spectra to the ground-state expectation values of orbital and spin-dependent effective operators, have provided a theoretical basis for the interpretation of CMXD spectra and have been used to determine the spin and orbital moments of transition elements in a variety of systems.[5] The details of the CMXD spectra at the L edges of transition elements (including $5d$ impurities in $3d$ hosts) and the M edges of the rare-earth elements can be reasonably well described by first principle calculations.[7,8] This is not the case for the L_2 and L_3 edges of rare-earth (RE) elements. While these transitions are mainly of the $2p$ to $5d$ dipolar character, complications arise due to the existence of the $4f$ shell in these elements. In particular, features are observed below the absorption edge,[1] as well as a pronounced asymmetry between L_2 and L_3 dichroic spectra above the absorption edge for some compounds.[2] In this article we summarize the work which has been done on these issues and discuss some of the difficulties with the current theoretical understanding of the CMXD of rare-earth magnets.

For the L_2 and L_3 edge CMXD spectra of rare-earth elements, it is generally accepted that the prominent feature above the absorption edge arises from dipolar transitions between the $2p$ core levels and the unoccupied $5d$ states. In order to explain the feature found below the edge, electric quadrupolar transitions were introduced by Carra *et al.*[6] This interpretation is further supported by the resonant magnetic x-ray scattering experiments.[11] Since the unfilled $4f$ shell in the rare-earth elements is highly localized, the quadrupolar peak appears below the edge due to strong Coulomb interactions, in the final states, between the $2p$ core hole and $4f$ electrons (excitonic state). Based on this consideration, a combined model which treats the $2p$ to $4f$ transitions using atomic multiplet theory and $2p$ to $5d$ transitions using one electron band theory was introduced.[6] Detailed calculations for Gd metal[6] and later for heavy rare-earth metals[12] have been done based on this model and agree remarkably well with the experiments on the elemental metals. Encouraged by these successes, we have developed a first principles program to calculate CMXD spectra within the one electron band model, which, taken together with the atomic multiplet calculations, can be used to describe the L_2 and L_3 spectra of rare-earth elements in different compounds. The band-structure calculation was carried out within the local spin density functional approximation (LSDA) which has been shown suitable for describing the ground state properties of heavy rare-earth magnets.

Experimental spectra taken at the Gd L_2 and L_3 edges of crystalline $GdFe_2$ along with theoretical spectra calculated using the method described below, are shown in Fig. 1. The theoretical curves have been scaled down by a factor of 2. The CMXD measurements were taken at Cornell High-Energy Synchrotron Source (CHESS) bending magnet D line making use of the off-axis elliptical polarization of the beam. The data have been normalized to $T=0$ K saturation magnetization of the sample and full circular polarization of the x-ray beam in order to directly compare the magnitude of the experimental spectra with the theory.[13]

In our atomic-sphere-approximation tight binding linear muffin-tin orbital (ASA-TB-LMTO) band-structure code, a spin-polarized, spin-orbit-coupled, one-electron Hamiltonian is solved using the scalar relativistic spin-dependent tight-binding muffin-tin orbitals as a variational basis.[14] The theoretical spectra have been convoluted with a Lorentzian of about 3.5 eV to account for the finite core hole life time and energy-dependent conduction state life time, and by a Gaussian of 1.5 eV to account for the experimental resolution. The theoretical curves, while giving the general shape, do not reproduce the experimental spectra well. We believe, however, that after taking into account of the core hole Coulomb attraction on the one electron orbitals, the agreement will be improved since the core hole effect will compress the theoretical spectrum toward the Fermi level, as observed in the experiment. The discrepancy between the absolute magnitude of the theoretical and experimental spectra (a factor of 2) can be reduced if we invoke the wave-function normalization factor to the conduction electron states. Further calculations are being undertaken to incorporate the effect of the core hole. While the full treatment of the transient impurity problem[15] is still formidable for a first principles calculation,

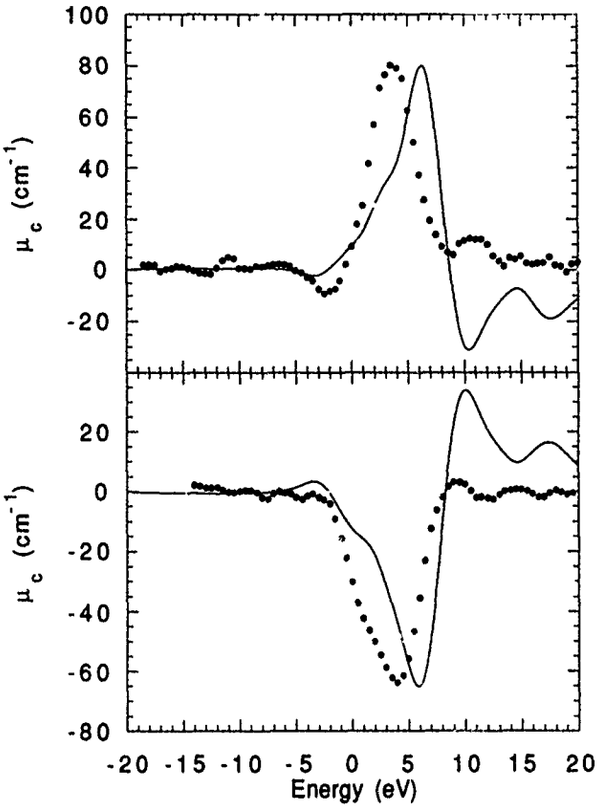

FIG. 1. Experimental (dots) and theoretical (solid line) CMXD spectra at the Gd L_3 (top), and Gd L_2 (bottom) edges. Theory curves have been scaled down by a factor of 2.

a calculation in the adiabatic approximation is essentially a static impurity problem and is well within the current computational capability. This work will be presented in a future publication.

Although the above-described model has successfully described some general features of the CMXD spectra of the L_2 and L_3 edges of heavy rare-earth elements, there are difficulties associated with it. Because of the different symmetry characteristics of the dipolar and quadrupolar transitions, the model unambiguously predicts different angular dependencies of the dipolar part (above edge) and quadrupolar part (below edge) of the CMXD spectra.[6,16] When scaled to the magnitude of the dipolar part at different angles, theory predicts that the quadrupolar transitions should yield a pronounced angular dependence for the magnitude of the feature below the edge. To firmly establish the validity of the model, it is essential to confirm this prediction experimentally. The theory predicts that Ho and Er should demonstrate the most pronounced angular dependence.

Several experiments have been carried out and have failed to observe any angular dependence.[17–19] This negative result has stimulated other explanations for the below edge feature, such as its assignment to the magnetic dipolar transitions involving hybridization between the $4f$ and $5d$ orbitals. Magnetic dipolar transitions, for core-level absorption spectroscopy, even when satisfying angular momenta selection rules, give basically null contributions due to a null radial matrix element as pointed out by Brouder.[20]

We point out here several possible explanations of the observed negative results for the quadrupolar angular dependence. Recently Carra *et al.* have derived sum rules for the quadrupolar CMXD spectra,[21] which associate the integrated quadrupolar spectrum with the expectation values of two kinds of operators in the ground state, namely the dipolar operators (not to be confused with the dipolar transitions) whose expectation values have the same angular dependence ($\cos\theta$) as the dipolar transitions and the octupolar operators whose expectation values have a different angular dependence $[(5\cos^2\theta\text{-}3)\cos\theta]$. It is the contributions of the expectations values of these octupolar operators that give the quadrupolar transition a different angular dependence from the dipolar transition. The quantitative prediction on the angular dependence was made using an isolated ion calculation.[6] When the crystal-field effects are taken into account, the ground-state expectation values of the dipolar and octupolar operators are expected to scale differently (crystal-field scaling).[21] Further theoretical investigations are required to see if the crystal field will reduce the octupolar contribution to a greater degree than the dipolar contribution and hence reduce the difference in angular dependence between the quadrupolar and dipolar transitions. Second, as we have mentioned, the theoretical prediction was made according to an isolated ion calculation, and has completely neglected the possible hybridization of the $4f$ shell with the conduction electron states both in the ground state and the excited states. When hybridization effects are taken into account, the feature below the edge will have some dipolar mixing due to the transitions from $2p$ to the ligand states. These states hybridize with the $4f$ shell and can be a mixture of d and f character because the $2p$ core hole has broken the local crystal-field symmetry for the outer shells. The mixing of these dipolar transitions below edge will reduce the relative weight of the quadrupolar transitions and make the experimental identification of the angular dependence of the feature more difficult. Although these hybridizations have to be very small, their effects may be enhanced by the dipolar matrix element which is two orders of magnitudes larger than the quadrupolar matrix element. Finally, we want to point out here that the "shake up," due to the core hole, of the $4f$ multiplets in the $2p$-$5d$ transitions can also modify the above edge feature as predicted by band calculations and this may be the origin for the strong asymmetry between the CMXD L_2 and L_3 edges of some heavy rare-earth compounds.

In conclusion, we believe that the combined model given in Ref. 6 gives the basic physics involved in the CMXD L_2 and L_3 edges of the heavy rare-earth compounds, although some detailed modifications are required to resolve the discrepancies between the theory and the experiment. In order to obtain a definite answer to the nature of the below edge feature of these spectra, experiments also need to be carried out at lower temperatures to reduce the thermal fluctuations, since thermal fluctuations, acting effectively as a random external field, will not only reduce the dichroic signal but also suppress the different quadrupolar angular dependence.

Note added in proof. Theoretical calculations done with the combined correction to the ASA-TB-LMTO[22] have shown better agreement of the Gd L_2 and L_3 dichroic spectra between the theory and the experiment.

Ames Laboratory is operated for the United States Department of Energy by Iowa State University under Contract No. W-7405-ENG-82. Work at CHESS was supported by the National Science Foundation under Grant No. DMR-87-119764.

Resonant photoemission and magnetic x-ray circular dichroism in the *M* shell of ultrathin films of Fe

J. G. Tobin and G. D. Waddill
Lawrence Livermore National Laboratory, Chemistry and Materials Science Department, Livermore, California 94550

Using magnetic ultrathin films (2–4 monolayers) of Fe on Cu(001) and bulklike Fe, the Fe 3*p* and Fe 3*s* core states have been investigated with resonant photoemission and core-level photoemission, including magnetic x-ray circular dichroism (MXCD) experiments. The resonant photoemission experiment has been done, to probe the parentage of various spectral structures. All the observations can be explained as simply due to the presence of Auger features: It is not necessary to invoke configuration interaction combined with strong photoemission resonance.

Although the observation of spin-dependent splitting in photoelectron spectroscopy of magnetic materials has become fairly common, a complete, quantitative understanding of the underlying causes remains elusive. Consider the case of the *M* shell core levels of Fe. The Fe 3*p* state can exhibit a dichroism or variation if either circularly polarized x rays[1] or linearly polarized x rays[2] are used with a magnetized sample. An example of magnetic circular dichroism is shown in Fig. 1. Here the sample is 2 monolayer (ML) Fe/Cu(001) and a binding-energy shift of 0.2 eV accompanies the change from a parallel to antiparallel configuration. Alternatively, one can use true spin detection to separate contributions in the Fe 3*p* spectra.[2–4] Each of these measurements gives a sort of "exchange splitting" but an exact analysis must await the application of full multiple scattering calculations that include spin specificity, selection rules, and band effects.[5] The Fe 3*p* case is further complicated by the fact that the exchange splitting is of nearly the same order of magnitude as the spin-orbit splitting, inducing additional extensive mixing of *j* states.

A potentially simpler case is the Fe 3*s* "doublet," examples of which are shown in the topmost spectra of Figs. 2 and 3. The components of this doublet or strongly asymmetric peak are associated with different spins in the local magnetic structure.[6] In fact, it is not necessary to macroscopically magnetize the sample in order to observe the splitting of the Fe 3*s* peak; however, the samples must be magnetized in order to use spin detection to resolve the separate spin contributions.[7,8]

The lower spectra in Figs. 2 and 3 are examples of resonant photoemission,[9] where additional channels for electron emission have opened up as the $2p_{3/2}$ and $2p_{1/2}$ core-level thresholds were reached. The interplay of the direct and resonant channels is a means to test theories concerning the origin of the 3*s* peak splitting, as discussed in Ref. 10. Here, we present detailed resonant photoemission spectra of Fe/Cu(001) and bulklike Fe which will call into question the analysis advocated in Ref. 10.

These experiments were performed at the Stanford Synchrotron Radiation Laboratory, using the University of California/National Laboratories Participating Research Team facilities,[11–13] on the spherical grating monochromator (SGM) beam line, 8-2. Beam line 8-2 can be used as a source of circularly polarized x rays.[1,6,14] The data were collected in a three-tiered, two-chamber photoelectron spectrometer,[15] equipped for photoemission with full energy and angular (±3°) resolution and multichannel detection.

The resonant photoemission spectra are now broken up into constant binding energy and constant kinetic-energy features. The constant kinetic-energy features are shown to be Auger peaks. The absence of strong intensity variations in the constant kinetic-energy features, as a function of photon energy, is demonstrated. This, in turn, argues against a specialized initial state (i.e., configuration-based) effect as the source of the 3*s* doublet intensity variations.

In resonant photoemission, new channels open up with the crossing of each core-level threshold. In Figs. 2 and 3, major spectral changes occur at $h\nu=707$ eV (L_3 or $2p_{3/2}$ threshold) and $h\nu=720$ eV (L_2 or $2p_{1/2}$ threshold). Because of finite energy broadening, the onset of these changes often occurs at photon energies just below the nominal threshold. New spectral features can be seen at the valence bands ($B^F\cong 0$; B^F is the binding energy with respect to the Fermi energy), the Fe 3*p* ($B^F=53$ eV) and the Fe 3*s* ($B^F=92$ eV).

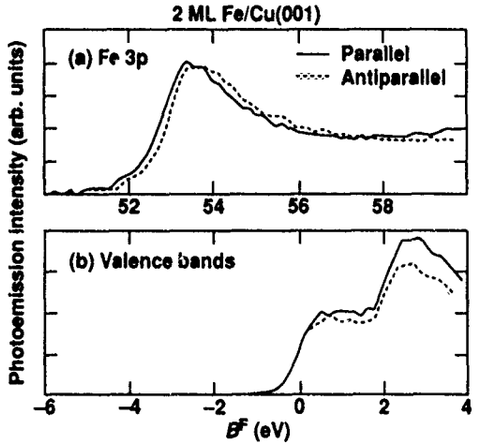

FIG. 1. Magnetic x-ray circular dichroism in photoemission of the fcc Fe 3*p* core level. The bottom panel shows the alignment of the Fermi edge, which allows for a direct comparison of the 3*p* binding energies in the top panel. The sample was 2 ML Fe/Cu(001), with perpendicular magnetization. The photon energy was 160 eV. The circularly polarized x rays were incident along the sample normal and the electron emission direction was at 55° from normal, approximately in the [210] plane. Parallel and antiparallel refer to the relative orientation of the photon helicity and sample magnetization (or minority spin) (Ref. 1). Parallel refers to both up or both down, and antiparallel is correspondingly up, down or down, up.

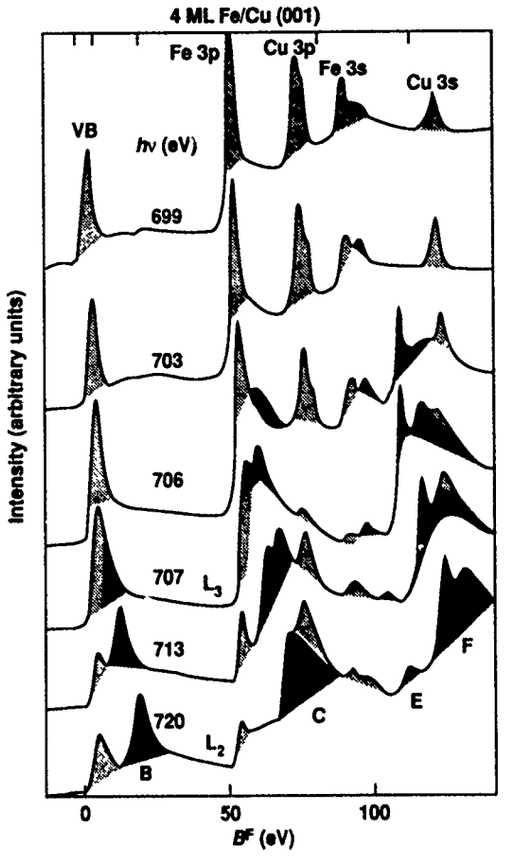

FIG. 2. Wide photoelectron emission scans of 4 ML of Fe/Cu(001) at a series of photon energies near the $2p_{3/2}$ (707 eV) and $2p_{1/2}$ (720 eV) thresholds. All scans shown were taken with linear polarization with the photons incident at 45° from the sample normal. The electrons were collected at an angle of 45° from the surface normal, with the electron momentum parallel to the photon electric polarization vector. Constant binding-energy features are shown with light shading. Constant kinetic energy reactions are shaded more darkly.

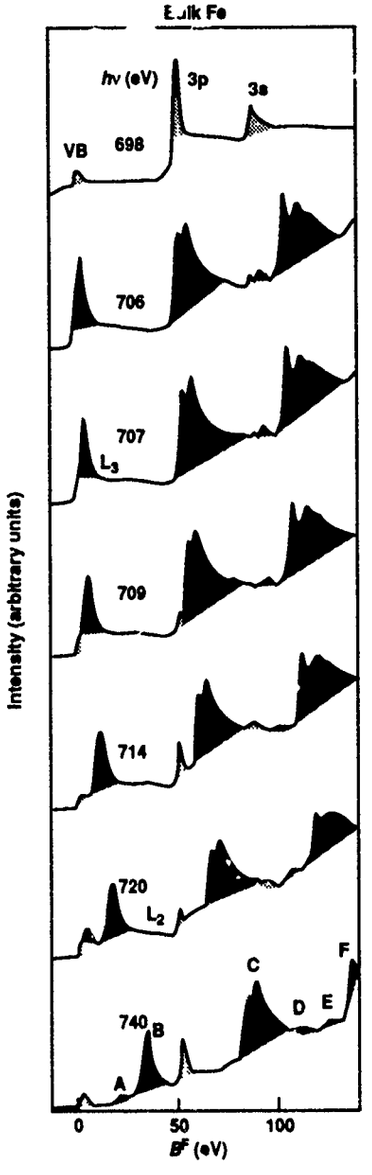

FIG. 3. Similar to Fig. 2, but here the sample is a bulklike Fe film (25 ML) on Cu(001). Note the absence of Cu spectral features. All scans were taken with linear polarization, at normal incidence, and the electrons were collected at an angle of 45° from the normal.

As the photon energies are increased, the new features move across the spectra, with a constant kinetic energy (KE) associated with each feature. (A summary of constant B^F and constant KE features is shown in Table I.) Well above threshold, these constant KE features are identified as Auger peaks. It is only at threshold that the resonance channels and direct channel are isoenergetic. In the third column of Table I are values taken from an Auger handbook:[17] All except one are printed-assigned values, with the exception being 620 eV, which corresponds to a smaller unmarked minimum. The constant difference between column 2 and column 3 arises from the measurement procedure. In this work we use peak maxima, and in Ref. 17 the minima of differential peaks is used. Thus, this shift is not unexpected and a one-to-one correspondence is found between the members of column 2 and those of column 3.

The strongest features, B, C, and F are associated with a hole in the L_3 ($2p_{3/2}$) level: $L_3M_{4,5}M_{4,5}$,L_3,$M_{2,3}M_{4,5}$ and $L_3M_{2,3}M_{2,3}$ respectively.[18] These are intense but broad transitions. The $L_3M_{4,5}M_{4,5}$ (KE=692 eV) and the $L_3M_{2,3}M_{4,5}$ (KE=642 and 637 eV) and the $L_3M_{2,3}M_{2,3}$ (KE=592 and 587 eV) are all intrashell interactions. The observed splitting in C and F, which were smeared out in the lower-resolution Auger handbook spectra, is well understood.[18] The other feature which first appears at the L_3 threshold is a weaker peak at KE=602 eV (E in Table I). This appears to be a $L_3M_1M_{4,5}$ transition. Also, when the L_2 threshold is reached, an additional transition will contribute intensity at this energy, as is described next.

The L_2MM transitions become accessible at $h\nu=720$ eV but in general are far less intense than their L_3MM counterparts, as discussed in Ref. 10. This is due in part to the Coster–Kronig[19] decay channel, $L_2L_3M_{4,5}$, which rapidly transfers the hole into the L_3 states and thus decreases the L_2MM intensities while maintaining the L_3MM intensities. A fairly strong $L_2M_{4,5}M_{4,5}$ peak can be observed at KE =702 eV (peak A in Table I). The other two possibilities,

TABLE I. Summary of constant B^F and KE features.

Constant	B^F, B^F (eV)[b]	Constant	KE KE (eV)	Auger features[a] KE (eV)	Frozen shell model KE=$B_1^F-B_2^F-B_3^F-\Phi$	
VB ($M_{4,5}$)	~2	A	702	716	$L_2M_{4,5}M_{4,5}$	712 eV
Fe 3p ($M_{2,3}$)	53	B[c]	692	703[c]	$L_3M_{4,5}M_{4,5}$	699 eV
Cu 3p	75,77	C[c]	642,637	651[c]	$L_3M_{2,3}M_{4,5}$	648 eV
Fe 3s (M_1)	92	D	612	(~620)	$L_2M_1M_{4,5}$	623 eV
Cu 3s	120	E	602	610	$L_3M_1M_{4,5}$	610 eV
					$L_2M_{2,3}M_{2,3}$	610 eV
		F[c]	592,587	598[c]	$L_3M_{2,3}M_{2,3}$	597 eV

[a]From Ref. 17.
[b]From Ref. 16.
[c]Strong feature.

$L_2M_{2,3}M_{4,5}$ and $L_2M_{2,3}M_{2,3}$ are difficult to observe, and the $L_2M_{2,3}M_{2,3}$ may overlap with the $L_3M_1M_{4.5}$ at KE =602 eV. The final feature, D in Table I at KE=612 eV, appears to be the $L_2M_1M_{4,5}$ peak and is fairly weak, although this is the strongest of the L_2MM features relative to its L_3MM counterpart. For the sake of argument, the results of a frozen shell model are shown in Table I. Obviously, this model is deficient and only energy differences make any sense quantitatively, e.g., $L_2M_1M_{4,5}$ vs $L_3M_1M_{4,5}$ and $L_2M_{2,3}M_{2,3}$ vs $L_3M_{2,3}M_{2,3}$. Nevertheless, it is clear that these assignments are quite reasonable. Moreover, the spectra shown here in Figs. 2 and 3 are only a part of the overall data set. A much finer grid of spectra, taken with $\Delta h\nu=2$ eV, were also collected and were used in this analysis, although space limitation precludes their inclusion here.

Having established that the constant KE features can be assigned as Auger features, the question arises: Is there a need to invoke a specialized initial state resonance and configuration interaction to explain our observations? The answer is no. As can be seen in Figs. 2 and 3, the constant KE features generally exhibit fairly constant intensity ratios relative to each other. The constant KE features (associated with L_3MM Auger peaks B, C, E, and F are generally much more intense that the constant B^F features, with the exception of the $L_3M_1M_{4,5}$ (peak E). Peak F does seem to turn on at a slightly lower photon energy than B, C, and F, but this is not unreasonable considering the significantly different electronic structure that contributes to these features. This appears to be analogous to the delayed onset of the 3p or 3d photoemission cross sections, due to the centrifugal barrier, which is not to be expected in an s state such as the Fe 3s.[20] Consistent with our interpretations, recent work[21] indicates that, resonant photoemission in Ni is also essentially due to intense Auger emission and is not actually photoemission at all.

Finally, one last observation should be made. Because x-ray absorption at the L_2 and L_3 edges is such a crucial part of the resonant photoemission process and because very strong absorption circular dichroism has been observed for both monolayers and multilayers,[14] it was plausible that a magnetic circular dichroism intensity effect might be seen in resonant photoemission. Unfortunately, no such effects were observed.

An extensive resonant photoemission investigation of 4 ML Fe/Cu(001) and bulk Fe were performed. All observed resonance features can be explained by assignment as Auger peaks; the increased intensity of the high-binding energy 3s multiplet feature at resonance appears to be related to the overlap with the $L_3M_1M_{4,5}$ (or $L_2M_1M_{4,5}$) Auger transition and does not uniquely establish this feature as arising from configuration interaction d mixing. This seriously calls into question the arguments proposed earlier in Ref. 10, where the variation in spectral intensities of the components of the 3s doublet was used to support a configuration-based model of photoelectron emission. The apparent variation of the 3s doublet components appears to be due merely to the onset of an Auger transition at the L_3 threshold.

Work was performed under the auspices of the U S. Department of Energy by the Lawrence Livermore National Laboratory under Contract No. W-7405-ENG-48. SSRL is supported by DOE/OBES Chemical Sciences. The authors wish to thank Karen Clark for clerical support of this work.

Molecular-orbital analysis of magneto-optical Bi-O-Fe hybrid excited states

Gerald F. Dionne
Lincoln Laboratory, Massachusetts Institute of Technology, Lexington, Massachusetts 02173

Gary A. Allen[a)]
Department of Physics, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

Molecular-orbital estimates of the excited-state spin-orbit coupling multiplet splitting are presented to support the theory that enhanced magneto-optical effects in $Y_{3-x}Bi_xFe_5O_{12}$ originate from covalent interactions between Bi^{3+} and Fe^{3+} ions. A self-consistent approximation is applied to a two-level bonding-antibonding hybrid formed from the excited ^4P term of Fe^{3+} and the excited ^3P of Bi^{3+}. For term energy values chosen from spectroscopic data, overlap integrals $s<0.05$ are sufficient to account for bonding-state depressions that match those reported for the tetrahedral and octahedral site-enhanced transitions at 2.6 and 3.15 eV. The hybrid eigenfunctions of the upper states can contain more than 30% of the Bi^{3+} ^3P orbital term. Multiplet splittings that are enhanced by the large Bi^{3+} spin-orbit coupling constant ($\lambda\approx 2$ eV) are found to be on the order of 0.5 eV with a full complement of Bi surrounding Fe in the garnet lattice, in agreement with estimates based on experiment.

I. INTRODUCTION

In a recent examination of the Kerr rotation and ellipticity enhancement in $Y_{3-x}Bi_xFe_5O_{12}$,[1] it was concluded that the principal source of the effect was large splittings of the upper states of selected optical transitions. In this interpretation, two strong lines of opposite sign with transition energies of 2.6 and 3.15 eV from Fe^{3+} in tetrahedral (d) and octahedral (a) sublattices were determined to be responsible for most of the magneto-optical enhancements across a band from 2 to 5 eV. To further this analysis, we now examine the origin of the excited-state splitting. For ferrimagnets with exchange-coupled Fe^{3+} ^6S ground states, polarization rotation of a wave propagating parallel to the magnetization vector (z direction) is described mathematically as a frequency-dependent off-diagonal element of the permittivity tensor. This requires interaction between the electric vector of the optical wave and the orbital angular momentum $\mathbf{L}$ of the excited state. For the magnetic moments to influence nonreciprocal effects, therefore, spin-orbit coupling is a necessary component. Since the excited-state splitting is the result of spin-orbit multiplet structure, contributions from the large Bi^{3+} spin-orbit interaction reflected through covalent molecular-orbital (MO) states is the focus of this investigation.

II. TWO-LEVEL MO APPROXIMATION

For the generic two-level system sketched in Fig. 1, the covalence Hamiltonian $\mathbf{H}$ may be treated self-consistently following the method developed by Wolfsberg and Helmholtz.[2] The determinant secular equation of the perturbation calculation formed from matrix elements $\mathbf{H}_{ij}=\langle\chi_i|\mathbf{H}|\chi_j\rangle$ is given by

$$\begin{vmatrix}\mathbf{H}_{11}-\Lambda & \mathbf{H}_{12}\\ \mathbf{H}_{21} & \mathbf{H}_{22}-\Lambda\end{vmatrix}=\begin{vmatrix}E_1-\Lambda & B-\Lambda s\\ B-\Lambda s & E_2-\Lambda\end{vmatrix}=0, \tag{1}$$

where $B\approx(\mathbf{H}_{11}+\mathbf{H}_{22})s$ (exchange integral), and $s=\langle\chi_1|\chi_2\rangle$ (overlap integral). Solution of Eq. (1) yields the following eigenvalues.[3]

$$\Lambda_\pm=\frac{(E_1+E_2)(1-2s^2)\pm\sqrt{(E_1-E_2)^2(1-s^2)+B^2}}{2(1-s^2)}. \tag{2}$$

The MO eigenvectors $\phi_i=\Sigma_j c_{ij}\chi_j$ are found from the standard relation $\Sigma_j(\mathbf{H}_{ij}-\Lambda_\pm\delta_{ij})c_{ij}=0$, where $\Sigma_j c_{ij}^2=1$. If $s>0$, additional normalization factors are necessary.[4] For the two-level case,

$$C_{ij}=c_{ij}(c_{ii}^2+c_{ij}^2+2c_{ii}c_{ij}s)^{-1/2}, \tag{3}$$

and the final eigenvectors become $\phi_b=C_{11}\chi_1+C_{12}\chi_2$ and $\phi_a=C_{21}\chi_1-C_{22}\chi_2$ for the bonding and antibonding states, respectively. There are two important results here: (i) ϕ_b is of lower energy than χ_1 by an amount Λ_--E_1, and (ii) the initial wave functions χ_1 and χ_2 mix in proportion to the values of C_{11} and C_{12}. For this generic example, $|\chi_2|^2$ mixes into $|\phi_b|^2$ by a fraction C_{12}^2.

III. SUPEREXCHANGE AND SPIN-ORBIT COUPLING

As discussed previously,[1] we believe that the enhanced magneto-optical effects arise from the cooperative action of Fe^{3+} ions with degenerate excited orbital terms that are split further by covalent interactions with Bi^{3+}. Because

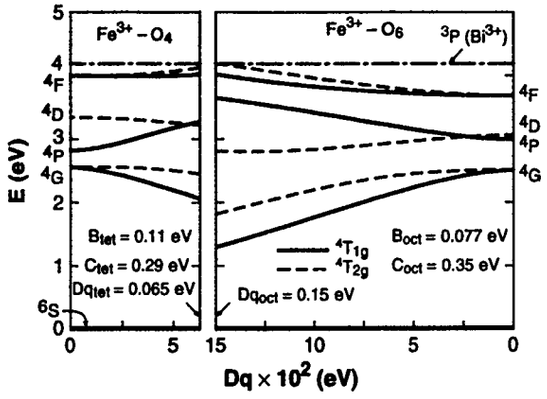

FIG. 2. Crystal-field-sensitive excited terms for (d^5) in d and a garnet sites as functions of crystal-field parameter Dq. Energies were computed from Tanabe and Sugano matrices (Ref. 7), with B and C values based on the spectral analysis of Wood and Remeika (Ref. 8).

crystal-field effects have already been accounted for (see. Fig. 2), the total angular momentum **J** remains a "good" quantum number in each part of the hybrid state. The upper-state splitting parameter Δ for individual ions is determined principally by the eigenstates of the operator $\lambda\mathbf{L}\cdot\mathbf{S}$. The z-axis collinearity of the N magnetic moments can occur through an applied field $\mathbf{H}(=\mathbf{H}_a)$ or an exchange field $\mathbf{H}(=\mathbf{H}_{ex})$. In both cases, the degree of alignment follows a Brillouin function $\mathcal{B}$, so that $N_{\text{eff}}=N\mathbf{B}(H,T)$. There is, however, an important distinction between these two situations—$\mathbf{H}_a$ influences **J** by splitting the M_J levels (Zeeman effect), but $\mathbf{H}_{ex}$ can affect only **S** by splitting the M_S states.

The magnetization of the garnet is saturated in the z direction by superexchange fields,[5] causing $\mathbf{B}\rightarrow 1$, and $N_{\text{eff}}\rightarrow N$. Through covalent interactions, the excited states of both Fe^{3+} and Bi^{3+} should also have nondegenerate spin states. If the exchange field perturbation is applied, the lowest state M_S value enters the calculation as a multiplier when the orbital magnetic moment degeneracies of the MO states are lifted by spin-orbit coupling $\lambda\mathbf{L}\cdot\mathbf{S}$. Because **S** is captured by $\mathbf{H}_{ex}$, and is therefore aligned with the z axis, $|\mathbf{S}|=S_z$ and $|\mathbf{L}|=L_z$. The value of S_z ($=M_S$) appropriate for the particular level of the $2S+1$ manifold simply multiplies each M_L ($=2L+1$) value of the L_z manifold. Expectation values of $\lambda\mathbf{L}\cdot\mathbf{S}$ are therefore determined by

$$\phi_b|\lambda L_z S_z|\phi_b\rangle\approx\lambda M_S\langle\phi_b|L_z|\phi_b\rangle. \tag{4}$$

This situation for a ^4P state is depicted in Fig. 3. For the hybrid state, the energies that determine the Δ splitting may be reduced to

$$E_\Delta(M_L)=C_{11}^2(\lambda_1 M_{S1}M_{L1}+C_{12}^2(\lambda_2 M_{S2})M_{L2}, \tag{5}$$

where M_{S1} now represents the value of the lowest spin state. For the case of ^4P (Fe^{3+}), $M_{L1}=0,\ \pm1$ and $M_{S1}=-3/2$; for ^3P (Bi^{3+}), $M_{L2}=0,\ \pm1$ and $M_{S2}=-1$. Where $\lambda_2\gg\lambda_1$ ($\lambda_{Bi}\gg\lambda_{Fe}$ in this case) and C_{12}^2 is significant, we may approximate $E_\Delta(M_{L2})=C_{12}^2(\lambda_2 M_{S2})M_{L2}$. The magnitude of the splitting then becomes $2\Delta\approx[E_\Delta(+1)-E_\Delta(-1)]$.

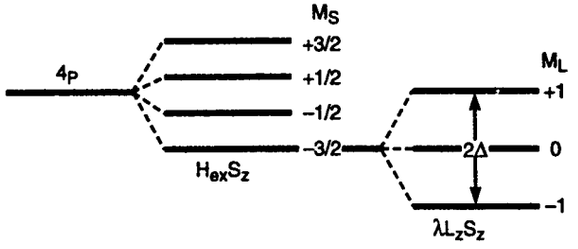

FIG. 3. Exchange field spin quenching and spin-orbit splitting of a ^4P term.

IV. GROUND- AND EXCITED-STATE ENERGIES

Before we examine the excited states of the $Bi_3Fe_5O_{12}$ molecule, it is necessary to determine the stabilization energy of the ground state. This energy may be estimated from the electrostatic interactions between ions and outermost electrons in the model shown in Fig. 4. Here the binding energy of the electrons of Fe^{3+} and Bi^{3+} may be computed from the algebraic sum of the cation ionization potentials (IP) and the energy of the field from the negatively charged anion. For the outermost electron, this repulsive energy (RE) is estimated by dividing the effective lattice energy (LE) by the ionic charge. For Fe^{3+}, IP$=-54.8$ and RE from $Fe_2O_3\approx+25.5$ eV; for Bi^{3+} and Bi_2O_3, the corresponding values are -45.3 and $+15.8$ eV, so that a common resultant ground-state ionic energy $E_g\approx-29$ eV is estimated for both Fe^{3+} and Bi^{3+}. Stabilization energies of the excited states are found by adding -29 eV to absorption energy values from spectral data.[1]

Interpreting the magneto-optical properties of $Bi_3Fe_5O_{12}$ is begun by analyzing the covalent interactions between the excited ^3P term of Bi^{3+} in the dodecahedral (c) sites of the garnet lattice, and the excited states of Fe^{3+} in the d and a sites. Since isolated Bi^{3+} has an excited state $\approx$4.2 eV above the ground state,[6] hybridization from covalence is possible with several Fe^{3+} excited states. Diagrams of the orbital terms[7,8] as functions of the crystal-field strength parameter Dq for the d and a sites are shown in Fig. 5.

V. MOLECULAR-ORBITAL EXCITED STATES

To construct the hybrid states that represent the bands of half-width Γ between the Bi^{3+} ^3P ($6s$, $6p$) and Fe^{3+} ($3d^5$) excited states that would produce electron transition matrix elements with Fe^{3+} ^6S ground states, consider the following rationale: The candidates that satisfy the selection rule

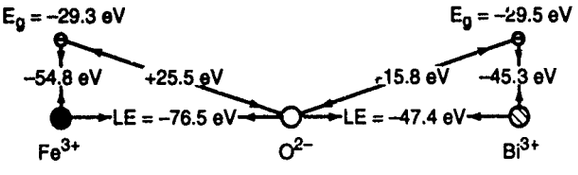

FIG. 4. Electron stabilization energies based on handbook values of ionization potentials of Bi^{3+} and Fe^{3+} and lattice energies of Bi_2O_3 and Fe_2O_3

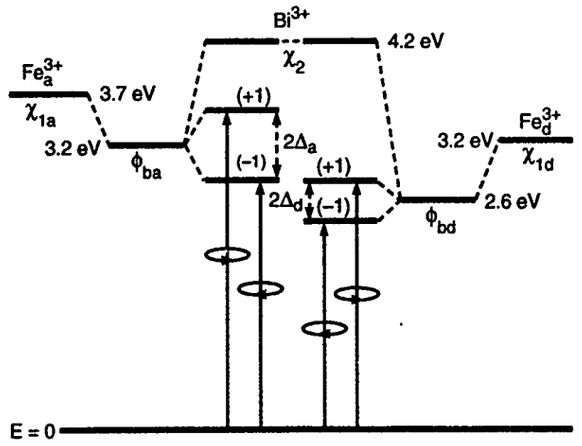

FIG. 5. Proposed molecular-orbital energy-level diagram of $Bi_3Fe_5O_{12}$. Oxygen interactions and all antibonding states have been omitted to reduce confusion. Overlap integrals can include invidual Bi-O-Fe, direct Bi-Fe, and linkages between Bi and Fe_a-O-Fe_d superexchange groups.

$\Delta M_L = \pm 1$, that have symmetry transformation properties similar to the Bi^{3+} ^3P state, and are crystal-field (i.e., Dq) selective are the $^4T_{1g}$ states. Inspection of Fig. 2 reveals three $^4T_{1g}$ states, associated with the ^4G, ^4P, and ^4F terms.

For the principal transitions that appear to cause the magneto-optical anomalies at 2.6 and 3.15 eV,[1] the obvious choice is the ^4P term, which has energies of 3.2 and 3.7 eV for the d and a sites, respectively, with corresponding Dq values of 0.065 and 0.15 eV. The bonding-state hybrid function is then expressed as $\phi_b = C_{11}|^4P\rangle + C_{12}|^3P\rangle$. If these quantities are used in Eqs. (1) and (2), values that agree with experiment are listed in Table I for the transition energies $(\Lambda_- - E_g)$ from the ground state to the bonding states for $C_{12}^2 = 0.26$ and 0.33, and $s = 0.04$ and 0.03 for the d and a sites, respectively. The larger value of s for the d site is consistent with its shorter bond lengths. To determine the Δ values listed in Table I, we ignore the first term (the Fe^{3+} part) of Eq. (5) by assuming that $\lambda_2 \gg \lambda_1$. With $\lambda_2 = \lambda_{Bi}$ and $M_{S2} = -1$, the multiplet energies $E_\Delta(M_{L2}) \approx +\lambda_{Bi}C_{12}^2$, 0, $-\lambda_{Bi}C_{12}^2$, thereby yielding $\Delta \approx \lambda_{Bi}C_{12}^2$. For $\lambda_{Bi} \approx 2$ eV,[9] and $C_{12}^2 < 0.5$, Δ values for d and a sites are 0.52 and 0.66 eV, respectively, in general agreement with the conclusions of experiment (see footnote to Table I). Calculated values of Γ ($\approx B/4$) are also in reasonable agreement with experimental values on the order of 0.5 eV.[1]

TABLE I. Molecular-orbital parameters of $Bi_3Fe_5O_{12}$.

$E_1 - E_g$ (eV)	$\Lambda_- - E_g$ (eV)	s	C_{12}^2	Δ (eV)	Δ_{expt} (eV)
3.2 (d)	2.6	0.04	0.26	0.52	0.11[a]
3.7 (a)	3.2	0.03	0.33	0.66	0.27[a]

[a]These values were determined for $Y_{3-x}Bi_xFe_5O_{12}$ with $x = 0.25$ (Ref. 1) For the full complement of Bi^{3+} interactions, i.e., $x = 3$, the effective s integrals, C_{12}^2 values, and Δ_{expt} magnitudes would be significantly larger.

VI. DISCUSSION

From the above calculations, Fig. 5 may be constructed to illustrate the origin of the Faraday rotation peaks at 2.6 and 3.15 eV. In addition, this work presents an opportunity to suggest that the weaker transition estimated to occur at 3.9 eV initially labeled as d site,[1] may result from a partial overlap cancellation of transitions that originate from the MO states formed with the ^4F terms ($E_1 \approx 4.1$ eV) of Fe^{3+} ions in both d and a sublattices. This situation would explain why the location of the second peak from the a sublattice should appear somewhere in this general energy regime. The experimental determination that the peak at 3.9 eV has the same sign as the tetrahedral peak at 2.6 eV is consistent with the ratio (3:2) of d to a sites.

Based on the notion that magneto-optical effects involving excited states are dependent on the product $N_{eff}\Delta$, we may speculate on the effects of magnetic dilution and temperature variations. If the temperature T remains below the Curie temperature T_C, N_{eff} should track with the magnetizations of the respective sublattices, subject to influence from loss of spin collinearity in the upper states of the individual transitions. Information about spin canting in both the ground and excited states may be extracted from the peak intensities as functions of Fe^{3+} content.

For other ions with a $(6s)^2$ ground-state electron configuration similar to that of Bi^{3+}, i.e., Pb^{2+}, Tl^{1+}, or neutral Hg, similar magneto-optical effects should be expected. With smaller λ values, however, the effects of the Δ splitting should be reduced somewhat from those of Bi^{3+}.

A new Faraday rotation glass with a large Verdet constant

Sui hua Yuan and Xiao Zhou Shu
Special Optics Laboratory, Xian Jiaotong University, Xian Chian, People's Republic of China

Heavily terbium-doped boron-silicate glasses (Tb^{3+}10.4 at. %) with a Verdet constant (632.8 nm, room temperature) as large as −0.338 min/Oe cm, 38% larger than that of the famous FR-5 glasses, have been made. The wavelength and temperature dependencies of the Verdet constants of samples have been investigated in the ranges of 400 to 800 nm and 100 to 300 K. The results show paramagnetic Faraday rotations. The measured susceptibilities between 77 and 300 K support this point but with an effective Bohr magneton number 7% smaller than the theoretical value for free Tb^{3+} ions. Susceptibilities are further measured at temperatures from 1.5 to 100 K and magnetic fields from 0.2 to 5.0 T. The results show saturation of magnetization and give a Néel temperature of about −9 K. The effective Bohr magneton number in the state of saturated magnetization is 55% smaller than the free ion value. These results may indicate the single ion anisotropy reduction of the magnetization of the disordered Tb^{3+} ions at low temperatures. The measured indices, Abel number, and nonlinear-index coefficient are 1.745 92 (N_c), 1.746 70 ($N_{632.8}$), 1.749 84 (N_D), 1.760 31 (N_F), 49.92, and 7.638×10^{-20} m^2/W, respectively. The transmittance of the sample (15.2 mm thick) is up to 85% in the range from 400 to 1500 nm. It is known that the lower transmittance is mainly due to Nd^{3+} and Pr^{3+} impurities in the raw material Tb_4O_7 by optical absorption analysis.

I. INTRODUCTION

The transparent range for visible and near infrared light Faraday rotation glasses, among which the Hoya FR-5 glass is the most famous, has attracted the attention of scientists and engineers for a long time. As a paramagnetic material, Faraday rotation glass has the disadvantage of a small Verdet constant.[1] Hoya Optics Inc. has developed FR-6 glass with better characteristics than FR-5,[2] but the details are not available to the author. A new Faraday rotation glass, known as the terbium glass with a Verdet constant (632.8 nm, room temperature) as large as −0.338 min/Oe cm, 38% larger than that of the FR-5 glass, has been made in this laboratory. In this glass a high concentration of terbium ions (Tb^{3+} 10.4 at. %) is doped into the boron-silicate matrices with BaF_2 and PbO_2 as flux in the melt at a temperature of about 1500 °C. Another two samples with different doping concentrations of terbium and dysprosium ions (Tb^{3+} 8.4 at. % and Dy^{3+} 7.2 at. %, respectively) were also made in the process. These three samples are known as samples I, II, and III. The light wavelength and temperature dependencies of the Verdet constants of the samples are measured to fit into a single ion theoretical model[3] above 100 K. The temperature dependencies of the magnetization and the magnetic susceptibilities of samples I and II measured from 1.5 to 300 K and from 0.2 to 5.0 T show the existence of superparamagnetic clusters with antiferromagnetic structure.[4]

The indices and Abel number of sample I are, respectively, larger and smaller than those of FR-5. The nonlinear index coefficient of sample I is smaller than that of TbAlG. The optical absorptivity of sample I at 632.8 nm is larger than that of FR-5. Optical absorption spectrum analysis for sample I may indicate that the impurity neodymium and praseodymium ions in raw material Tb_4O_7 cause the larger absorptivity.

II. EXPERIMENTS

According to Crossley,[3] the Verdet constant V can be written as

$$1/V=\lambda^2/C-\lambda_0^2/C, \tag{1}$$

where λ is the light wavelength, λ_0 is the resonance wavelength, and $C\propto T$ is a constant for a certain temperature. At first, the temperature was set to 303 K, the Verdet constants of samples I, II, and III were measured with a light wavelength scanned from 400 to 800 nm because of the probe limit. Second, for sample I, the temperature was set to 208 and 173 K and the wavelength was scanned again from 400 to 800 nm; the magnetic field was 0.22 T for all of the measurements. Experimental data are fit to Eq. (1) by least-squares as shown in Fig. 1. The numbers 1, 2, 3, 4, and 5 in the figure indicate samples III, II, and I at 303 K, and sample I at 208 and 173 K, respectively. The resonance wavelength λ_0 for terbium ions in samples I and II are calculated from

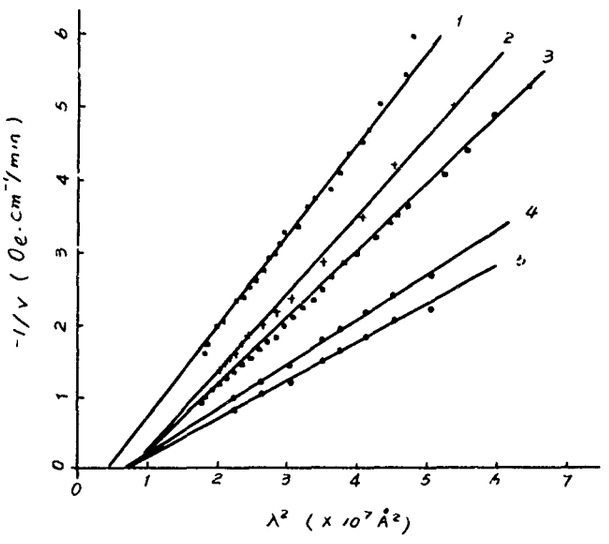

FIG. 1. The wavelength dependencies of the Verdet constants of samples I, II, and III. The numbers at the lines 1, 2, 3, 4, and 5 indicate data for samples III, II, and I at temperature 303 K and for sample I at 208 and 173 K. The applied magnetic fields are all 0.2 T.

 0021-8979/94/75(10)/6375/3/$6.00 © 1994 American Institute of Physics

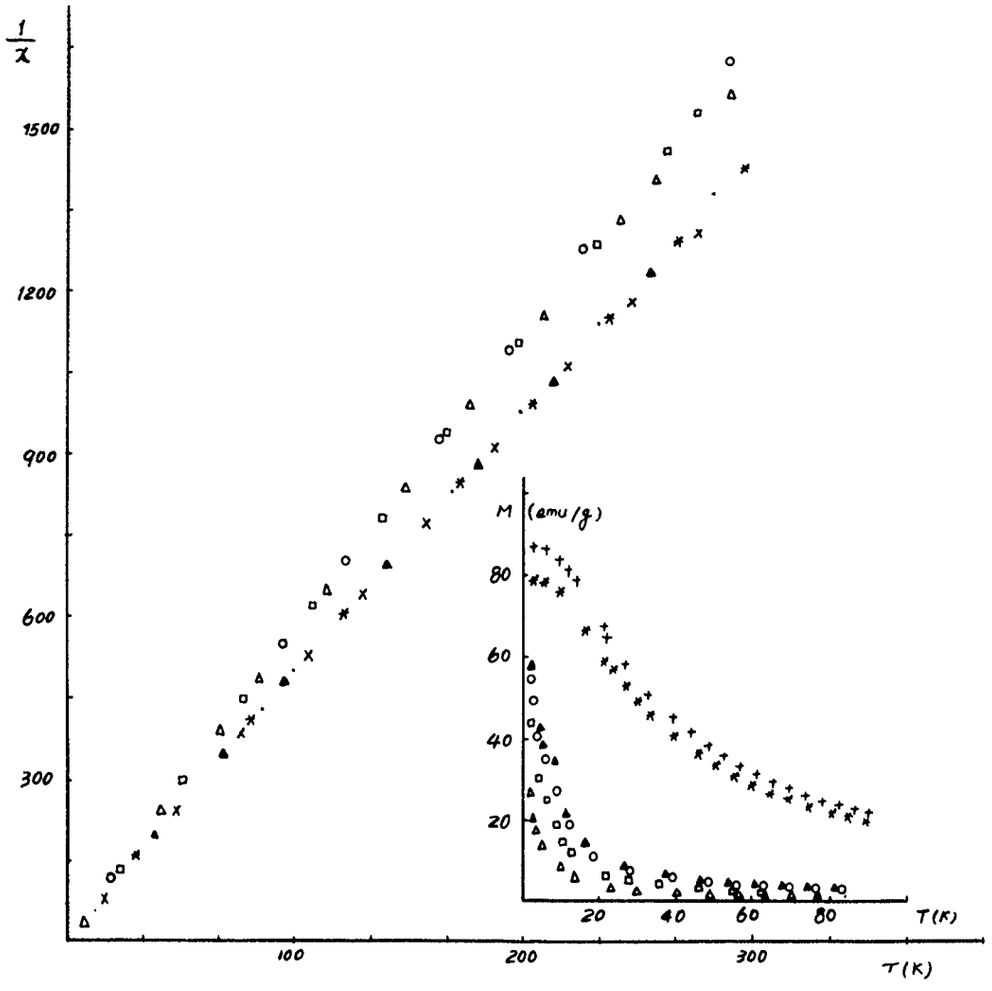

FIG. 2. The temperature dependencies of the magnetic susceptibilities of samples I and II. The upper line is for sample I and the lower sample II. The symbols △ and × are for the applied magnetic field 0.2 T, □ and ∗ for 0.4 T; and ○ and ▲ for 0.6 T. The insert shows the temperature dependencies of the magnetization of samples I (upper) and II (lower). The symbols † and ∗ are for the applied magnetic field 5.0 T; ▲ and ○ for 0.6 T; and □ and △ for 0.4 and 0.2 T, respectively

the slope and intersection of the lines 2, 3, 4, and 5 to be in the range from 258.6 to 280.0 nm with 267.6 nm as an average. This is very close to λ_0=268.0 nm for a terbium ion in TbAlG.[5] The resonance wavelength λ_0 for the dysprosium ion in sample III is calculated from line 1 as 223.1 nm which is also close to λ_0=220.5 nm for the dysprosium ion in DyAlG.[5] The temperature dependence of the Verdet constant of sample I was measured from 100 to 300 K to give a paramagnetic result, $1/V \propto T$. However, the hysteresis of sample I measured at 77 K is 2.5 times wider than that at 282 K. The susceptibility and magnetization of sample I were measured with a vibrating-sample magnetometer (VSM) at temperatures from 1.5 to 300 K and at applied magnetic fields from 0.2 to 5.0 T. As shown by the upper curves in Fig. 2, the magnetization at high applied magnetic fields approaches saturation at low temperature while the susceptibility curves give a negative intercept θ of about -9 K.

Using the measured density of the terbium glass and the atomic concentration of Tb^{3+} ions in the glass, the concentration of Tb^{3+} ions N is calculated to be $1.08 \times 10^{22}/cm^3$. The effective Bohr magneton number can be calculated for sample I using the value of N and the slope of the upper line in Fig. 2. The value is 9.01 μ_B which is about 7% smaller than the value for the free Tb^{3+} ion. From the insert in Fig. 2, the magnetic moment per volume of sample I below 5 K is 433.87 emu/cm^3. The averaged effective Bohr magneton number for each Tb^{3+} ion is thus 4.33 μ_B which is 55% smaller than the free ion value.

The conventional optical parameters, of sample I, such as transmittance and index are measured with a Lambda-9 spectrophotometer. For measuring the index the sample was processed into a prism. The transmittance is up to 85% within the range between 400 and 1500 nm as shown in Fig. 3, the insert is the transit spectrum of FR-5.[6] The indices for standard spectrum lines are 1.745 92 (N_c) 1.749 84 (N_D), and 1.760 31 (N_F), which are about 4% larger than those of FR-5 glass.[7] The Abel number is 49.92 while the Abel number of FR-5 is 53.49.[7] For comparison with the absorptivity, 0.0597 cm^{-1} of FR-5 at 632.8 nm,[6,7] the index of sample I at 632.8 nm was particularly measured to be 1.746 70 and the absorptivity of the sample is calculated to be 0.0948 cm^{-1} according to the equation

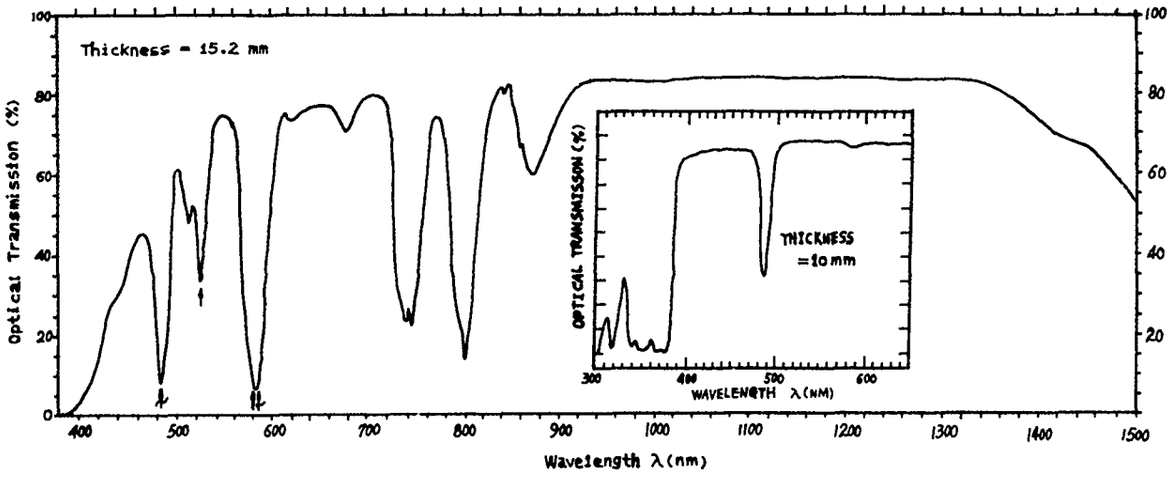

FIG. 3. The optical transmission spectrum of sample I. The insert is the optical transmission spectrum of FR-5 glass, courtesy of P. E. Sanders, SPIE **566**, 317 (1985) (Fiber Optic and Laser Sensors III).

$$\eta=(1-r)^2e^{-\alpha l}, \tag{2}$$

where η is the transmittance, $r=(N_{632.8}-1)^2/(N_{632.8}+1)^2$ for normal incidence, α is the absoptivity, and $l=15.2$ mm is the thickness of the sample. The nonlinear index coefficient of sample I is calculated according to the equation[8]

$$N_2=K\frac{(N_D-1)(N_D^2+2)^2}{\nu[1.517+(N_D^2+2)(N_D+1)N_D\nu/6]^{1/2}}\times\frac{10^{-6}}{2.39}, \tag{3}$$

where N_2 is the nonlinear index coefficient, v is the Abel number, N_D is the index at 589.6 nm, and K is a constant assumed as 68. The value of N_2 is 7.638×10^{-20} m^2/W which is a little smaller than that of TbAlG, 8.6×10^{-20} m^2/W.[9]

III. DISCUSSION

Being different from the magnetic structure of FR-5, which is paramagnetic in the whole temperature range,[9] the terbium glass made in our laboratory has a paramagnetic structure above 100 K and a superparamagnetic structure[10] below 60 K. Like the formation of clusters composed of oxygen and gadolinium ions in germanite IR glasses,[10] oxygen and terbium ions may form clusters in the terbium glass. The bigger absolute value of Neél temperature $T_{N,9\ K}$, for sample I of higher Tb^{3+} concentration 10.4 at. % than that, 6 K, for sample II of Tb^{3+} concentration 8.4 at. % may indicate a stronger magnetic interaction in sample I. The single ion anisotropy of the non-S-state Tb^{3+} ions in the disordered cluster at low temperatures may give rise to the value of the magnetic moment per Tb^{3+} ion as half of the free ion value in an applied magnetic field. Further measurements of the susceptibilities and magnetization of the samples with several different Tb^{3+} concentrations are being conducted to give the details.

The temperature dependence of the Verdet constant follows that of the susceptibility above 100 K. This fits to the single ion model.[3] Further effort should be made to extend the temperature to 1.5 K in the measurement.

As seen in Fig. 3, three absorption peaks can be assigned to Nd^{3+} and Pr^{3+} ions.[11] The raw material Tb_4O_7 used in the process is of engineering purity only. It is considered that the higher absorptivity of the terbium glass is mainly due to the existence of the impurity ions Nd^{3+} and Pr^{3+} in the raw material Tb_4O_7.

To support the model of the oxygen–terbium clusters microscopically, electron paramagnetic resonance (EPR) and Mössbauer studies are being conducted on the samples.

IV. CONCLUSIONS

Tb^{3+} ions may aggregate in combination with O^{2-} ions to form fine superparamagnetic clusters in Tb^{3+} heavily doped boron–silicate glasses. Simply increasing the concentration of Tb^{3+} in the glass may not result in a larger Verdet constant. Nevertheless, Tb^{3+} heavily doped glass may be useful in the study of superparamagnetism.

High quality $L_{2,3}$ edges magnetic circular dichroism (MCD) data of *in situ* grown Fe, Co, and Ni ferromagnetic thin films were measured using transmission x-ray absorption technique. These data were utilized to investigate the validity of the recently proposed x-ray MCD sum-rules that offer a new means for deducing orbital- and spin-magnetic moments from MCD data.[1,2] We find that the orbital to spin magnetic moment ratios of Fe, Co, and Ni deduced from MCD data according to the sum-rules are at ±30% discrepancy with those deduced from neutron scattering data. This inconsistency may be attributed to the neglecting of multi-electron excitations and band structure effects in the derivation of the sum-rules or due to uncertainties in the neutron scattering results. Caveats for MCD data taken with the fluorescence yield x-ray absorption technique will also be discussed.

Linearity and hysteresis in the magnetoresistive response of (NiFe,NiFeCo)/Cu and Co/Cu/NiFe multilayers in patterned stripes

K. Noguchi, S. Araki, T. Chou, D. Miyauchi, Y. Honda, A. Kamijima, Ø. Shinoura, and Y. Narumiya
R&D Center, TDK Corporation, 2-15-7 Higashi Owada, Ichikawa, Chiba, 272, Japan

The linearity and hysteresis in the magnetoresistive (MR) response of NiFe/Cu and NiFeCo/Cu multilayers prepared by ion beam sputtering, and Cu/Co/Cu/NiFe multilayers prepared by MBE are investigated. These characteristics in the linear regions for the second peak of antiferromagnetically coupled NiFe/Cu multilayers are almost the same as those of NiFeCo/Cu ones at 50-Hz ac applied fields. The MR amplitude at the first peak is inferior to that at the second one, whereas, the linearity and hysteresis are superior. In weakly coupled Cu/Co/Cu/NiFe multilayers, a nonhysteretic MR response is obtained at a NiFe layer thickness of 10 Å. The linearity and symmetry around the zero magnetic field of the MR curve depend on the Cu layer thickness. When the thicknesses of the NiFe and Cu layers are 10 and 45 Å, respectively, good linearity and no hysteresis are observed without biasing techniques. The output levels in the linear regions of three different multilayers are 1.5–2.5 times as large as that of the conventional Permalloy film. These multilayers are promising materials for the fabrication of MR head for ultrahigh density recording.

I. INTRODUCTION

Since the discovery of the giant magnetoresistance effect (GMR) in Fe/Cr multilayers,[1] a large number of studies have been made on the GMR effect in multilayers.[2–5] GMR effect is attracting great interest for magnetoresistive read (MR) heads. MR heads require large resistance changes in low excitation fields. In addition, good linearity and no hysteresis of the MR curve are required to prevent distortion in the output signal wave form. Antiferromagnetically (AF) coupled NiFe/Cu and NiFeCo/Cu multilayers, which contain magnetically soft magnetic layers, exhibit MR ratio of 8%–12% with a saturation field of about 100 Oe.[5,6] On the other hand, MR ratio of 7% has been obtained in weakly coupled Cu/Co/Cu/NiFe multilayers for fields changes of 100 Oe.[7] However, the linearity and hysteresis in the MR curves have not been reported in these multilayers. In this paper we report the linearity, hysteresis and MR amplitude both with dc and ac applied fields at 50 Hz in three different multilayers, NiFe/Cu, NiFeCo/Cu, and Cu/Co/Cu/NiFe, and compare the results with the anisotropic magnetoresistance (AMR) of conventional Permalloy film.

II. EXPERIMENTAL DETAILS

NiFe/Cu and NiFeCo/Cu multilayers were prepared by ion beam sputtering, using $Ni_{82}Fe_{18}$, $Ni_{66}Fe_{16}Co_{18}$, and Cu targets. The films were deposited in an argon pressure of 1.5×10^{-4} Torr at R.T. with a magnetic field of 60 Oe in the film plane. The acceleration voltage of ion gun was 300 V with an ion current of 30 mA. Cu/Co/Cu/NiFe multilayers were prepared by successively depositing Cu, Co, Cu, and $Ni_{82}Fe_{18}$ at R.T. by evaporation in ultrahigh vacuum in a MBE system. The base pressure was below 2×10^{-10} Torr, and the pressure during deposition was maintained at the order of 10^{-9} Torr. NiFeNb or Ta buffer layers (50 Å thick) were first grown on glass substrates in the IBS system and Cr buffer layers (50 Å thick) in the MBE. The deposition rates were controlled at 0.2–0.4 Å/s in both cases. The thicknesses of the NiFe, NiFeCo, and Co layers were varied between 10–15 Å and that of the Cu layers between 10–50 Å in all three multilayers. The periods and structures of the multilayers were investigated by measuring low angle x-ray diffraction. The magnetic properties for the films were investigated using a vibrating sample magnetometer. The MR properties with dc applied fields were measured using a standard four-terminal method on specimen with a stripe of 0.5×10 mm^2. The MR ratio is defined as $\Delta\rho/\rho_s$, where the ρ_s is the resistivity at the saturation magnetic field and the $\Delta\rho$ is the resistivity change. The specimens for ac MR measurements were formed into stripes with dimensions $3–7\times150$ μm^2 by photolithography. Au films were deposited on the top of the stripe as conductors by vacuum evaporation to make the track width of 4.5 μm. The magnetic field was applied in the direction of the width of the stripes in both dc and ac cases. The MR response curve with ac applied fields was measured at 50 Hz, and the sense current was 15 mA. The magnetic domain walls were observed by a magneto-optical Kerr effect apparatus.

III. RESULTS AND DISCUSSION

A. NiFe/Cu and NiFeCo/Cu multilayers

The changes of MR ratio on varying Cu layer thickness were investigated in NiFe/Cu and NiFeCo/Cu multilayers. Here, each magnetic layer thickness is fixed at 15 Å. The multilayers have 20 bilayers of NiFe or NiFeCo and Cu. The

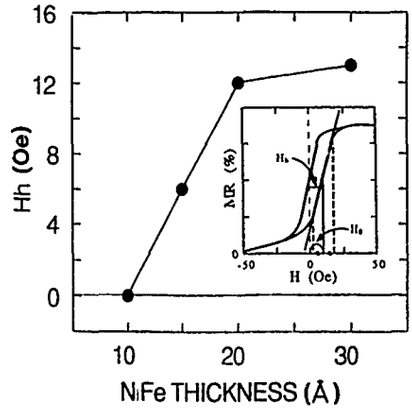

FIG. 2. The H_h values with dc applied fields on varying NiFe layer thickness for Cr(50 Å)/[Cu(50 Å)/Co(10 Å)/Cu(50 Å)/NiFe(x Å)]$_{10}$. Inset shows schematic diagram of the H_h and H_0 values in the minor loop of the MR profile.

well-defined oscillations in the changes of the MR ratio are confirmed in both multilayers.[5,6] The peaks of the MR ratio are observed at the Cu layer thicknesses of 9 and 20 Å. At the first peak (t_{Cu}=9 Å), an MR ratio of 12.3% for NiFe/Cu and 16.6% for NiFeCo/Cu multilayers are obtained. At the second peak (t_{Cu}=20 Å), the MR ratios of 6.4% and 9.1% are obtained, respectively.

The MR response curves for three samples of (a) [Cu(9 Å)/NiFe(15 Å)]$_{20}$/Cu(9 Å), (b) [Cu(20 Å)/NiFe(15 Å)]$_{20}$/Cu(20 Å) and (c) [Cu(20 Å)/NiFeCo(15 Å)]$_{20}$/Cu(20 Å) with 50-Å-thick NiFeNb buffer layers are shown in Fig. 1. Data are shown for the 7×150 μm^2 stripe with the applied fields of ±300 and ±50 Oe. In order to investigate the characteristics in the linear regions, a dc biasing field of about 30 Oe is applied for the low field measurement by a permanent magnet. To evaluate the linearity, hysteresis and the MR amplitude, we define the following values of the MR response: the overall MR amplitude with ±300 Oe V_{max}, the MR amplitude with ±50 Oe V_L, the remanent MR amplitude at zero applied field with ±50 Oe ΔV, hysteresis of the MR response with ±50 Oe ΔH, as indicated in Fig. 1. Therefore, we define here the linearity as $L=(V_L-\Delta V)/V_L$. The linearity becomes better when the L value is close to 1. The V_{max} value is 4.5 mV for sample (a), 3.2 mV for (b) and 4.3 mV for (c), and the V_L value is 1.59, 1.89, and 1.85 mV, respectively. The V_{max} for sample (c) is 1.5 times as large as that for (b). These values are in good agreement with the MR ratio, because the MR ratio of NiFeCo/Cu multilatyers is 1.4 times as large as that of NiFe/Cu ones. However, the V_L values are almost the same. This indicates that these multilayers have the same field sensitivity in the linear regions of the MR response. In addition, the L and ΔH values are also the same in both sample (b) and (c), as shown in Fig. 1. There is no significant difference in the characteristics in the linear regions between NiFe/Cu and NiFeCo/Cu multilayers. On the other hand, a linear and nonhysteretic MR response is observed in sample (a). In paticular, the ΔH value for sample (a) is smaller than that for (b). Obviously, hysteresis at the second peak is larger than that at the first peak. From domain wall observations on the specimen at the second peak, Ta(50 Å)/[Cu(t Å)/NiFeCo(30 Å)]$_2$(t_{Cu}=20), domain walls nucleate and move on the specimen with changing external fields, which are applied perpendicular to the stripe axis. The observed domain walls move irregularly, not perpendicular to the stripe axis. On the contrary, the domain walls are not observed on the specimen at the first peak (t_{Cu}=9). This proves that domain wall displacement exists at the second peak. S. Zhang *et al.* gave a interpretation that the multilayers except for the first peak are not completely AF coupled.[8] It is considered that ferromagnetically aligned layers locally exist at the second peak. Our results support their picture. Magnetization reversal of ferromagnetically aligned layers is caused by domain wall displacement. Consequently, the MR response with larger hysteresis are observed at the second peak.

To compare the MR responses of these murltilayers with the AMR response of a Permalloy film, a trilayered MR element, consisting of an amorphous CoZrMo film as a soft adjacent layer, a Ta film as a magnetic separation layer, and a 300-Å-thick Permalloy film as a MR layer were prepared by ion beam sputtering. This film has an output level of 1.0 mV with an applied field of ±50 Oe for the same specimen size. As a result, the output levels in the linear regions for the above multilayers obtained are 1.5–2 times as large as that of the Permalloy film.

B. Cu/Co/Cu/NiFe multilayers

MR properties of weakly coupled [Cu(x Å)/Co(y Å)/Cu(x Å)/NiFe(z Å)]$_{10}$ multilayers on varying each layer thickness were investigated. In order to evaluate the symmetry and hysteresis in the MR curve, we define the center field of the linear region and the width of the MR minor loop as

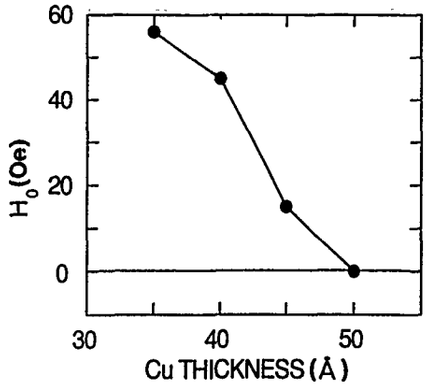

FIG. 3. The H_0 values with dc applied fields on varying Cu layer thickness for Cr(50 Å)/[Cu(x Å)/Co(10 Å)/Cu(x Å)/NiFe(10 Å)]$_{10}$.

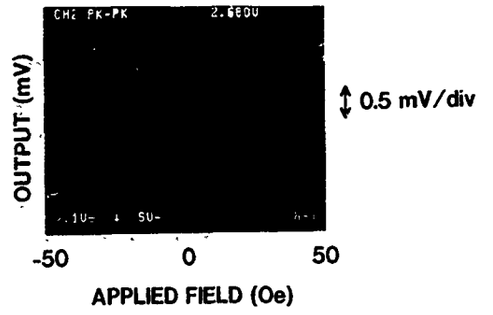

FIG. 4. MR response with a 50 Hz ac applied fields of ±50 Oe for Cr(50 Å)/[Cu(45 Å)/Co(10 Å)/Cu(45 Å)/NiFe(10 Å)]$_{10}$.

H_0 and H_h, respectively, as indicated schematically in Fig. 2. From the technological point of view, the H_0 of zero and the H_h of zero are desirable to get a symmetric signal wave form without distortion.

Figure 2 shows the H_h values with dc applied fields on varying NiFe layer thickness, in these cases the Cu and Co thicknesses are fixed to be 50 and 10 Å, respectively. In weakly coupled Cu/Co/Cu/NiFe multilayers, the MR profile at around zero field is determined by the reversal of the magnetization of the NiFe layer. Therefore, the most effective parameter of the H_h value is the coercive force (H_c) of NiFe layer. The H_c of the NiFe layer decreases as the NiFe layer thickness decreases. For example, 10 Oe for [NiFe(20 Å)/Cu(50 Å)]$_{10}$ and 7 Oe for [NiFe(10 Å)/Cu(50 Å)]$_{20}$. The H_h values decreases with decreasing NiFe layer thickness and reaches zero at a NiFe layer thickness of 10 Å. This is in agreement with the tendency of the H_c of NiFe layers in NiFe/Cu multilayers. However, the H_c of 10-Å-thick NiFe layer is not zero. Therefore, another explanation for the H_h of zero should be considered. One reason would be a little reversal of the magnetization of the Co layers. The remanent magnetization of the Co layers was about 74% of saturated magnetization for [Co(10 Å)/Cu(50 Å)]$_{20}$. Some part of Co spins rotate at zero field, and this rotation would play a role for the H_h of zero. Figure 3 shows the H_0 values with dc applied fields on varying Cu layer thickness, in these cases the NiFe and Co thicknesses are fixed to be 10 Å. The H_0 decreases as the Cu layer increases, and becomes zero at a Cu layer thickness of 50 Å. When the Cu layer thickness is large enough, the magnetic interaction between NiFe and Co layers is negligible. However, the ferromagnetic interaction increases with decreasing Cu layer thickness. As a result, the magnetic moment of the NiFe layer cannot rotate independently of the Co layer. Therefore, the magnetization reversal of the NiFe layer begins at larger applied field and H_0 increases with decreasing Cu layer thickness.

The MR response with ac applied fields for (x,y,z) $=(50,10,10)$ of 3×150-μm^2 stripe exhibits zero hysteresis. However, the center field of the linear region is -20 Oe, not zero. The demagnetizing field (H_d) for the ac mesurement cannot be negligible because of the narrow stripe (3×150 μm^2). Thus the effective external field is shifted by about H_d, so that H_0 shifts toward the negative direction. Figure 4 shows the MR response curve with ac applied fields of ±50 Oe for $(x,y,z)=(45,10,10)$ of the 3×150-μm^2 stripe, which is the H_0 of about 20 Oe in the dc fields with 0.5×10 mm^2 stripe. The output level with ±50 Oe is 2.7 mV. That is roughly two and a half times as large as that of the conventional Permalloy film, which shows an output level of 1.2 mV for the same size of the specimen. A large and symmetric MR response with no hysteresis is realized in our Cu/Co/Cu/NiFe multilayers.

Microstructural origin of giant magnetoresistance in a new sensor structure based on NiFe/Ag discontinuous multilayer thin films

M. A. Parker, T. L. Hylton, K. R. Coffey, and J. K. Howard
IBM Fellow Program, IBM Storage Systems Division, 5600 Cottle Rd., San Jose, California 95193

The origin of giant magnetoresistance (GMR) in a new sensor structure incorporating discontinuous multilayers (DML) of NiFe thin films separated by Ag interlayers is elucidated by means of x-ray diffraction, x-ray reflectivity, and cross-section transmission electron microscopy. It is shown that the observed magnetoresistance, ~4%–6% in fields on the order of 5–10 Oe at 25 °C, is associated with the breakup upon annealing of the initially dense, columnar superlattice structure into discontinuous multilayers of NiFe due to highly mobile Ag forming Ag bridges between the Ag layers. This observation supports a micromagnetic model for these structures that is based on the concept of initially large ferromagnetic domains in the as-deposited NiFe structure, exhibiting negligible GMR, breaking up into discontinuous layers, exhibiting an appreciable GMR, with antiferromagnetic ordering across the Ag interlayers.

Giant magnetoresistance (GMR) in multilayer systems is by now a well-known effect.[1–4] The application of this effect to magnetic read-head technology, as the so-called "spin-valve," has also been well documented.[4] More recently, the appearance of GMR in nonmultilayer systems of granular magnetic particles in a nonmagnetic, immiscible matrix, which one might call granular GMR (GGMR or G^2MR),[5–8] has been discovered, leading many to speculate on its application to head technology, as well. In this paper, we demonstrate how to overcome the limited sensitivity of G^2MR structures[9] through a novel sensor structure[10] incorporating characteristics of both multilayer GMR and G^2MR in "discontinuous" multilayers (DMLs). We have previously speculated on how the low field sensitivity[10] is achieved due to reduced shape anisotropy in DML as compared with G^2MR, and better control of the interlayer coupling in DML, as compared with continuous multilayers (CMLs). We believe that this is a consequence of magnetostatically induced antiferromagnetic order in DMLs caused by the layer discontinuities, which distinguish these structures from their CML counterparts,[11] which are dominated by exchange coupling between layers. Here, we present microstructural evidence confirming the existence of these discontinuities. In addition, we demonstrate that this is a result of the high mobility of the interlayer, nonmagnetic species, Ag, migrating into the magnetic permalloy multilayers, most probably at grain boundaries in the columnar structure.

The structures consisted of the following nominal multilayer stack: Ta (100 Å)/Ag(y/2)/[NiFe(x)/Ag(y)]$_4$/NiFe(x)/Ag(y/2)/Ta(40 Å), where y was approximately 40 Å, and x, 20 Å, deposited on approximately 1000 Å of SiO_2 on Si. They were prepared by S-gun magnetron sputtering in a 4% H_2/Ar mixture at a pressure of 3 mTorr at ambient temperature. The composition of the NiFe target was nominally that of low magnetostrictive permalloy, i.e., $Ni_{81}Fe_{19}$. A ~150 Oe magnetic field was applied during deposition to give a weak uniaxial anisotropy field of ~3 Oe. The samples were broken into strips 8 mm×1.5 mm and annealed at 1 atm in 5% H_2/Ar in a rapid thermal annealer (RTA) at 305 °C, 315 °C, 325 °C, 335 °C, 345 °C, 365 °C, and 395 °C for 10 min, respectively. Magnetoresistance measurements were made at room temperature with an in-line, four-point probe geometry with the magnetic field applied perpendicular to the direction of current flow, but in-plane and along the easy axis of the sample.

X-ray diffraction scans were obtained with a D-Max 1000 system equipped with a rotating anode source in the conventional θ–2θ reflection geometry. X-ray reflectometry curves were obtained with a GIXR x-ray reflectometer in the specular scattering geometry. Cross-section TEM (XTEM) samples were prepared using conventional methods;[12] special precautions were taken during ion milling: a LN_2 cold stage was employed to preclude annealing; and a specially designed holder was used to blank the beam when incident from the film side of the sample, and to allow milling at a 5° angle of incidence to enhance uniformity. Images were taken in both bright field (BF) and dark field (DF) imaging conditions on a 4000FX with especially small apertures to allow the resolution of the superlattice reflections, giving rise to contrast from the individual NiFe and Ag layers. Care was taken to align the sample along the Si zone axis, to assure that interfaces between the multilayers were aligned approximately parallel to the beam during imaging.

Table I shows the results of annealing the multilayers in the RTA. It is significant that the as-deposited structures exhibit no GMR, although a small anisotropic magnetoresistance (AMR) was measured. Upon annealing, significant GMR develops in these structures; the highest value being >5% for the 335 °C anneal. Note, however, that the highest

TABLE I. Measured values of the magnetoresistance in NiFe/Ag multilayers as a function of annealing temperature.

Temperature	$\Delta R/R$ (%)	FWHM (Oe)	Sensitivity (%/Oe)
As-deposited	0.22	36.3	0.006
305 °C	2.33	6.2	0.370
315 °C	4.06	5.1	0.790
325 °C	4.95	12.6	0.390

sensitivity, i.e., $\%\Delta R/R$ per FWHM of applied field, the relevant figure of merit for a head sensor, was obtained for the 315 °C anneal with a value of 0.8%/Oe. It is also worth noting that for progressively higher temperature anneals beyond the optimum of 315 °C, the FWHM of the peak increases; also, the absolute magnitude of GMR begins to decrease.

Figure 1 shows the results of the θ–2θ diffraction scans. The strong 111-type superlattice reflections of Ag and NiFe clearly indicate that these samples have a strong ⟨111⟩ fiber-axis texture. The spacing of the peaks in the as-deposited sample indicates a ~70 Å superlattice period. Upon annealing, it is apparent that the two dominant Ag peaks begin to shift position, while the peaks associated with NiFe remain relatively unaffected. The effect on the Ag peaks is even more pronounced when examining the Ag (222) reflections, which change from a clearly split peak in the as-deposited structure to a single broad peak near the position for the equilibrium lattice parameter of Ag for the sample annealed at 395 °C. These changes in the Ag peaks with annealing are consistent with the deterioration of the continuity of layers in the superlattice structure, and the formation of agglomerations of Ag, having the equilibrium lattice parameter within the structure. Since this occurs primarily with the Ag peaks and not the NiFe peaks, it is apparent that the deterioration is not equivalent for both the Ag and NiFe layers. This is consistent with the TEM results presented below. Thus, the Ag peaks are a complex mixture of nearly bulk-like scattering from regions of the film, where the Ag bridges across two or more NiFe layers in agglomerations, and scattering from the remnants of the initial Ag layers that are separated by the NiFe layers in the remaining superlattice structure. Since the displaced NiFe rather than bridging across the Ag tends to agglomerate on the initial NiFe layers, the spacing of the NiFe reflections tends to preserve that of the initially continuous multilayer structure, which is confirmed by the cross-section TEM.

The most likely way this might occur is by grain boundary migration of the Ag. Modeling of these changes based on the concept of superlattice period is problematic because this is fundamentally a new class of structure, a "discontinuous" multilayer (DML), for which no x-ray diffraction models have been published. Nevertheless, by way of analogy with continuous multilayers, one might define a "pseudosuperlattice period" based on the position of the two dominant Ag peaks. Preliminary analysis based on this purely phenomenological parameter showed that it changed linearly with annealing time, so that an Arrhenius analysis of the change in this parameter as a function of temperature could be performed; the activation energy was found to be 1.30±.07 eV, which is close to values published for the grain boundary diffusion of Ag.[13] However, this is not the same as identifying the mechanism with grain boundary diffusion; as in the case of Ag/Ni,[14] it is likely that strain, as well as interfacial energies, provide a significant driving force for Ag migration. These observations are consistent with our earlier work[8] on codeposited metastable NiFeAg alloys, which, upon annealing, produced large precipitate agglomerations of Ag, strong evidence for the high mobility of Ag in this system at these annealing temperatures.

Figure 2 shows the results of the GIX scans on these samples. The intensity of the higher angle Bragg peaks is reduced upon annealing, which is characteristic of "roughening" of the interfaces.[15] However, as the TEM data will show below, this was not the simple interfacial "roughening" that is often seen during the annealing of superlattices, but is undoubtedly affected by the formation of Ag intrusions into the NiFe layer, as well. Due to the mutual insolubility and immiscibility of Ag with NiFe, it is problematic to use the term "intermixing" for this effect.

The XTEM micrographs of Fig. 3 show definitive micro-

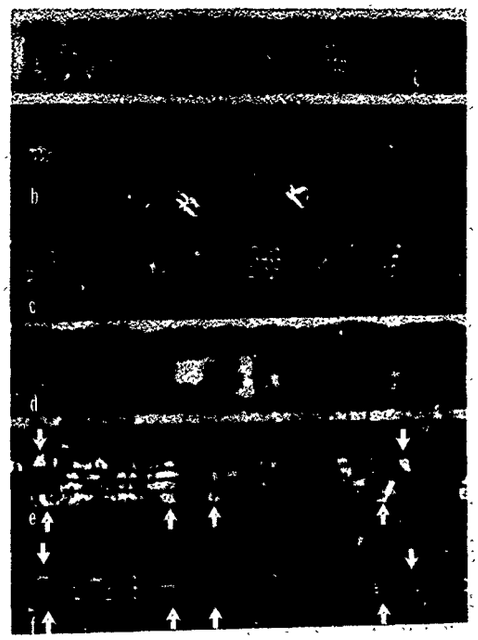

FIG. 3. Cross-section TEM micrographs of the as-deposited NiFe/Ag multilayer and the sample annealed at 395 °C for 10 mins. Legend: micrographs of the as-deposited structure (a) in BF, (b) in DF using the Ag 111* reflection, and (c) in DF using the NiFe 111* reflection; and micrographs of the post-annealed structure (d) in BF, (e) in DF using the Ag 111* reflection, and (f) in DF using the NiFe 111* reflection. "Ag-bridges" (arrowed in e) are apparent in the post-annealed structure, as are the corresponding "NiFe gaps" (arrowed in f).

structural evidence in support of the interpretation of the previous x-ray data. Figure 3(a) is a BF micrograph of the as-deposited structure; the overall thickness of the film is ~552 Å. Note that the interface with the substrate is rather smooth, but that the upper layer has what appears to be a relatively "rough" oxide on the Ta layer, ~10 Å peak to valley. The roughness of the interfaces of the intervening layers is somewhere in between these two values. Streaks are present in the image that cross the layers transversely, indicative of a columnar structure, as reported for other multilayers.[16] Figure 3(b) is a DF micrograph of the as-deposited structure obtained with the Ag superlattice reflections. Columnar stacks of silver layers are clearly in evidence at the location of the previously identified streaks. The edges of these stacks are located where the film changes crystallographic orientation, and thus are most likely grain boundaries. It is clear that even though the layers are rather rough, there are no locations where a Ag layer "bridges" across the NiFe layer to make contact with an adjacent Ag layer, i.e., the layers are well separated. The DF image of the NiFe layer [see Fig. 3(c)] likewise shows well-delimited columns, and well-separated layers. The BF image of the post-annealed sample (at 395 °C) is shown in Fig. 3(d). The DF image using the Ag superlattice reflections [see Fig. 3(e)] shows "Ag bridges" across the NiFe layers [the arrow in Fig. 3(e)]. Although "Ag bridges" were seen in structures annealed at lower temperatures, the sample annealed at 395 °C much more dramatically shows this effect. The "Ag bridges" give rise to regions where the Ag layer thickness is in excess of two times its initial value. Figure 3(f) shows that the excess intensity in the Ag DF image is complemented by a lack of intensity in the NiFe DF image at the location of "Ag bridges," indicating that "NiFe gaps" have formed, where NiFe has been displaced by Ag.

In conclusion, clear structural evidence has been presented for the attendant breakup of the NiFe layer with a concomitant appearance in GMR upon annealing. It is a reasonable inference that the formation of such discontinuous multilayers should give rise to corresponding micromagnetic changes. Magnetostatic coupling between layers in these DMLs may well give rise to the hypothesized antiferromagnetically ordered structure, accounting for the observed GMR increases.[10,17]

Micromagnetics of GMR spin-valve heads

Samuel W. Yuan
Applied Magnetics Corporation, 75 Robin Hill Road, Goleta, California 93117

H. Neal Bertram
CMRR, University of California at San Diego, La Jolla, California 92093-0401

Three-dimensional micromagnetic modeling of shielded giant magnetoresistive heads with a spin-valve sensor is presented. If the pinning field from the exchange layer is not large enough, partial unsaturation of the pinned layer occurs upon excitation from the medium, which may cause down-track output noise. Increasing the pinning strength diminishes the playback instability, however, a larger sensor height is then desirable for the ease of proper biasing, but at the expense of on-track signal level. The free layer magnetization is nominally horizontal, reducing off-track asymmetry compared to heads with smaller sensor height.

I. INTRODUCTION

The spin-valve structure exhibits giant magnetoresistance (GMR)[1] and is an ideal candidate for high density MR reproduce sensors. When placed within two soft ferromagnetic shields, such a GMR head yields significantly larger signals and sensitivities compared to conventional MR heads that utilize the anisotropic magnetoresistance effect. Recently, an unshielded spin-valve sensor was demonstrated, and its operation in a shielded environment was predicted by a two-dimensional model.[2] A three-dimensional micromagnetic model[3,4] is presented here to characterize the performance and optimization criteria of such a shielded spin-valve head. Narrow gap and read track-width are assumed in this work to assess head response in ultrahigh density recording applications. Proper biasing, as well as down-track and off-track responses are simulated by the model, and design issues on final heads are addressed.

II. MODELING SCHEME

A generic spin-valve structure consists of two ferromagnetic transition metal or alloy layers separated by a nonmagnetic noble metal layer, with one of the magnetic films pinned by an adjacent exchange film. A nominal structure of NiFe (100 Å)/Cu (30 Å)/NiFe (70 Å)/AF (e.g., FeMn) is chosen in this work. A giant magnetoresistance ratio $\Delta R/R = 6\%$, and a small ferromagnetic interlayer coupling field of 10–20 Oe between the two ferromagnetic permalloy films[5] are assumed. A schematic of the head structure is shown in Fig. 1 (the shields are not shown). Outside the track-width defining region, the current is assumed to flow horizontally only in the current leads; in the active region, the current density is distributed only in the NiFe/Cu/NiFe sandwich, mostly in the Cu spacer layer, since the resistivity of the FeMn layer is typically much higher.[6] A detailed calculation of the current distribution for such a thin multilayer system can be carried out using semiclassical electro-transport theory.[7] The spin-valve magnetoresistance is proportional to the cosine of the relative angle $\Delta\theta$ between the magnetizations of the two magnetic films,[5] therefore the output response can be expressed as follows:

$$V = I\left(\frac{\Delta R}{R}\right) R_S \frac{W}{h} \frac{1-\langle\cos(\Delta\theta)\rangle}{2}, \tag{1}$$

where R_S is the sheet resistance of the entire sandwich structure, assumed to be 20 Ω/□. When the actual change of output is calculated, Eq. (1) should be subtracted by its value at the biased state. The anisotropic magnetoresistance is neglected, since the $\Delta R/R$ ratio is smaller than that of the GMR effect, typically by an order of magnitude.[8]

Only the magnetic layers are discretized for micromagnetic simulations, and a periodic boundary condition is utilized at the horizontal edges of the discretized region, to simulate a large total track width. The detailed formulation of the model has been discussed previously.[4] The gap length is 0.18 μm, and the active track width is 0.5 μm. The spin-valve sensor is centered within the gap, with the center of the free layer at the midpoint. The distance between the air bearing surface (ABS) and the medium center is 250 Å, and the medium moment thickness product is 0.8 memu/cm^2. Isolated transitions with transition width of 200 Å, and nominal recorded track width of 0.75 μm are utilized as dynamic excitation sources.

III. SHIELDED SPIN-VALVE HEAD RESPONSE

A. Proper biasing

The biasing principle and operation scheme of the spin-valve sensor have been discussed previously.[2] The goal is to maintain the pinned layer in vertical saturation, while biasing the free layer magnetization in the horizontal direction as

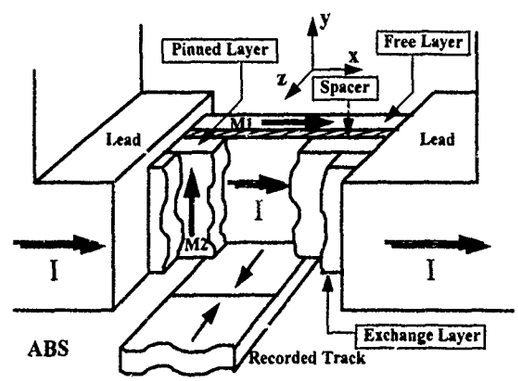

FIG. 1. Schematics of a GMR spin-valve head (shields not shown).

 0021-8979/94/75(10)/6385/3/$6.00 © 1994 American Institute of Physics

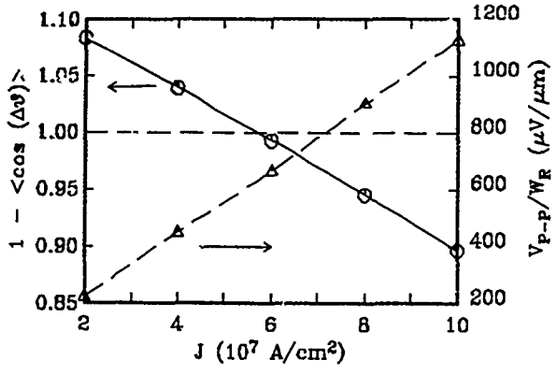

FIG. 2. Biasing level (circles) and peak-to-peak voltage (triangles) vs sense current density for $h=0.5$ μm, coupling field of 10 Oe, and pinning field of 100 Oe. The isolated transition width is 0.75 μm.

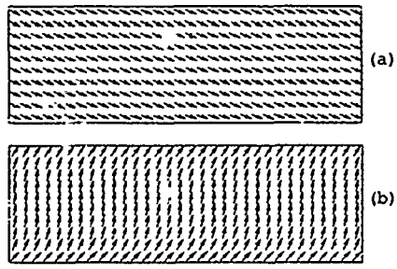

FIG. 3. Biasing magnetizations for $J=6\times10^7$ A/cm^2, with head parameters identical to Fig. 2. (a) Free layer; (b) pinned layer.

much as possible, in order to achieve maximum response symmetry and linearity under external excitation. For a properly biased state, the magnetizations of the two magnetic layers are perpendicular to each other, therefore $\langle\cos(\Delta\theta)\rangle\cong0$. Figure 2 shows the biasing level and on-track peak-to-peak output voltage dependencies on the sense current density when the sensor height is 0.5 μm. The pinning field from the exchange layer is 100 Oe, and the interlayer coupling field is 10 Oe. The current direction is along the positive x direction, as shown in Fig. 1, in order to generate an opposing field to the demagnetizing field from the pinned layer acting on the free layer. Optimum biasing is obtained at 6×10^7-A/cm^2 current density, at which the peak asymmetry from reading an on-track isolated transition is also minimized. With this biasing current, the output amplitude is 660 μV per micron of read track width, which exceeds the regular MR output level of 300–400 μV/μm for the next generation 1–2-Gbit/in.^{2} areal density read head demonstrations.[9,10]

Figure 3 shows the magnetization configurations of the biased state with current density $J=6\times10^7$ A/cm^2. For clarity, only half of the actual discretized magnetization vectors are shown. It is seen that the magnetization of the pinned layer is not fully saturated vertically, due to a large demagnetizing field and a relatively small pinning field. Correspondingly, the free layer magnetization is not horizontal, in order to be perpendicular to the pinned magnetization on the average; its biasing angle measured from the positive x axis is approximately $-15°$ throughout the stripe height. The net horizontal magnetization components are parallel for the two films, due to the interlayer ferromagnetic coupling. This small ferromagnetic coupling field is advantageous for properly biasing the free layer, since it opposes the demagnetizing field from the pinned layer and inhibits irreversible switching of horizontal magnetizations favored by the magnetostatic coupling between the two films. However, if this field is too large, its coupling could bring the pinned layer out of saturation and induce response nonlinearity;[2] worse yet, if the two permalloy films are strongly coupled, their magnetizations would be nominally parallel to each other under most excitations, and the spin-valve GMR effect would be lost.[5]

B. Down-track response

Figure 4 shows the down-track response to an isolated (tail-to-tail) transition with negative polarity. The solid curve represents the case with the above biasing condition. Only the change of the average normalized resistance $\cos(\Delta\theta)$ is plotted, in order to illustrate the actual swing of magnetization from its quiescent value. The maximum signal occurs before the transition center is directly underneath the free layer, and a finite reversible jump is observed on the trailing side of the gap center. As a comparison, the down-track pulse for the same transition with the following different head parameters is also included in Fig. 4: sensor height $h=1$ μm, sense current density $J=2\times10^7$ A/cm^2, interlayer coupling field of 20 Oe, and pinning field of 1000 Oe. The maximum output now occurs when the transition center is directly underneath the free layer, and no noise spike appears. This indicates that with a weaker pinning field, the pinned layer also participates in responding to the excitation from the medium, modulating the free layer response and inducing nonlinearity or even read-back noise.

The magnetization state corresponding to the jump is shown in Fig. 5. The magnetizations of the pinned layer near the ABS come out of saturation and reverse their orienta-

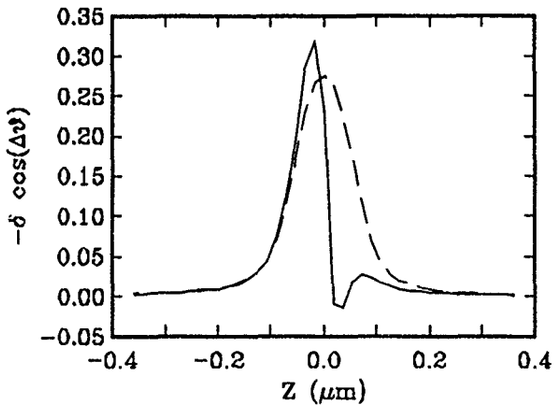

FIG. 4. Down-track responses to an isolated negative transition. Solid: head biased as in Fig. 3; dashed: $h=1$ μm, coupling field of 20 Oe, pinning field of 1000 Oe, and $J=2\times10^7$ A/cm^2.

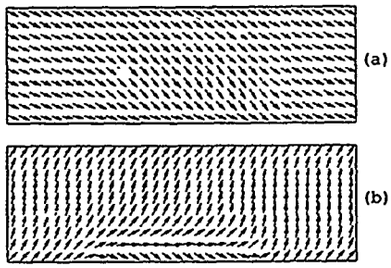

FIG. 5. Magnetization states corresponding to the noise spike in Fig. 4.

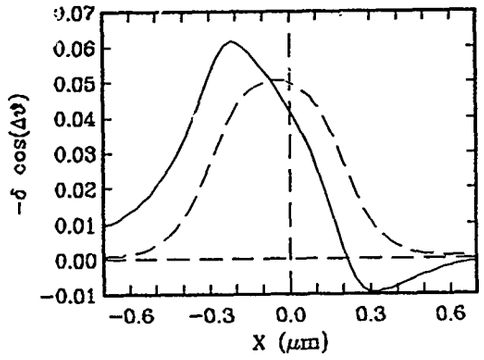

FIG. 6. Microtrack off-track profiles. S id and dashed curves have the same correspondences as in Fig. 4.

tions, forming an edge domain wall along the lower film surface. The free layer magnetization, however, does not show irregular domain activity, indicating that additional stabilization may not be necessary for this layer. The maximum transition field at the ABS is larger than 1000 Oe, for the chosen head-medium parameters, which, together with the current field, appears to overcome the demagnetizing field and the pinning field combined on the pinned layer. When a transition with positive polarity (head-on transition) is played back, the output pulse has a noise-free unipolar shape, because the transition field is now along the saturation direction of the pinned layer.

From Fig. 4, it is seen that the positive maximum change of $\cos(\Delta\theta)$ is smaller for larger sensor height (0.24 for $h=1$ μm as compared to 0.31 for $h=0.5$ μm). The peak-to-peak change of the average $\cos(\Delta\theta)$ is also slightly smaller for the larger sensor height (0.60 for $h=1$ μm vs 0.61 for $h=0.5$ μm), caused by the increase of biasing angle at midsensor, in agreement wi h Ref. 2. For the 1-μm sensor height, the biasing angle of the free layer is more than $-30°$ at the surfaces and slightly above 0° at the midheight. The pinned layer is now almost completely saturated, with a demagnetizing field characteristic of a permanent magnet. Increasing the sense current density to 10^8 A/cm^2 still cannot drive the surface magnetizations of the pinned layer to the horizontal direction.

C. Off-track response

The off-track responses of the above two head configurations are compared to each other. Figure 6 shows the microtrack profiles with a record track width of 0.05 μm. The solid curves represent the case with smaller sensor height and smaller pinning field, and clearly show an offset of the magnetic center and an undershoot of peak signals on one side of the head-medium alignment, due to the nonzero biasing angle mentioned in Sec. III B. The off-track asymmetry in this case is more severe than those predicted in a conventional shielded MR-SAL head with comparable gap spacing.[4] The head with a larger sensor height is biased better around 0°, therefore the off-track profile is more symmetric with no undershoots. The magnetic center is only slightly offset, due to the fact that the magnetizations of the free layer close to the ABS are still not horizontal. Patterned exchange biasing the free layer horizontally at the edge regions does not seem to reduce this offset substantially.

IV. REMARKS

Given a limited biasing current density, a larger sensor height is desirable for the ease of biasing the free layer horizontally and for reducing off-track asymmetry. However, increasing the sensor height results in a loss of on-track signal due to the following two reasons: first, the required biasing current density is smaller, and the total resistance of the sandwich structure is smaller, so that the prefactor in Eq. (1) decreases; second, the peak change of the average $\cos(\Delta\theta)$ upon excitation from the medium also decreases, since the biasing angle at midsensor increases. This tradeoff must be considered when optimizing the spin-valve head design.

Micromagnetic study of narrow track orthogonal giant magnetoresistive heads

Yimin Guo and Jian-Gang Zhu
The Center for Micromagnetics and Information Technologies, Department of Electrical Engineering, University of Minnesota, Minneapolis, Minnesota 55455

Orthogonal narrow track magnetoresistive heads using giant magnetoresistive multilayers have been studied by micromagnetic modeling. The modeling shows that the hysteresis arises from irreversible switching of the edge-curling wall (ECW) on the side edges of the giant magnetoresistive (GMR) sensor layers. Effects of thickness and interlayer exchange coupling on the switching of the ECW are analyzed. It is also found that if the interlayer exchange coupling is ferromagnetic, the GMR orthogonal head has significant high signal amplitude.

I. INTRODUCTION

Future high track density recording requires submicron track width magnetoresistive heads. The orthogonal MR head design has been proposed for narrow track recording since its signal amplitude is independent of track width.[1,2] However, since the current flows vertically to the air bearing surface, the recession of the magnetoresistive (MR) sensor sensing region due to the bottom conducting lead yields a reduction of the head sensitivity. Utilizing the giant magnetoresistive (GMR) film as a sensor, the small signal amplitude can be overcome by the relatively large magnetoresistance ratio of GMR films.[3]

In this paper, we present results of a micromagnetic modeling study on orthogonal GMR heads with narrow track width ($W=1$ μm). The model assumes that the sensor element is made of a giant magnetoresistive sandwich film. The study focuses on hysteresis in the GMR output response and underlying physical mechanism. Dynamic range and head sensitivity are also analyzed.

II. MODEL AND HEAD GEOMETRY

Figure 1 shows a schematics for the modeled GMR sensor. The GMR element is a trilayer film $ML(t$ nm$)/NML($2.5 nm$)/ML(t$ nm$)$, which is 4 μm in height and 1 μm in width. In the modeling, the thickness of each magnetic layer is varied in a range from 7 to 20 nm. An interlayer exchange coupling field, H_{exch}, between the two magnetic layers in the GMR film is assumed. The value of H_{exch} is varied from -30 to $+30$ Oe, i.e., from antiferromagnetic to ferromagnetic in nature. The intrinsic anisotropy easy axis is assumed to be horizontal with a magnitude of $H_k=2.5$ Oe. The vertical sensing current generates antiparallel horizontal fields (H_z) in the two magnetic layers. An additional vertical biasing field (H_y) is provided by the current flowing horizontally in a conductor over the GMR element. The sensor is placed at the center of two soft magnetic shields with assumed infinite permeability. The distance between the two shields, i.e., the gap length, is assumed to be 0.5 μm.

A three-dimensional micromagnetic model[4] is utilized to study the performance characteristics and domain structures of the GMR trilayer film. Each magnetic layer is discretized into a two-dimensional array of 200×50 elements. Within each element, the magnetization is assumed to be always uniform. Both the magnetostatic and the exchange energies are included. The saturation magnetization of each magnetic layer in the sensor is chosen to be $M_s=800$ emu/cm^3 and the within-layer exchange energy constant $A=1.0\times10^{-6}$ erg/cm. Coupled Landau–Lifshitz dynamic equations are integrated for the magnetization distribution in the GMR sensor.

It is assumed that external field away from the gap of shields is spatially uniform and the field along the GMR sensor is calculated exactly by using two-dimensional conformal mapping method with assuming infinite permeability for the shields. In this study, the values of the external field referred in this paper are the field intensities at the bottom of GMR element (at ABS). Keep in mind that the field at ABS is much higher than the uniform field far away due to the soft shields. Most of the calculations are performed on a Sun SPARC-2 workstation.

III. RESULTS AND DISCUSSION

A. Hysteresis mechanism and switching field

The magnetizations of the two magnetic layers are initially set antiparallel in the horizontal direction before the application of the vertical bias field. The magnitude of the

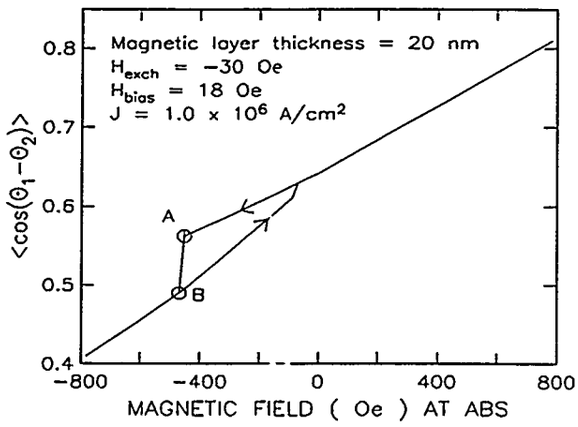

FIG. 2. Calculated GMR output for the external field varied from zero to −800 Oe and then to +800 Oe.

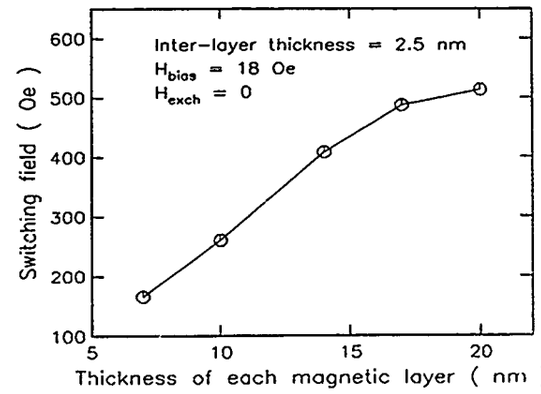

FIG. 4. Calculated switching field as a function of the thickness of each magnetic layer.

bias field is set such that the angle between magnetization orientations of two magnetic layers in the center region is about 90° at external field free equilibrium state. The current leads on the sensor are 0.5 μm in height. Figure 2 shows a calculated GMR output as a function of the external field. In this case, the two magnetic layers, each 20 nm thick, are separated by a nonmagnetic layer with 2.5 nm thickness. An $H_{exch}=-30$ Oe antiferromagnetic exchange field is assumed between the two magnetic layers.

The external field value is varied from zero to −800 Oe then to +800 Oe quasistatically. As shown in the figure, at −450 Oe, the GMR output, $\langle \cos \theta_{1,2} \rangle$, exhibits a large abrupt jump. As the field returns to zero, the GMR output takes a different path, starting where the jump occurred, yielding a well-pronounced hysteresis.

The simulated magnetization patterns show that the irreversible jump in the GMR output is caused by an irreversible switching of the edge-curling wall at side edges of the two-layer sensor element.[5] Figures 3(a) and 3(b) show the corresponding magnetization patterns of the two magnetic layers before the switching (a) and after the switching (b), respectively. Prior to the application of the external field, the magnetizations in the middle region of two magnetic layers are oriented about 45° and −45° away from the vertical axis, respectively; while the magnetizations at side edges of both magnetic layers essentially point upward along the side edge due to the edge demagnetizing field, yielding formation of ECW. At point A, due to the downward external field, the magnetization near the bottom region of the sensor is almost horizontal, leaving narrow ECWs at two sides. A slight increase of the external field yields an irreversible reversal of the ECW on one of the side edges (point B). The reversal only occurs at one side edge on one layer and the opposite side edge on the other layer, because a switched ECW stablizes the unswitched ECW in the other layer through both the interlayer magnetostatic coupling and antiferromagnetic exchange coupling. The reversal of the ECW yields a relatively large change of the magnetization orientations in the sensor, thereby resulting in a large jump in the GMR output. Further increasing the external field actually yields a steady propagation of the ECW reversal along the edge. Reducing the field magnitude, the reversed ECW reverses magnetization direction again to initial upward direction, starting from the top of the reversed segment. When the field magnitude returns to a small value, the reversed ECW irreversibly vanishes from the sensor corner, yielding a small jump in the GMR output shown in Fig. 2. The above results clearly demonstrate that the hysteresis of the GMR output is caused by irreversible switching and propagation of the edge-curling wall.

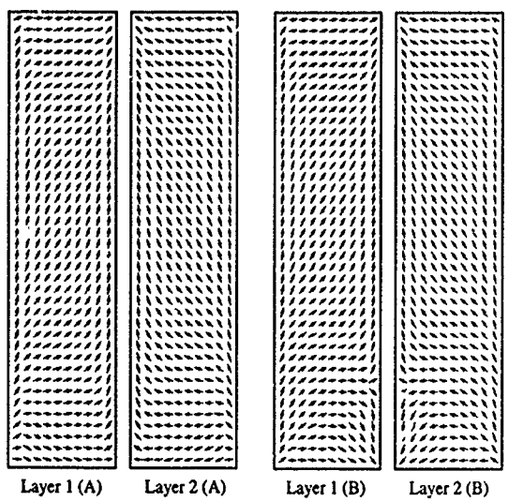

FIG. 3. (a),(b) Simulated magnetization configurations in the two magnetic layers at point A and B on the GMR output curve shown in Fig. 2.

In the above case, before the external field reaches the field value where the jump occurs, referred to as switching field here after, the GMR output is completely without hysteresis. Figure 4 shows the calculated switching field as a function of the thickness of magnetic layer. It is found that the switching field increases almost linearly with the thickness. This is because that in thicker films, the width of ECW is larger due to the larger demagnetizing field, therefore a larger switching field is needed to result in ECW reversal. Figure 5 shows the calculated switching field as a function of

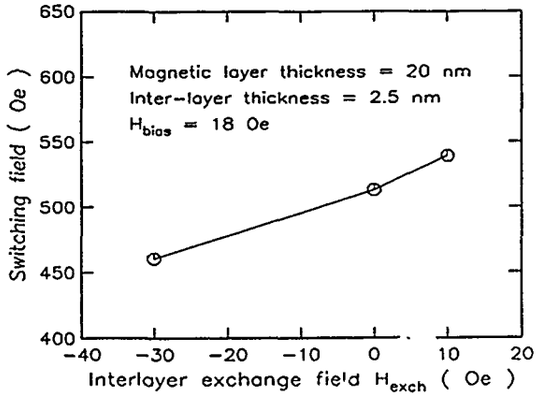

FIG. 5. Calculated switching field as a function of the interlayer exchange coupling field.

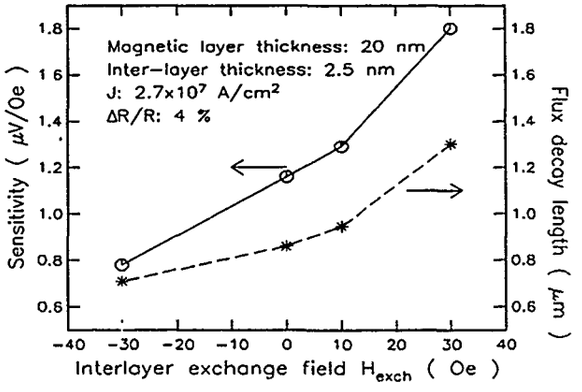

FIG. 6. Calculated sensitivity and estimated flux decay length as functions of the interlayer exchange coupling field.

the interlayer exchange field. As the exchange coupling changes from antiferromagnetic to ferromagnetic, the switching field increases.

B. Sensitivity and flux decay length

The flux decay length, defined as λ in $\Delta M_y(y) = \Delta M_y(0)e^{-y/\lambda}$, y is the vertical distance measured from ABS, is an important factor in orthogonal head design due to the bottom current lead. In GMR head, the interlayer exchange coupling can significantly affect the flux decay length. The interlayer exchange energy density: $E_{exch} = tH_{exch}M_s \cos(2\theta) = -2tH_{exch}M_s \sin^2(\theta) + \text{constant}$, results in an effective anisotropy field $-2H_{exch}$ in the horizontal direction. Following the same approach by Wang,[2] the flux decay length can be approximately expressed as

$$\lambda = \sqrt{\frac{4\pi M_s g t}{H_k - 2H_{exch} + H_z/\cos^3\theta}}, \quad (1)$$

where t is the thickness of each magnetic layer, g is the gap length between the shields, and θ is the angle of the magnetization orientation of the film with respect to the horizontal direction. Figure 6 shows the calculated sensitivity and estimated flux decay length as functions of exchange strength. As shown by the formula and curves in the figure, a ferromagnetic exchange gives rise to a larger flux decay length and consequently a higher head sensitivity.

IV. CONCLUSION

A micromagnetic modeling study has been performed to study a narrow track orthogonal MR head with a GMR sandwich film as the magnetoresistive sensor. It is found that irreversible switching of the edge-curling wall at the side edges of the sensor film is one mechanism for hysteresis in the orthogonal GMR output. Irreversible propagation of the edge-curling wall reversal yields a large jump in the GMR output. Reduction of antiferromagnetic interlayer exchange coupling and increase of the magnetic layer thickness can increase the critical switching field of ECWs. Ferromagnetic interlayer exchange coupling also enhances the head sensitivity.

Dynamic domain instability and popcorn noise in thin-film heads

F. H. Liu and M. H. Kryder
Data Storage Systems Center, Carnegie Mellon University, Pittsburgh, Pennsylvania 15213

The effects of dynamic domain instability on popcorn noise probabilities were studied by correlating the measured popcorn noise probabilities with the instantaneous observations of dynamic domain states of thin-film heads during and after writing. Heads with large peak popcorn noise probabilities at intermediate values of write current amplitude were observed to exhibit asymmetric domain patterns and occasional popping wall motion in the yoke structure during writing. The occurrences of dynamic domain instability were imaged by comparing many instantaneous domain patterns at 10 μs after a specific write current excitation. Delayed-relaxation Barkhausen wall jumps near the backgap closure were observed occasionally in several noisy heads. Quantitative correlation between the probabilities of popcorn noise and dynamic domain instability was also obtained in a very noisy head. Dynamic domain instabilities in the yoke are thus responsible for the peak popcorn noise probabilities in thin-film heads.

I. INTRODUCTION

As the areal density and data rates in magnetic recoring continue to increase, it is important to limit the readback noise in thin-film heads. Popcorn noise, which consists of large noise spikes occurring shortly (on the order of microseconds) after writing, is detrimental to the reading operation immediately after write, for instance, in disk drives utilizing sector or imbedded servo schemes. This noise phenomenon has been explained to be caused predominantly by stress-induced delayed-relaxation Barkhausen wall jumps.[1] The stress changes were, in turn, explained to be caused by the rapid cooling off of thin-film heads after write. Assuming the domain patterns during writing are stable and fixed, the occurrence of popcorn noise was modeled as a Poisson process.[1] However, dynamic domain state conversions due to different write current amplitudes and frequencies as well as the dynamic domain instabilities associated with conversion boundaries between different dynamic domain states have been observed in thin-film heads.[2–4] In this investigation, the effects of dynamic domain instability on the popcorn noise probabilities were studied by measuring the popcorn noise probabilities with a Barkhausen noise tester and correlating them with 0.5-ns exposure time wide-field Kerr effect microscope observations of changes in dynamic domain states of several 30-turn thin-film heads during and after writing.

II. EXPERIMENTAL APPARATUS

A Barkhausen noise tester, similar to those described in Refs. 1 and 4, was used to measure the popcorn noise probabilities in thin-film heads. A wide-field Kerr-effect microscope with a 0.5 ns exposure time was used to observe the instantaneous magnetization response on the top yoke of thin-film heads during and after the write current cycles. In this system, a pulsed laser with a pulse width of 0.5 ns is used as the light source for a wide-field polarized light microscope, equipped with a high-sensitivity TV camera and an image processor.[5] All images in this paper were observed with magneto-optic contrast optimized to measure the component of magnetization in the trackwidth direction.

III. EXPERIMENTAL RESULTS

The effects of write current amplitude on the popcorn noise probabilities of two 30-turn heads that exemplify the heads with high and low popcorn noise probabilities are shown in Fig. 1. In head A, a very large peak popcorn noise probability at 33 mA p-p was observed to be riding on top of an exponentially increasing noise floor;[6] whereas, in head B, a small and exponentially increasing popcorn noise probability as a function of write current amplitude was observed.

An asymmetric domain pattern with respect to the head symmetry axis and occasional popping wall motion during write current excitation were observed in head A, as depicted in Fig. 2. These images were created by subtracting two images of which one was taken with a +dc drive current of a specific amplitude and the other with a −dc drive current of the same amplitude. A pinned edge closure domain wall near the left edge of the backgap closure was clearly observed with a dc+/−13 mA excitation, as shown in Fig. 2(a). As the excitation was increased to DC+/−22 mA, a small displacement was observed for this wall, as shown in Fig. 2(b). When the excitation was increased to DC+/−23 mA, this wall suddenly exhibited large displacement, as shown in Fig. 2(c). Utilizing real-time live-subtraction image processing, large

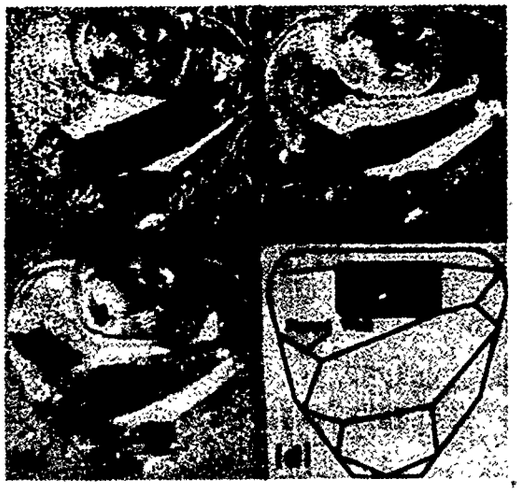

FIG. 2. The domain wall displacement images of head A with DC excitation of (a) +/−13 mA, (b) +/−22 mA, and (c) +/−23 mA, and (d) a schematic diagram of its static domain pattern.

and occasional popping motion of this wall was also observed during sine-wave current excitation of 23 mA o-p at 1 Hz. As the current amplitude was increased further, the large motion of this wall was observed to become more repeatable. A schematic diagram of the asymmetric static domain pattern in head A is depicted in Fig. 2(d). In comparison, symmetric closure domain patterns with smooth and repeatable wall motion during write current excitation were observed in head B.

By repeatedly subtracting two instantaneous domain patterns imaged 10 μs after a specific write current excitation, occasional occurrences of dynamic domain instability were actually imaged. A 256-frame-averaged image observed 10 μs after a specific write current excitation was first taken as the reference image. A large number of 32-frame-averaged images (typically 700) were also taken 10 μs after the same writing condition and then subtracted from the reference image. Occurrences of delayed-relaxation Barkhausen wall jumps after write were observed as shades of black and white contrast, as shown, for instance, in Fig. 3(a). Low stochastic occurrences of domain instability were observed as uniform gray contrast, as shown, for instance, in Fig. 3(b). The probability of domain instability after a specific write current was thus obtained by dividing the number of subtracted images that exhibited strong contrast, such as in Fig. 3(a), by the total number of images observed. The head was ac demagnetized to the same static domain state before each measurement of domain instability probability.

Probability (normalized by the peak values) of domain instability and of popcorn noise in head A as functions of write current amplitude are shown in Fig. 4. A strong correlation between the normalized probability of domain instability and popcorn noise in head A is clearly seen. In comparison, almost no domain instability was observed in head B, which has low popcorn noise probabilities for all write current excitation applied. It was also found that the probability of domain instability and popcorn noise decrease exponentially as the delay time after write increases,[1] as shown in Fig. 5.

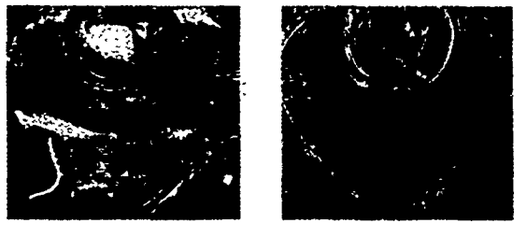

FIG. 3. Dynamic difference images of head A observed at 10 μs after the write current excitation of (a) 33 mA and (b) 43 mA, at 5 MHz.

The specific write current amplitude that gives rise to the peak popcorn noise probability is observed to be a function of frequency, as shown in Fig. 6. The curve joined by the data points of peak popcorn noise probabilities was also observed to be the conversion boundary of two dynamic domain states, of which one contains the pinned edge closure domain wall near the left edge of the backgap closure, and the other with a large motion of the same edge closure domain wall, as indicated in the insets of Fig. 6. At the write current excitations that coincide with this conversion boundary, high probabilities of dynamic domain instability were observed.

IV. DISCUSSION

Thermal transients after write are believed to serve as a "drive" to move the walls from metastable positions just after write to their static equilibrium positions.[1] During this thermal-transient-driven relaxation process, Barkhausen wall jumps occur when walls encounter and subsequently overcome the localized pinning sites. As the write current amplitude increases, the "drive" of the thermal-transient-driven Barkhausen wall jumps increases. In the case where the initial domain states just after write are microscopically unstable, the occurrences of Barkhausen wall jumps thus increase as the write current amplitude increases. Consequently, popcorn noise probabilities increase exponentially as write current amplitude increases.[1] This mechanism

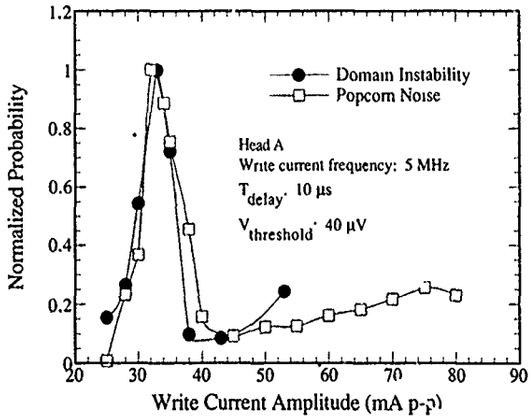

FIG. 4. Normalized probabilities of domain instability and popcorn noise in head A, as functions of write current amplitude.

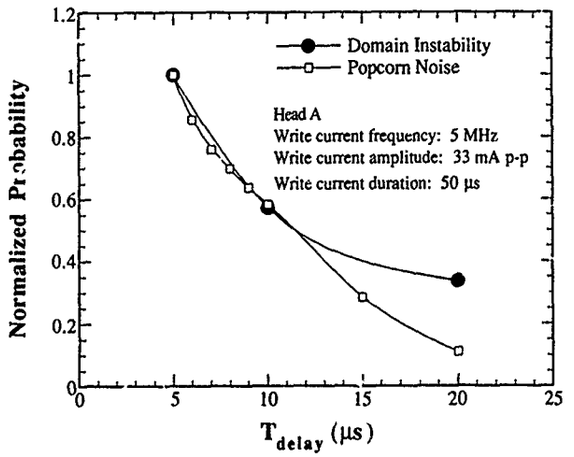

FIG. 5. Normalized probabilities of domain instability and popcorn noise in head A as functions of delay time after the write current of 33 mA p-p at 5 MHz.

of microscopic wall jumps driven by thermal transients after write is consistent with the observations of exponentially increasing popcorn noise probabilities as functions of write current amplitude in head A (between 45 to 80 mA p-p, as shown in Fig. 1) and head B, in which no large probabilities of domain instability were observed.

At the specific write current frequencies and amplitudes which coincide with the conversion boundary of two dynamic domain states, as depicted in Fig. 6, high probabilities of domain instability were observed. When domain instabilities occur during write, the initial domain states just after write are macroscopically unstable. Higher occurrences of Barkhausen wall jumps may thus occur even with moderate thermal transients after the intermediate write current amplitude. A large peak in the popcorn noise probability consequently results in addition to the exponentially increasing noise floor, as shown in Fig. 1. This mechanism of macroscopic domain instability driven by thermal transients after write is consistent with the strong correlation observed between dynamic domain instability and popcorn noise probabilities as functions of write current amplitude and delay time after write, as shown in Figs. 4 and 5, respectively. The observed result of exponentially decreasing domain instability probability as a function of delay time in Fig. 5 indicates that domain instability is caused predominately by delayed-relaxation Barkhausen wall jumps, and not by different stable remanent domain patterns after write.

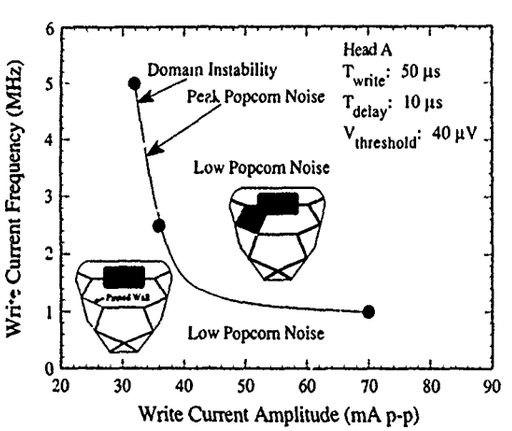

FIG. 6. The peak popcorn noise probability contour and conversion boundary of two dynamic domain states in head A, as a function of write current frequency and amplitude.

The observations of nonrepeatable domain wall displacement, as shown in Fig. 4(a), indicate that the locations of Barkhausen wall jumps, and thus the major noise sources, are fixed. In head A, the dynamic domain instability is largely related to the erratic popping wall motion near the left edge of the backgap closure, as evident by Figs. 2, 3(a), and 6. This erratic popping wall motion was observed to occur when the drive field produced by the specific write current amplitude is just enough to bring the pinned wall into motion. This specific write current amplitude was also observed to be a function of frequency. This conversion boundary between two dynamic domain states, as shown in Fig. 6, is similar with the conversion boundaries of different dynamic domain states observed by Trouilloud *et al.*[2] Dynamic domain instability associated with the conversion boundary of different dynamic domain patterns thus cause high probabilities of popcorn noise in thin-film heads.

V. CONCLUSIONS

Two major mechanisms of popcorn noise were observed in thin-film heads studied here. While both appear to be driven by thermal transients after write, the mechanism of microscopic wall jumps is responsible for the relatively small and exponentially increasing popcorn noise probability as a function of write current amplitude; and the mechanism of macroscopic domain instability is responsible for the large peak popcorn noise probability at intermediate write current amplitudes. The dynamic domain instability is caused mainly by the erratic popping motion of domain walls near the backgap closure of thin-film heads, and is associated with the conversion boundary of different dynamic domain states. By designing and fabricating heads with stable domain structures and dynamics, much lower probabilities of popcorn noise should result.

Dynamic response of domain walls on the air-bearing surface of thin-film heads

X. Shi, F. H. Liu, Yuet Li,[a] and M. H. Kryder
Data Storage Systems Center, Carnegie Mellon University, Pittsburgh, Pennsylvania 15213

The domain configurations on the air-bearing surface (ABS) of inductive thin-film recording heads were studied. It was found that, instead of being a single domain structure, the ABS of a thin-film head usually has multidomains. The direction of the domain walls is neither parallel nor perpendicular to the gap plane. The magnetization was found to be in the plane of the ABS along the track width, with the magnetizations on the two sides of the domain walls either "head-to-head" or "tail-to-tail." The domain walls are slanted in order to spread the magnetic charges along the wall over a larger region, thereby reducing magnetostatic energy in this configuration. The responses of the domain walls are not all in phase, and they are generally out of phase with the rotational process along the gap edge. The magnetization configuration on the ABS and in the throat and the sloped region were investigated in one head and correlated with the domain walls on the ABS.

INTRODUCTION

Previous studies of the dynamic domain configurations and the dynamic response of domain walls in thin-film recording heads were carried out primarily on the yoke of heads and the sloped region between the yoke and the pole tip.[1–5] These earlier studies related dynamic characteristics and noise to the response of the domain walls in the yoke and in the sloped region. The work described in this paper focuses on the dynamic processes at the air-bearing surface (ABS) of thin-film heads. With a scanning magneto-optic photometer, we measured the dynamic response at the ABS of several thin-film heads and discovered the existence of complex domain configurations on the pole tips of the heads. The phase response of the domain walls relative to the response of the rotational magnetization was studied. The magnetization configurations on the ABS and in the throat and sloped region were investigated.

APPARATUS AND METHODS

The scanning magneto-optic photometer used in this work was described in detail in Ref. 6. It detects the dynamic changes in magnetization on the surface of a sample. With a lock-in amplifier, both the amplitude and the phase lag of the magnetic response can be obtained. In a picture displaying the amplitude information, darker shade represents stronger magnetization response, while in a phase picture, contrast difference represents phase difference. Results measured on two different heads will be discussed. Head no. 1 is a nine-turn head with a track width of 23 μm and a pole thickness of 2 μm. Head no. 2 is a 30-turn head with a track width of 10 μm and a pole thickness of 2.5 μm.

RESULTS

The dynamic domain configuration on the ABS of head no. 1, driven by a current of 15-mA peak-peak (p-p) at 1 MHz, is shown in Fig. 1(a), (b), and (c), which correspond to three different laser configurations used in the measurements. The image in Fig. 1(a) was obtained by using the longitudinal Kerr effect. The laser beam was *s* polarized and had an incidence plane parallel to the gap plane. This laser configuration detects primarily the dynamic change in the component along the track width. The longitudinal Kerr effect was also used for obtaining the image in Fig. 1(b); however, the laser beam (also *s* polarized) had an incidence plane perpendicular to the gap plane. This laser configuration detects primarily the dynamic change in the component perpendicular to the gap plane. The polar Kerr effect was used to produce the image in Fig. 1(c). In this configuration, only the out-of-plane component of magnetization is detected.

The dynamic domain configuration on the ABS of head no. 2, driven by a current of 5 mA p-p at 1 MHz, is shown in Fig. 2. The laser configuration used is the same as that used to map Fig. 1(a). Laser configurations used to map Figs. 1(b) and (c) were also used to measure this head, and a uniform

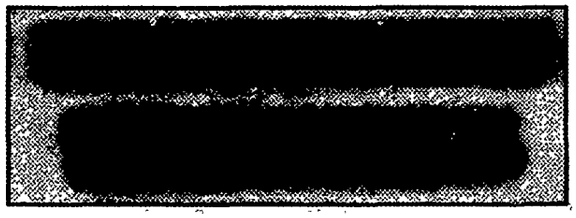

FIG. 2. Dynamic domain picture measured on the ABS of head no. 2.

response similar to the top pole tip in Fig. 2 was obtained across the track width of both pole tips.

The phase response on the ABS of head no. 2, driven by a current of 5 mA p-p at 1 MHz and a current of 10 mA p-p at 20 MHz, is shown in Figs. 3(a) and (b), respectively. Only the trailing pole is shown in Fig. 3(b). As stated previously, white and black contrasts in a phase picture indicate phase differences in the magnetic response. That the wall on the left in Fig. 3(a) has the same brightness as the gap edge suggests the response of this wall is in phase with the rotational magnetization process taking place along the gap edge. The white–black contrast between the two walls indicates that the magnetization changes caused by the two walls are out of phase. When the frequency was increased to 20 MHz, both domain walls were out of phase with the rotational magnetization process along the track edge, and the two walls were also out of phase with each other. The scanned data used to produce Fig. 3(a) indicate that the response of the domain wall on the right is 150° out of phase with the domain wall on the left and the rotational magnetization along the gap edge. At 20 MHz, the two domain walls become 180° out of phase with one another, and they both are out of phase with the rotational process.

DISCUSSION

The black stripes on the trailing pole of Fig. 1(a) are produced by the response of domain walls. The fact that no wall response was detected by using the polar Kerr effect suggests that the motion of the domain walls seen in Fig. 1(a) does not cause magnetization change in the direction perpendicular to the ABS, and consequently, the magnetization inside the domains is believed to be in the plane of the ABS. That the response of domain walls produced a much stronger Kerr signal in Fig. 1(a) than in Fig. 1(b) suggests that the dynamic change in magnetization caused by domain wall translation is mainly in the direction of the track width. Therefore, the magnetization configuration of this pole tip is apparently as shown in Fig. 4. The domain walls are presumably slanted because slanting spreads the magnetic charges along the walls over a longer region and thereby reduces magneto-static energy in this configuration. Based on similar reasoning, the magnetization configuration on the ABS of head no. 2 is believed to be as shown in Fig. 5.

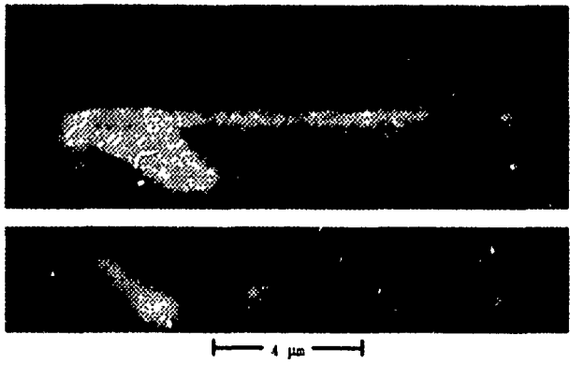

FIG. 3. Phase information in the response on the ABS of head no. 2 at (a, top) 1 MHz and (b) 20 MHz.

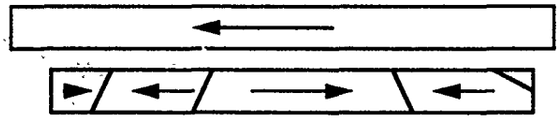

FIG. 4. Magnetization configuration on the ABS of head no. 1.

Different phase shifts in the rotational response and the response of domain walls mean different delay times of magnetic flux conduction are associated with the two processes. As suggested by Jones,[7] superposition of two or more pulses with different delay times produces a pulse with "wiggles." The results shown in Fig. 3(a) and (b) suggest that the readback signal of this head could be quite noisy.

To reveal the complete domain configuration in the region near the pole tip, we mapped the domain configurations in both the ABS and the sloped region of head no. 2 with three different drive conditions: 6-mA p-p ac at 1 MHz superposed upon a dc of 20, 0, and −20 mA, and the results are shown in Figs. 6(a) and (a′), (b) and (b′), and (c) and (c′), respectively. An *s*-polarized laser beam with an incidence plane along the symmetry axis of the head was used to measure the sloped region. Because of the sharp angle between the throat and the sloped region, Fig. 6 does not include the surface of the throat and a short section (about 2 μm) of the sloped region near the throat. However, these pictures suggest that the domain wall on the right-hand side of Fig. 6(a) is not connected to the domain wall on the right-hand side of Fig. 6(a′) because they do not move in the same direction under the same dc bias. However, the domain beneath the ABS to the right of the wall in Fig. 6(a) is believed to be magnetized in the same direction as the left-hand side domain in Fig. 6(a′) because they expand under the same dc drive. For the same reasons, the domain wall in Fig. 6(c) is not connected to the wall on the left-hand side of Fig. 6(c′),

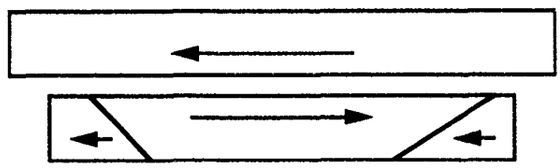

FIG. 5. Magnetization configuration on the ABS of head no. 2.

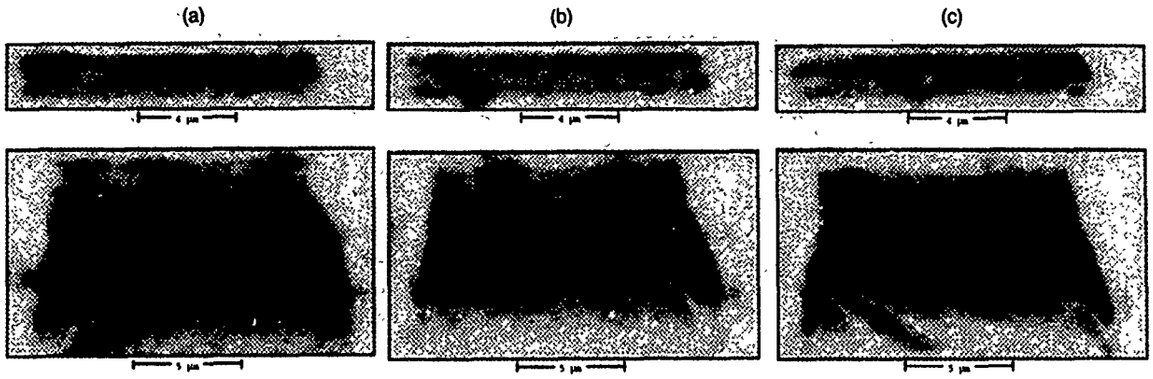

FIG. 6. Domain configuration in both the sloped region and the trailing pole tip of head no. 2. From left to right, top row: (a), (b), and (c); bottom row: (a′), (b′), and (c′). See text for detail.

and the domain to the left side of the wall in Fig. 6(c) beneath the ABS is likely magnetized in the same direction as the domain on the right-hand side of Fig. 6(c′). From the above observations, a possible complete domain configuration near the pole tip is plotted in Fig. 7. Because of the sharp angle between the throat and the sloped region, closure domain walls (a) and (a′) do not extend to the corners of the pole tip. Instead, they close at the junction between the throat and the sloped region. The magnetization on the corners of the pole tip curls to reduce the large magnetostatic energy which a configuration with magnetization perpendicular to any surface would cause. The slanting of the domain walls on the ABS reduce the magnetostatic energy along the walls by spreading the magnetic charges over a longer region. Although a perfect self-closed domain configuration in the throat, like that in the sloped region, could potentially eliminate the magnetostatic energy, the need for more domain walls in such a small dimension ($1\times2.5\times10$ μm) may actually cause a higher energy state because of the increase in total wall energy.

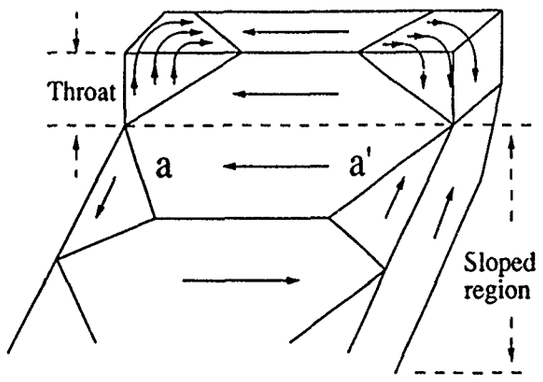

FIG. 7. Domain configuration in the region near the pole tip of head no. 2.

CONCLUSIONS

With a scanning magneto-optic photometer, the dynamic domain configurations on the ABS of several thin-film recording heads were studied. It was found that the pole tip of thin-film heads is usually a multidomain structure. The direction of the domain walls is neither parallel nor perpendicular to the gap plane. Based on the laser configuration used in the measurements and the corresponding results; the magnetization on the ABSs of most heads is believed to be in the plane of the ABS along the track width, with the magnetizations on the two sides of the domain walls either "head-to-head" or "tail-to-tail". This configuration produces strong magnetic poles along the walls. The domain walls are slanted in order to spread the magnetic charges along the walls over a larger region, thereby reducing magnetostatic energy. The responses of the domain walls are not all in phase, and they are generally out of phase with the rotational response. This phase shift phenomenon may cause "wiggles" in the readback signal. By correspondingly measuring the domain pattern in both the sloped region and the pole tip, a possible magnetization configuration in the throat and the sloped region near the pole tip was suggested for one head. More work is required to provide a conclusive explanation for these complex domain patterns on the ABS and to understand their effect on head performance.

Experimental 120-turn thin-film inductive heads have been built. The key features of this head are the 6-μm pitch helical coils and an omega-shaped, planar yoke structure having dual easy axes. Hardbaked photoresist insulator layers are used to encapsulate the yoke and to smooth out the wafer surface topography. Micro-Kerr studies show that the easy axis remains in the transverse direction in the yokes after multiple anneals. The $P1/G/P2$ is 3.8/0.3/3.8 μm, and the yoke length is close to 1 mm. The helical coils were built with a novel process that combines yoke/stud coplating and a photoresist planarization process. The coil resistance is 68Ω and the inductance is 5.5 μH. The yoke saturates at 5 mA. The heads were tested over disks having Mrt of 2.5 memu/cm^2 and H_c of 1500 Oe. The write threshold current is 5.3 mA (peak-to-peak) and the overwrite is 30 dB. The isolated pulse amplitude V_{pp} is 10.3 $\mu V/(T_w V)$, where track width T_w is in μm and the linear velocity V in m/s.

I. INTRODUCTION

Increasing coil turns and reducing track width of inductive heads have been the means to improve the recording density. To accommodate the increasing coil layers, the separation between $P1$ and $P2$ of today's head is typically 25 to 30 μm, beyond which it becomes increasingly more difficult to control the pole tip dimension and the composition of the plated permalloy.[1] Many different head designs were invented to tackle these problems. The most notable extension of the pancake head structure is the Diamond[2] design. Here, a planar head design[3] was explored for higher density recording. In a planar head, the $P1$ and $P2$ yokes are separated in the plane rather than overlapping each other. Thus, the yokes can be separated farther than 30 μm and the yoke topology is kept below 12 μm. The tight winding helical coil permits much tighter inductive coupling, and therefore offers coils with lower inductance per turn square than conventional pancake heads. This paper presents exploratory work on a 120-turn planar inductive head called Omega Head (as its physical resemblance of the Greek character). The magnetic design issues, a novel head process and the recording characteristics of the head will be described.

II. MAGNETIC DESIGN ISSUES

(1) To reduce the flux leakage between $P1$ and $P2$, they should be separated far apart. Figure 1 shows the normalized flux coupling through the air (leakage) between $P1$ and $P2$ yokes based on a two-dimensional analysis. The leakage is lowered to 0.6× when the two yokes are offset by one yoke width, and is reduced to 0.25× when the yokes are on the same plane and are offset by 3 times the yoke width. Figure 2 shows the yoke configuration of the present design. The flux leakage in the back yoke is minimized. The dominant leakage of this particular design comes from the overlap portion of $P1$ and $P2$ near the throat.

(2) For small sliders, the slider height limits the coil turns to a maximum of 60 turns of 6-μm helical pitch coil[3] where coils were wound on two legs of the yoke. The yoke of our Omega head is made up of two pairs of legs. The coils are wound on all four legs. The number of coil turns is no longer limited by the slider heights. To maximize the flux

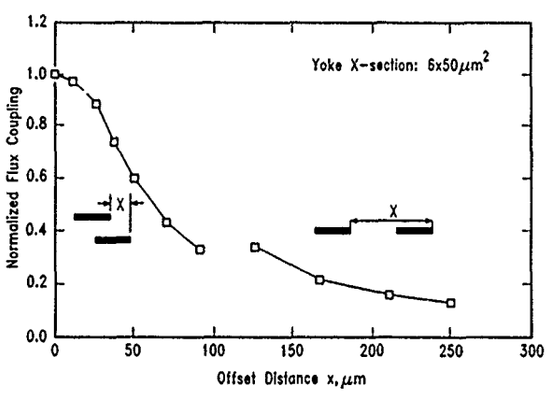

FIG. 1. Flux coupling between two yokes. Normalized to offset $x=0$. S is the vertical separation of $P1$ and $P2$. The coupling is reduced to 0.6× when the two yokes are offset by one yoke width, and reduced to 0.25× by 3× yoke width.

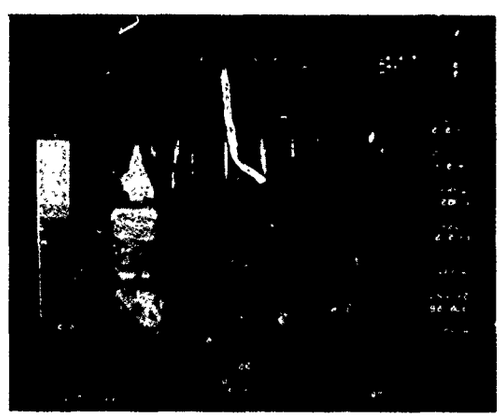

FIG. 2. SEM micrograph of an OMEGA head with 120-turn coils. Key features are helical coils, planar yoke with two easy axes, and hardbake resist encapsulated yokes.

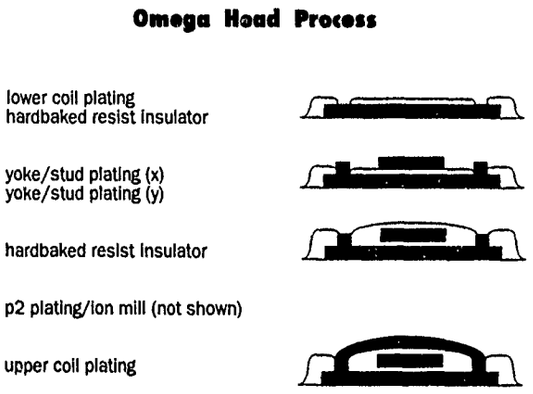

FIG. 4. Key steps of the OMEGA head process flow. Permalloy studs are plated together with the yoke in the same step. Hardbake photoresist is used for passivation.

FIG. 5. Domain images of yokes. The top and bottom yokes having easy axis in the y direction and the left and right yokes having easy axis in the x direction.

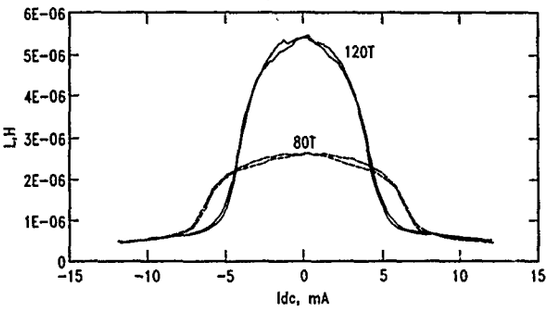

FIG. 6. Head inductance vs dc bias current in coil.

conduction efficiency, we chose a dual-axis yoke design. The easy axis of the yokes is oriented in two directions: Referring to Fig. 2, the easy axis is in the x direction for the left and right yokes, and in the y direction for the top and bottom yokes.

(3) Both hardbaked photoresist or sputtered alumina were investigated for planarizing the coil and isolating the coil from the yoke. Although the mismatch in the thermal expansion coefficient between the permalloy and the hardbaked photoresist is larger, hardbaked photoresist is much softer (Young's modulus is two orders smaller[4]) than alumina, thus, it exerts a more uniform stress to the permalloy and induces less stress anisotropy when process incurs temperature cycles. The μ-Kerr image studies (Fig. 3) confirmed that the electroplated permalloy encapsulated in the hardbaked photoresist does not show any annealing-induced changes in the domain wall density.

III. HEAD PROCESS AND CHARACTERISTICS

While the spiral coil is built over a flat surface, the helical coils must wrap around a yoke. It is more difficult to pattern many of these fine coil features over a severe topography: A new helical coil process was developed. The key concept is planarize-then-build-fine-features. In this case, we raise the lower coil contacts[5] to the same height as the yoke with vertical coil extensions (studs), planarize the surface, and then pattern the fine features of the upper part of the coils. Figure 4 shows the major steps of the head processing.

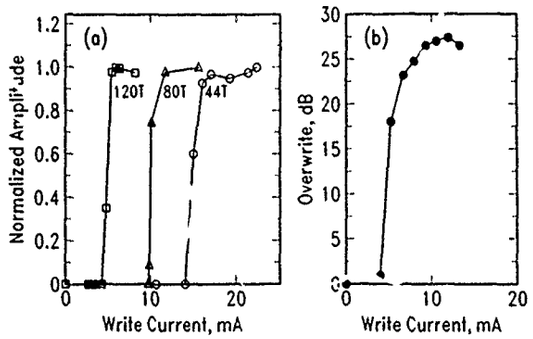

FIG. 7. (a) Threshold write current of a 120- and a 80-turn head with a 44-turn pancake head as reference, (b) overwrite characteristics of a 120-turn 3.1-μm track width head.

Co–Pt–Cr thin-film disk (Mrt=2.5E-3 emu/cm^2, Hc=1500 Oe).
Magnetic spacing=103.3 nm, gap length=0.3 um.
Transition length (W-C model) a=136 nm.

First, the lower coils are plated and later planarized with photoresist. The photoresist is patterned to expose the contacts to the lower coils and then hardbaked. Yokes and studs with easy axis in the x direction are plated in one step. Then, those in the y direction are plated by rotating the wafer 90°. A second photoresist layer is spun and exposed to open the tops of the studs for contacting the upper coils. Notice that the hardbaked photoresist fills the recess between the yoke and the studs and provides a smooth surface with a gentle slope for the subsequent construction of the upper part of the helical coils. Then two more hardbaked photoresist steps are employed to form a 3.7-μm apex spacer between the $P1$ and $P2$ in the pole tip area. Alumina gap material is then deposited and etched open at the "backgap." In this design, the "backgap" is actually located to the left of the apex spacer (see Fig. 2) $P2$ is plated. At this step, the maximum device topography is below 11 μm. The entire yoke, except the short $P2$, is encased in hardbaked photoresist passivation. The yokes have experienced three photoresist hardbake heat cycles and for those with easy axis in the y direction, the oven field is in the hard-axis direction. The micro-Kerr image of the head is shown in Fig. 5 and the domains are oriented in the transverse direction as predicted in our previous studies. The pole tip is trimmed with an ion milling process. Upper coils are then patterned and plated to complete the coils. The head is embedded in a 30-μm-thick alumina overcoat.

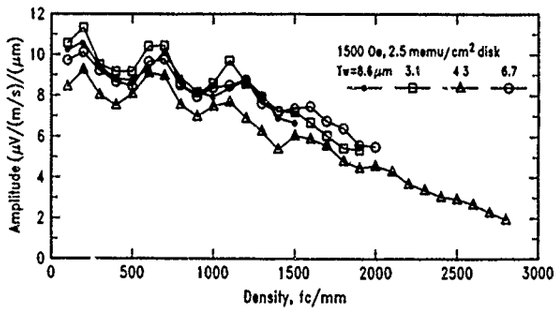

FIG. 8. Density roll-off of four 120-turn heads of different track width on thin-film disk.

The head inductance is shown in Fig. 6. The normalized head inductance is typically 0.382 nH/N^2, about half of today's spiral coils. The coil resistance is 68 and 38 Ω for the 120- and 80-turn heads, respectively, about half of the spiral coils. Heads were tested on Co–Pt–Cr thin-film disks with Mrt=2.5 memu/cm^2 and Hc=1500 Oe at a fly height of 50 nm (estimated magnetic spacing is 103 nm). Figure 7(a) shows the write threshold currents. For the 120-turn head, the threshold current (peak-to-peak) is 5.3 mA. Figure 7(b) shows the overwrite of a head with T_w=3.1 μm at write and overwrite flux density of 490 and 1600 fc/mm, respectively. Table I summarizes the head characteristics. The normalized readback signal is 10.3 μV/(T_wV), where T_w is the track width in μm and V is the linear velocity in m/s. The half-height pulse width PW_{50} is 600 nm. Figure 8 shows the density roll-off plot of four heads with T_w from 8.6 to 3.1 μm. The estimated read efficiency is 60%. The head instability was measured by repeating the erase-write-read operation. The standard deviation divided by the mean value of the readback signals is in the range of 1.5% to 2%. The error rate of the heads were tested in a peak detect channel without an equalizer at a flux change of 1288 fc/mm. The on-track bit-error rate is 6.25×10^{-10} for a 80-turn 8.6-μm track width head and 7.65×10^{-9} for a 120-turn 4.3-μm track width head.

The authors would like to thank K. Ju and J. S. Best for encouragement.

Local magnetoresistance and point-source excitation of Ni-Fe thin films (abstract)

R. W. Cross and A. B. Kos
Electromagnetic Technology Division, National Institute of Standards and Technology, Boulder, Colorado 80303

The magnetoresistive (MR) response was measured in Ni-Fe thin films, representative of the films used in magnetic recording read heads, with sense areas as small as 6×6 μm. For the bulk, central, and edge regions of the film, the MR response was measured as a function of magnitude and angle of a uniform in-plane applied magnetic field. Measurements were made using a four-contact technique which included two scanning microprobes and two orthogonal field sources.[1] The microprobes could be scanned with a resolution of 0.1 μm and positioned separately. The field sources produced a maximum field of 24 kA/m (300 Oe) that could be rotated up to ±15°. From the local MR response, the local magnetic behavior was obtained and compared to micromagnetic theory.[2] The bulk MR response was also measured as a function of position on the film of a microfield source used for point-source excitation. The microfield source was a Fe wire electrochemically etched to a 0.1 μm tip diameter. From these results the local MR sensitivity was determined for the central and edge regions. The sensitivity profile of the film is important in optimizing the design of the device. The large variations observed in the MR response between the central and edge regions as a function of uniform field and point source excitations are indicative of the fact that magnetostatic fields dominate the response in these small structures.

Sensitivity distribution asymmetries in magnetoresistive heads with domain control films (abstract)

N. Koyama, C. Ishikawa, Y. Suzuki, H. Aoi, and K. Yoshida
Central Research Laboratory, Hitachi, Ltd., Kokubunji, Tokyo 185, Japan

Suppression of the sidetrack reading behavior is important in achieving high track-density recording with a magnetoresistive head. In the present work, we investigate the sensitivity distribution profiles of MR heads through experimentation using a microtrack technique[1] and computer simulation. Shielded, soft, adjacent-layer-biased MR heads with 3~6−μm-wide tracks are used. The ends of the MR elements are coupled to antiferromagnetic or hard ferromagnetic films for domain control. In the simulation based on the Landau–Lifshitz–Gilbert equation,[2] the magnetization configurations in the MR elements of the domain stabilizing films are calculated to analyze the sensitivity distribution. The measured sensitivity profiles in all cases have asymmetries that are reversed when the sensing current direction or the magnetization direction of the MR element is reversed. These results agree with the simulation. The asymmetries of sensitivity profiles are explained by the magnetic poles at the domain control film edges and at the transverse edges of the element which generate a diagonal demagnetizing field distribution in the sensing region.

Overlayer-induced perpendicular anisotropy in ultrathin Co films (invited)

Brad N. Engel, Michael H. Wiedmann, and Charles M. Falco
Department of Physics and the Optical Sciences Center, University of Arizona, Tucson, Arizona 85721

We have used *in situ* polar Kerr effect measurements to study the magnetic anisotropy of MBE-grown X/Co/Y trilayers, where X and Y are combinations of the nonmagnetic metals Ag, Au, Cu, or Pd. The competition between the perpendicular anisotropy of the initial underlayer X/Co interface and the in-plane shape anisotropy of the Co film allows us to adjust the total anisotropy of the uncovered Co to be in plane and of moderate strength. In this way, we can measure hard-axis (perpendicular) polar hysteresis curves *in situ* as a function of overlayer Y coverage, and directly deduce the anisotropy field. Polar hysteresis curves were measured *in situ* for systematically varied Co and overlayer Y layer thicknesses 2 Å$\leq t_{Co} \leq$20 Å and 0 Å$\leq t_Y \leq$100 Å. We find, for particular combinations, the magnitude of the X/Co/Y perpendicular anisotropy is strongly peaked at ~1 atomic layer overlayer Y coverage.

I. INTRODUCTION

One of the most interesting unresolved problems remaining in modern magnetism is the underlying mechanism of perpendicular interface anisotropy.[1] This anisotropy arises from the interface between magnetic and nonmagnetic metal films, and is observed only in particular material systems.[2] Possible explanations advanced for this strong anisotropy include the reduced coordination symmetry,[3] altered electronic structure,[4] and localized epitaxial strain at the interface between two different materials.[5]

In this paper we review our recent studies of interface magnetic anisotropy using *in situ* Kerr effect measurements in our molecular beam epitaxy (MBE) system. We have investigated the evolution of the magnetic and structural behavior of ultrathin Co films during the progressive formation of interfaces with different nonmagnetic overlayers.

II. BACKGROUND

There has been a great volume of research on magnetic surface and interface anisotropy since Néel's first prediction[6] and Gradmann's first experimental observation.[7] Investigations into the influence of nonmagnetic overlayers on the behavior ultrathin magnetic thin films have been carried out by many groups. The majority of these studies have concentrated on determinations of the magnetic moment and interface anisotropy resulting from coverage by relatively thick overlayers.

Investigations of the evolving magnetic behavior of an ultrathin film during interface formation have been performed only recently due to the stringent requirements of *in situ*, monolayer-sensitive measurements carried out in ultrahigh vacuum (UHV). Previous evidence of changes in magnetic behavior with nonmagnetic monolayer coverage include a reduction in Curie temperature of ultrathin Co(001) films when covered by Cu[8] and an epitaxial structure-induced change in the in-plane easy axis of Fe(110) films when covered by Au.[9]

In our first work on the magnetic behavior during interface formation, we studied the perpendicular magnetism of MBE-grown Pd/Co/Y sandwich structures where Y=Ag, Cu, and Pd using *in situ* polar Kerr ellipticity measurements.[10] We found the surprising result that deposition of any of the overlayers caused nonmonotonic behavior in the perpendicular coercivity H_c as a function of coverage. We found a sharp peak in H_c at a coverage of $t_Y \approx 2$ Å for all materials with a monotonic increase above $t_Y \approx 4$ Å. The peak was most pronounced for Cu, where H_c changed by more than 200%.

The pronounced peak in coercivity we observed at ~1 ML suggested an abrupt change in anisotropy. We have therefore directly measured the uniaxial anisotropy of Co films *in situ* as a function of nonmagnetic overlayer coverage and confirmed the existence of a peak in the perpendicular anisotropy at ~1 ML coverage as well.[11] This unusual anisotropy behavior also recently has been independently confirmed for Au/Co/Au.[12]

III. EXPERIMENTAL TECHNIQUE

A. Film growth

We used molecular beam epitaxy (MBE) to grow single-crystalline Co films in the thickness range 2 Å$\leq t_{Co} \leq$30 Å on single-crystalline Pd(111) and Au(111) buffer layers. The buffer layers were epitaxially grown on Co-seeded GaAs(110) substrates. The background pressure during deposition was $\leq 5\times10^{-10}$ Torr, and was composed predominantly of H_2. We used effusion cells for Ag and Pd deposition at 0.1 and 0.15 Å/s, respectively, and optical-feedback-controlled e-beam evaporators to deposit the Au(0.1 Å/s), Co(0.25 Å/s), and Cu(0.1 Å/s). All deposition rates were determined from Rutherford backscattering spectrometry analysis of calibration films, and were reproducible to within ±10%. Film quality and crystal structure were monitored during growth with reflection high energy electron diffraction (RHEED). The RHEED pattern images were captured

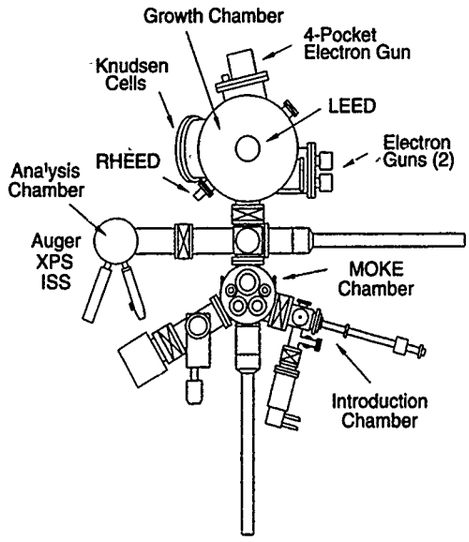

FIG. 1. Schematic representation of our modified Perkin–Elmer 433S molecular beam epitaxy system with *in situ* magneto-optic Kerr effect (MOKE).

and digitized with a computer-based video system capable of resolving changes in surface lattice spacings of 1%.

B. *In situ* Kerr effect measurement

In our MBE system, a sample can be transferred between the deposition chamber and another connected ultrahigh vacuum chamber ($P<2\times10^{-10}$ Torr), where it is aligned between the poles of an external electromagnet for *in situ* Kerr effect measurements. Figure 1 is a schematic of this system. The magnetic field is applied along the sample normal with a maximum field of ±2.2 kOe. We use a 50 kHz photoelastic modulator and lock-in-amplifier-based detection scheme with a HeNe laser to measure the polar Kerr ellipticity of the sample as a function of applied field. Measuring the ellipticity rather than the Kerr rotation eliminates the background Faraday rotation from the quartz vacuum window. Optical access is provided by a hole along the axis of one of the magnet poles. The sample can be moved repeatedly between the measurement and the deposition chambers without the need for optical realignment.

C. *In situ* anisotropy measurement

We grew our samples on Au(111) or Pd(111) buffer layers, so that the initial X/Co (X=Au,Pd) interface would provide a perpendicular anisotropy in competition with the in-plane shape contribution of the Co film. We could therefore adjust the initial total anisotropy of individual samples to be either perpendicular or in-plane by selecting the proper Co film thickness. This allowed us to work within the 2.2 kOe limit of our perpendicular magnetic field. Using this idea of designing samples, which balance the relatively strong shape and interface anisotropies against each other, allows us to very easily observe small changes in the total anisotropy energy due to overlayer deposition.

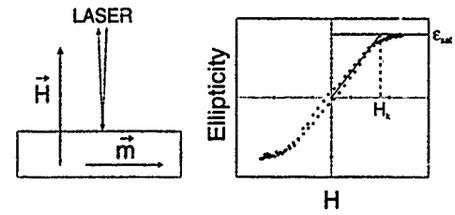

FIG. 2. Schematic of the *in situ* anisotropy energy measurement. The magnetization m lies in the plane of the sample, while the applied field H is perpendicular to the film plane.

To directly determine the total anisotropy energy, we measured hard-axis magnetization curves and deduced the anisotropy field by extrapolating the linear curves to saturation. Because our MBE system is equipped with only a 2.2 kOe perpendicular magnetic field, we are limited to making these measurements on films with in-plane easy axes of moderate anisotropy strength. However, we can create films of this type by selecting the proper Co film thickness that we grow on the Pd or Au buffer layers. Figure 2 is a schematic of this measurement technique.

The properly chosen Co thickness allows saturation of the magnetization by our 2.2 kOe field after overlayer coverage, while still maintaining an in-plane easy axis. In this way we can directly determine the anisotropy field from extrapolation of the hard-axis curves to saturation and calculate the total anisotropy energy from the relation

$$K_1=H_kM_s/2, \tag{1}$$

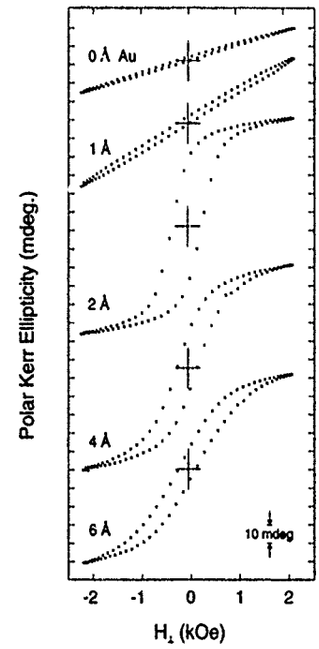

FIG. 3. Hard-axis (perpendicular) hysteresis curves from a 30 Å Co film grown on Au(111) as it is progressively covered with Au. The perpendicular anisotropy contribution from the Co/Au interface is seen to be a maximum at 2 Å Au coverage.

where M_s=1422 emu/cm^3 is the bulk saturation magnetization of Co. Refinement of this technique to include higher-order anisotropy constants was found to be unnecessary for the majority of samples studied. To assure the validity of this technique, after completing our complete set of *in situ* measurements we removed representative samples and verified the bulk magnetization behavior of the Co with a vibrating sample magnetometer. We also verified the saturation ellipticity $\epsilon_{sat.}$ with an *ex situ* Kerr measurement to 10 kOe.

IV. RESULTS AND DISCUSSION

A. Anisotropy versus coverage

Figure 3 is a series of hard-axis (perpendicular) hysteresis loops of a 30 Å Co film grown on Au(111) and covered by ultrathin overlayers of Au. The top curve is that of the uncovered film; the linear behavior indicates that it has an in-plane easy axis. However, upon coverage by 1 Å of Au (slightly less than one-half of a monolayer) the slope increases. This indicates the Co/Au interface has contributed a perpendicular component to the anisotropy, although the overall easy direction still remains in plane. Continuing the coverage to 2 Å Au causes a further increase in the perpendicular component of the anisotropy, allowing the magnetization to be saturated by our 2.2 kOe field. It is clear from the figure that further Au coverage above 2 Å then decreases the perpendicular anisotropy contribution.

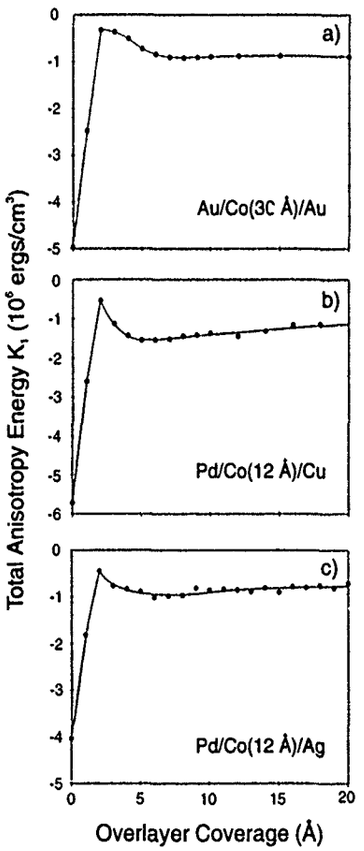

FIG. 4. Total magnetic anisotropy energy vs overlayer coverage for X/Co/Y structures, where (a) Au/Co(30 Å)/Au; (b) Pd/Co(12 Å)/Cu; and (c) Pd/Co(12 Å)/Ag. Pronounced peak at 2 Å coverage is evident for all three overlayer materials.

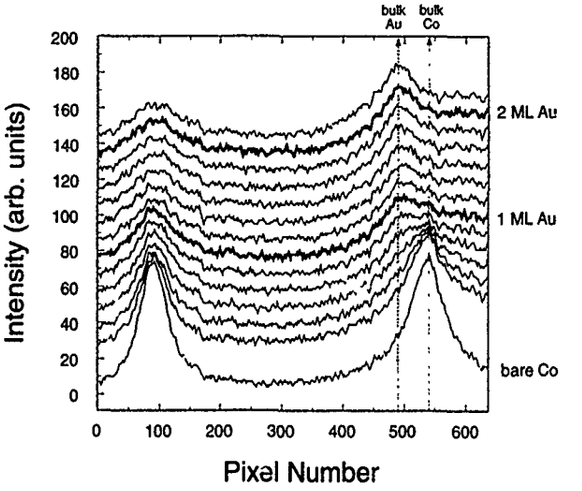

FIG. 5. Time-evolution series of line intensity profiles measured across the RHEED pattern of a Co surface as it is progressively covered by Au. Heavier traces indicate approximate coverage equivalents of 1 and 2 ML. The Au growth is found to be incoherent and strain-free from the first stages of coverages. See the text for a discussion.

Because we can saturate the moments in this sample, we are able to deduce the anisotropy field from extrapolation of the hard-axis curve to saturation and hence directly calculate the total anisotropy energy. Figure 4(a) is a plot of the anisotropy constant K_1 vs Au coverage. Here we have adopted the convention used by many researchers, where a positive K_1 indicates perpendicular anisotropy. The most striking feature is the pronounced peak at ~2 Å coverage, which, to within our resolution and control, is located just below 1 ML of Au. The total anisotropy energy displays the same nonmonotonic behavior with Au coverage we observed in the coercivity of the perpendicular films discussed earlier.[10] Above 2 Å Au coverage, the total anisotropy becomes increasingly negative, indicating a reduction of the perpendicular contribution. The overall negative anisotropy values of Fig. 4(a) indicate an in-plane easy axis was maintained throughout the coverage range for this particular Co thickness.

Figures 4(b) and 4(c) are plots of the total anisotropy energy of 12 Å Co films as a function of Cu and Ag overlayer coverage, respectively. A pronounced peak in the perpendicular anisotropy is also evident at 2 Å coverage for both of these materials.

B. Changes in crystal structure

The role of crystal structure in our observed coverage-dependent anisotropy is an important question that is difficult to address. Because magnetic anisotropy is very sensitive to the local environment, subtle changes in atomic spacings could cause significant effects. We have used RHEED to investigate coverage-dependent changes in the surface lattice spacing. However, it must be emphasized that the RHEED

geometry measures only the in-plane spacings. Information about the out-of-plane spacings can, in principle, be obtained from low energy electron diffraction (LEED) intensity versus voltage measurements. These are presently in progress and will be presented at a later date.

Figure 5 is a series of intensity profiles measured across a RHEED streak pattern showing the time evolution of a Co surface as it is progressively covered with Au. The starting surface is a freshly prepared 30 Å Co film deposited on a 500 Å Au(111) buffer layer. The RHEED images were captured every 4 s during uninterrupted Au deposition at a rate of 0.1 Å/s, giving a coverage interval between traces of ~0.4 Å. Approximate coverage equivalents of one and two atomic monolayers are indicated with heavier traces in the figure. The distance (pixel number) between the specular beam maximum on the left and the diffracted beam maximum on the right is inversely proportional to the surface lattice spacing measured transverse to the *e*-beam direction.

The first profile from the bare Co surface shows intensity maxima that are sharp and symmetric. Upon partial coverage with just 0.4 Å Au, or roughly 1/6 ML, the diffraction peak becomes asymmetric with a shoulder forming at smaller pixel number, and hence larger lattice spacing. This indicates that the Au grows incoherently and unstrained at its larger bulk lattice constant in the very early stages of deposition. This incoherent growth is similar to that seen for Co grown on bulk single-crystal Pd(111),[13] and is not surprising in view of the large 14% lattice mismatch between Au and Co. At the coverage equivalent of 1 ML (2.4 Å), the diffraction peak is composed of contributions from both bulk Au and bulk Co spacings. After 2 ML of coverage, the peak is dominated by diffraction from the bulk Au spacing.

These measurements suggest that because the Au immediately grows incoherently and strain-free, the Co in-plane lattice spacing is unaffected by the Au overlayer. Hence, magnetoelastic anisotropy arising from an in-plane strain in the Co is unlikely to account for our observed peak in perpendicular anisotropy at 1 ML. In addition, the fact that overlayers of very different lattice mismatch with Co (2% for Cu and 14% for Au) display similar anisotropy behavior further supports this conclusion.

C. Changes in electronic structure

Another possible explanation of the observed coverage-dependent anisotropy is that the magnetic interface anisotropy is very sensitive to details of the electronic band structure.[4] Recent photoemission measurements of Cu monolayers deposited on ferromagnetic transition metals have found electronic states that deviate significantly from bulk behavior.[14,15] If the hybridization of electronic states at the Co/*Y* interface plays an important role in magnetic anisotropy, then variations of the overlayer band structure could cause significant alterations of the total anisotropy. It is interesting to note that the very recent photoemission measurements of 1 ML of Cu deposited on Co(0001) found the Cu peak at significantly lower binding energy than that of bulk (a shift of approximately 0.25 eV).[14] With further Cu coverage the bulk peak rapidly emerged, so that by 2 ML only the bulk Cu peak remained. This coverage dependence of the Cu electronic band structure is very similar to what we observe for the magnetic anisotropy of our Co/Cu structures. This suggests a possible relation between the two phenomena, although more work is needed before this can be uniquely determined.

D. Co/vacuum interface anisotropy

In Fig. 4, the initial total anisotropies of the uncovered Co films are strong and in-plane (negative K_1). As the overlayer coverage is increased from 0 to 2 Å, the magnitude of this anisotropy energy rapidly approaches zero, indicating the presence of an increasing perpendicular contribution for each of the materials Au, Cu, and Ag. In the cases of Ag and Cu, this large increase in perpendicular anisotropy after overlayer coverage is surprising, in light of the very weak interface anisotropy displayed in Co/Ag and Co/Cu multilayers.[16] One possibility is the existence of a large, in-plane Co/vacuum interface anisotropy that is being replaced by a perpendicular contribution from the forming Co/*Y* interface. Such a large in-plane vacuum interface anisotropy has recently been observed in FCC Co(100) films.[17]

We can estimate the strength of the Co/UHV interface anisotropy, K_s^{UHV}, by calculating the difference between the total anisotropy energy of the uncovered and completely covered Co films of Fig. 4. The total anisotropy of the uncovered film can be written as

$$K_u = K_v + \frac{K_s^X}{t_{\mathrm{Co}}} + \frac{K_s^{\mathrm{UHV}}}{t_{\mathrm{Co}}}, \tag{2}$$

where K_v is the volume anisotropy including crystalline and shape contributions, K_s^X is the interface anisotropy from the Co/substrate interface, and t_{Co} is the Co film thickness.

If we now make the reasonable assumption that there is no change in volume or substrate interface anisotropy upon complete coverage by the nonmagnetic overlayer, then K_u after coverage can be written as

$$K_u' = K_v + \frac{K_s^X}{t_{\mathrm{Co}}} + \frac{K_s^Y}{t_{\mathrm{Co}}}. \tag{3}$$

Here the UHV interface has been completely replaced by the *Y* overlayer.

Taking the difference between Eqs. (2) and (3) gives for the Co/UHV interface anisotropy

$$K_s^{\mathrm{UHV}} = \Delta K_u t_{\mathrm{Co}} + K_s^Y. \tag{4}$$

Using values from the multilayer literature[2] for K_s^Y (Y=Au, Ag, and Cu) yields a range of values $-0.2 \leq K_s^{\mathrm{UHV}} \leq -0.5$ erg/cm^2, depending on the substrate/overlayer combination. These variations may be due to changes in volume anisotropy not accounted for in this analysis. However, all the estimates suggest a fairly strong in-plane Co/UHV interface anisotropy for the FCC (111) face. More work is needed to refine these values.

V. SUMMARY

We have used *in situ* polar Kerr ellipticity measurements to study the perpendicular magnetic behavior of MBE-grown *X*/Co/*Y* sandwich structures, where X=Au and Pd and

Y=Ag, Au, and Cu. For all three nonmagnetic overlayer materials, we find a rapid increase in the perpendicular anisotropy after only 2 Å (~1 ML) overlayer coverage. We find this perpendicular anisotropy is anomalously peaked at a coverage of ~1 ML and decreases significantly with further overlayer deposition. From these measurements, we find the Co(111)/UHV interface anisotropy to be strong and in plane. The unusual coverage-dependent anisotropy presented here will provide an additional test for theoretical explanations of the magnetic anisotropy at surfaces and interfaces in layered metallic systems.

Interfacial anisotropy and magnetic transition of cobalt films on Cu(111)

F. Huang, G. J. Mankey, and R. F. Willis
Department of Physics, The Pennsylvania State University, University Park, Pennsylvania 16802

We measure the magnetic properties of ultrathin films of Co epitaxially grown on single crystal Cu(111) using surface magneto-optic Kerr effect. The magnetic behavior is compared with that of the same films, but covered by Cu overlayers to study the effects of film morphology on ferromagnetism. The uncapped films show mainly in-plane anisotropy, but a weak perpendicular magnetization is always present. Capping a 1.5 monolayer (ML) Co film with Cu significantly enhances perpendicular anisotropy with 1 ML of Cu overlayer eliminating the in-plane magnetization completely. The perpendicular magnetization reaches its maximum value with 3 ML of Cu overlayer, ~5 times higher than the uncapped films, and then decreases as more Cu is deposited. Annealing can further increase the perpendicular magnetization with the in-plane component remaining weak. In sharp contrast, this perpendicular anisotropy enhancement by Cu overlayers is not seen for Co films on Cu(100). The temperature dependence of magnetization fits to the phenomenological power law $M \sim (1 - T/T_C)^{\beta}$ with $\beta = 0.15 \pm 0.05$ for the uncapped 1.5 ML Co film and shows a linear behavior after the film is covered by Cu overlayers.

INTRODUCTION

Cu-coated polycrystalline thin films of Co grown on Cu(111) have been shown to have strong perpendicular anisotropy and exhibit Ising behavior over a wide temperature range.[1] This is an interesting result, since as-grown Co films generally show in-plane anisotropy,[2,3] and Ising behavior is usually observed in highly flat single crystal films with strong uniaxial anisotropy.[4,5] The crucial factor could be the Cu overlayer, which tends to enhance the perpendicular anisotropy. This enhancement has been previously reported in many sandwich systems, such as Au/Co/Au(111),[6] Pd/Co/Pd(111),[7,8] Cu/Co/Pd(111)[8] and Ni/Co/Ni superlattices.[9] However, the question of what happens to the magnetic phase transition behavior when the anisotropy is deliberately altered, e.g., by transition metal coating, remains open.

In this paper, we report measurements of ultrathin Co films grown on a Cu(111) single crystal. The magnetic properties are compared with those of the same films but covered by Cu overlayers. Using the magneto-optic method, we have investigated the anisotropy, magnetic transition behavior, and the effects of crystal symmetry on the magnetic properties.

EXPERIMENTAL

Thin Co films were grown at room temperature on a Cu(111) single crystal using molecular beam epitaxy (MBE). The Cu crystal was cut along the [11] direction within 0.5° using x-ray alignment. It was mechanically polished down to 0.05 μm followed by electropolishing before being introduced into the vacuum. After a few cycles of 500 eV Ar^+ bombardment and annealing to 700 K for hours, the crystal was free of contamination as determined by Auger electron spectroscopy (AES) and showed a sharp $p(1\times1)$ low-energy electron diffraction (LEED) pattern.

Film thickness was controlled by quartz crystal microbalance calibrated with reflection high-energy electron diffraction (RHEED) oscillations. Co on Cu(111) does not show RHEED oscillations, although it has been shown to be a good epitaxial system with metastable FCC layer-by-layer growth up to three monolayers of Co.[10,11] However, Co on Cu(100) does have well-resolved RHEED oscillations, and can be used to calibrate the film thickness for Co on Cu(111). Since the atomic area density of Cu(100) is 86.6% of the Cu(111) surface, the thickness on Cu(111) is 86.6% of that on Cu(100), given the same amount of deposited material.

Magnetic properties were studied *in situ* using surface magneto-optic Kerr effect (SMOKE) in the UHV chamber with a base pressure lower than 2×10^{-10} mbar. The external magnetic field can be applied both parallel and perpendicular to the film plane to detect longitudinal and polar hysteresis loops, respectively. To study the magnetic transition, the Kerr intensity (retentivity of the hysteresis loops) was measured as a function of substrate temperature, which was ramped at a constant rate of 6 K per second. Assuming the transition follows a phenomenological power law $M \sim (1 - T/T_C)^{\beta}$, we fit the Kerr intensity data to obtain the Curie temperature T_C and power law exponent β.

RESULTS AND DISCUSSION

The ultrathin Co films on Cu(111) have predominantly in-plane anisotropy, but a weak perpendicular magnetization with high coercivity is always present. Generally, a mild annealing reduces the coercivity and increases the perpendicular magnetization. However, a more dramatic change in anisotropy is seen from the effect of a Cu coating. As shown in Fig. 1 for a 1.5 ML of Co film, one monolayer of Cu completely wipes out the in-plane hysteresis loop and enhances the perpendicular magnetization by a factor of 3. At the same time, the coercivity of the perpendicular loop is significantly reduced. This trend continues until a Cu overlayer thickness of three monolayers, where the perpendicular magnetization is nearly five times higher than the uncovered film, Fig. 2.

The enhancement of perpendicular anisotropy by transition metal overlayers can be counted for by two competing anisotropies: a surface anisotropy that is due to reduced symmetry at the surface and favors perpendicular spin orientation; and a shape anisotropy, which tends to orient the magnetization parallel to the film plane and increases with

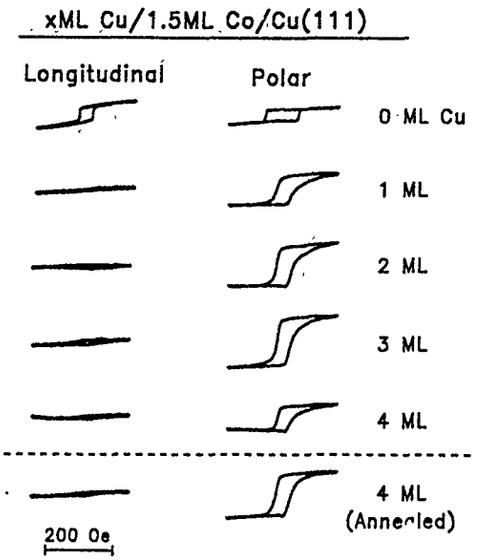

FIG. 1. Longitudinal (in-plane) and polar (perpendicular) hysteresis loops of x ML Cu/1.5 ML Co/Cu(111) measured at room temperature (x =0,1,2,3,4). The loops under the dashed line are for the 4 ML Cu/1.5 ML Co/Cu(111) film after annealed to 600 K.

increasing film thickness. A balance between these competing anisotropies determines the overall direction of the magnetization of the film. The Cu overlayers provide a second interface, which increases the surface anisotropy and orient the spins perpendicular to the film plane.

Also shown in Fig. 1 is the annealing effect on the thin film anisotropy. For the same Co film with 4 ML of a Cu overlayer, the perpendicular loop is much larger after annealing to 600 K. Similar results have also been observed in Fe–Pd alloy films.[12] The similarity between annealing and Cu capping suggests that annealing causes Cu segregation on top of Co to form an overlayer,[13] and hence changes the surface anisotropy. In addition, annealing changes the microstructure of the film, such as roughness and lattice mismatch-

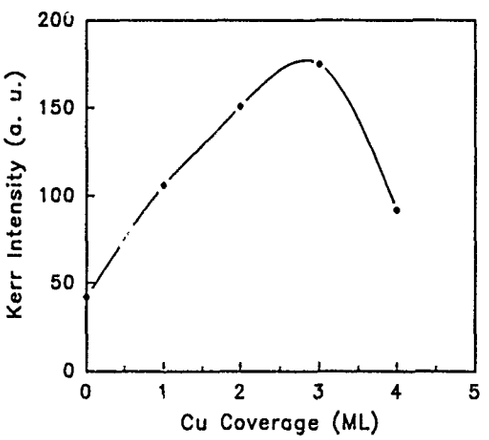

FIG. 2. Polar Kerr Intensity of x ML Cu/1.5 ML Co/Cu(111) films as a function of Cu overlayer thickness x, showing the enhancement of perpendicular magnetization by Cu capping.

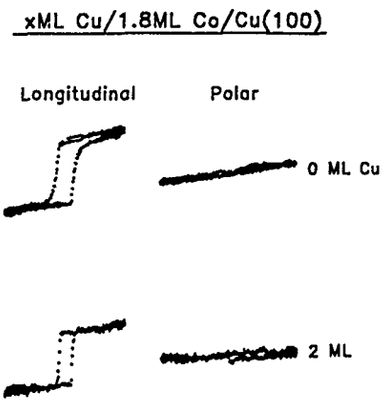

FIG. 3. Longitudinal and polar hysteresis loops of 1.8 ML Co/Cu(100) measured at 150 K before and after the coverage of 2 ML of Cu.

induced strains, which can give rise to a modified magnetocrystalline and magnetoelastic surface anisotropy.[14]

This is in sharp contrast to the same experiment on Cu(100) shown in Fig. 3, where the hysteresis loops of a 1.8 ML Co film are compared before and after 2 ML of Cu coverage. The magnetization of ultrathin Co films on Cu(100) lies in plane. Cu capping has little effect on both parallel and perpendicular loops. This is consistent with the Brillouin light scattering measurements,[15] which showed that Cu capping can increase the perpendicular surface anisotropy (k_s from -0.46 to 0.15 erg/cm^2) for the Co films on Cu(100) at thicknesses larger than d_C ~2 ML. However, below d_C, where the uncovered Co films already have positive k_s, it remains nearly the same after Cu capping.

The [111] direction is the easy axis for a bulk Co crystal. Thin films of Co grown on (111) FCC surfaces have a much stronger perpendicular anisotropy than those grown on the (100) surfaces due to magnetocrystalline anisotropy. For example, the magnetization of Co was found to experience a crossover from perpendicular to in plane at about 1–2 ML on Pd(100) and at 6 ML on Pd(111).[16] Cu capping generally enhances the perpendicular anisotropy, but this change could be small compared with the strong in-plane anisotropy on the (100) surface.

Figure 4 shows the magnetic phase transition behavior of a 1.5 ML of Co on Cu(111), comparing before and after Cu capping. For the uncovered film (solid circle), the Kerr intensity was taken from the in-plane hysteresis loops. Fitting to the power law $M \sim (1-T/T_C)^{\beta}$ gives $\beta=0.15\pm0.05$. Although it is close to the Ising β value of 0.125, this is by no means an ideal Ising system, due to the presence of both in-plane and perpendicular anisotropy, and the pronounced finite size rounding above T_C (Fig. 4). The Cu-capped same Co film (open circle) displays a strong perpendicular anisotropy. However, the polar Kerr intensity now decreases linearly with increasing temperature. The linear decrease of magnetization with temperature is often associated with the formation of islands and clusters, which exhibit superparamagnetic behavior over a broad range of temperature and cluster sizes.[17,18] These superparamagnetic islands and lateral inhomogeneities lead to a fast linear decrease at lower tem-

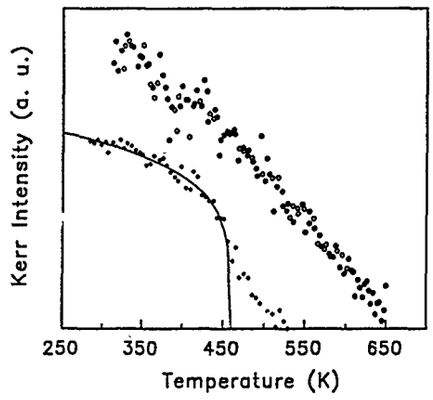

FIG. 4. Kerr intensity as a function of temperature comparing the 1.5 ML Co/Cu(111) film (●, longitudinal) and the same film but covered by 4 ML of Cu (○, polar). The solid line is the power law fit with T_C=460 K and β=0.15.

peratures. Similar results have also been reported in Mössbauer studies.[19,20]

These results are very different from those reported in Ref. 1, which showed that the magnetic phase transition of a monolayer Co follows the exact Ising behavior. The Co film, quite different from our single crystal Co films, was prepared on the polycrystalline Cu(111) grains grown on sapphire ($11\bar{2}0$) surface then coated with Cu before taken out to the air for the torsion oscillation magnetometry measurements. Although we cannot say for sure what has caused or destructed the Ising character, the different film surface and interface microstructure is certainly playing an important role in determining the magnetic critical behavior. More experiments are underway to study the structure–property relationships.

SUMMARY

We have observed a dramatic enhancement of the uniaxial perpendicular anisotropy by depositing Cu overlayers on Co films on Cu(111). One monolayer of Cu on top of a 1.5 ML Co(111) film can raise the perpendicular magnetization by a factor of 3, reduce the coercivity by a factor of 2, and eliminate the in-plane magnetization completely. Annealing has the similar effect to Cu capping on anisotropy due to changes in film microstructure and copper segregation at the free surface. The anisotropy change induced by Cu overlayers is small for Co films on Cu(100). The uncovered film exhibits a power law behavior with β=0.15±0.05, in contrast to the linear temperature dependence of magnetization for the Cu-capped same film. These results emphasize the dramatic role of the interface properties in determining the magnetic behavior of magnetic superlattices and sandwich systems.

Local spin-density theory of interface and surface magnetocrystalline anisotropy: Pd/Co/Pd(001) and Cu/Co/Cu(001) sandwiches

Ding-sheng Wang,[a] Ruqian Wu, and A. J. Freeman
Department of Physics and Astronomy, Northwestern University, Evanston, Illinois 60208-3112

The interface magnetocrystalline anisotropy (MCA) of Cu/Co/Cu(001) and Pd/Co/Pd(001) sandwiches are investigated, employing our recently developed state tracking approach based on the full potential linearized augmented plane wave energy band method. The strong negative MCA energy for the Co monolayer is found to be decreased for Co/Cu, and even becomes positive for Co/Pd due to the interfacial hybridization, which reduces the spin orbit coupling (SOC) between the $d_{xz,yz} - d_{z^2}$ pair at $\bar{M}$.

Although some first principles calculations of the magnetocrystalline anisotropy (MCA) energy for interfacial systems have been carried out (e.g., for X/Co/X(111) with X=Cu, Ag, and Pd[1]), a simple physical picture has not been provided due to the strong numerical random fluctuations in the results (with respect to both the occupation and number of k points).[2] Based on our recently proposed state tracking approach[3] and the full potential linearized augmented plane wave (FLAPW) method, we found a close relationship between the MCA energy and the electronic structure for reduced symmetry systems. The strong negative MCA energy of the Co monolayer,[4] for example, results mainly from the spin–orbit coupling (SOC) perturbation between antibonding z^2 and bonding $xz(yz)$ states near $\bar{M}$.[4,5] Interfacial hybridization was found to affect the MCA in the Co layer mainly via the reduction of the SOC perturbed energy between this pair by enlarging their energy separation (in Co/Cu)[5] or by changing their occupancies (in Co/Pd).[6]

In this paper we discuss the calculated results of the MCA energy for Cu/Co/Cu(001) and Pd/Co/Pd(001) sandwiches and reveal the underlying physics. A five layer slab model is adopted to simulate the interfaces with the Co atom lying at the ideal position in the substrate lattices (without possible atomic relaxation). From the well-converged charge density and potential obtained through the semirelativistic FLAPW calculations, the SOC induced change of the total energy is derived from a second variational procedure,[3] i.e., based on a force theorem[7] and the state tracking approach.[3] Summation over 66 k points in the $\frac{1}{8}$ irreducible two-dimensional BZ (corresponding to 400 k points in the full BZ) is found to be sufficient to provide stable MCA energies.

It is well known that the MCA is determined by the SOC interaction between the occupied and the empty valence states ($3d$ for Co). Due to the lowered symmetry at surfaces and interfaces, the MCA energy depends on the second-order perturbation of the SOC Hamiltonian ($H^{soc}=\xi \mathbf{s}\cdot\mathbf{L}$). Therefore, any coupling through $L_{x,y}(L_z)$ will favor the in-plane (perpendicular) MCA. For the free-standing Co monolayer, the coupling (through $L_{x,y}$) between the $d_{xz,yz}$ bonding and the d_{z^2} antibonding states dominates around $\bar{M}$ and most parts of the BZ—resulting in a strong negative MCA energy (−1.35 eV/atom).

Upon contact with a nonmagnetic substrate at the interface, the energies and the wave functions of the Co-d_{z^2} and Co-$d_{xz,yz}$ states (both point out of the plane) will be changed by the interfacial hybridization. Figure 1 presents the energy positions of the hybridized states at $\bar{M}$ for Cu/Co/Cu(001) and Pd/Co/Pd(001) sandwiches and their components projected back to the states for the free-standing Co monolayer. For the Cu/Co/Cu system, the out-of-plane $d_{xz,yz}$ states is pulled down by the Cu d bands, while the Co-d_{z^2} state remains almost unaffected, since it separates far from the Cu-d bands in energy. By contrast, at the Co–Pd interface, both Co-$d_{xz,yz}$ and Co-d_{z^2} states are strongly affected. A substantial component (53%) the Co-$d_{xz,yz}$ wave function is now in the hybridized states, which are shifted upward by about 0.7 eV—already lying slightly above E_F.

These hybridizations are expected to affect the strength of the SOC perturbation between the Co-$d_{xz,yz}$ and the Co-d_{z^2} states, and thus the MCA energy. Figure 2 gives the band filling dependences of the MCA energies for the Cu/Co/Cu and Pd/Co/Pd sandwiches. For comparison, the MCA energy of a free-standing Co monolayer is also shown in Fig. 2, which exhibits the band filling dependence typical for $3d$ transition metal monolayers.[3] It is characterized by the strong

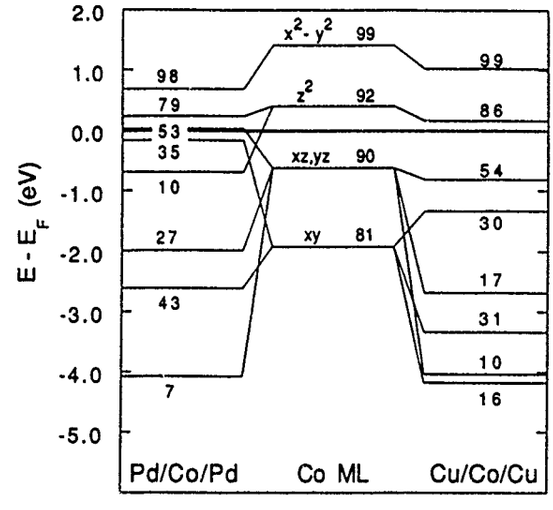

FIG. 1. Comparison of the effect of the Co–Pd and Co–Cu interface on the Co-d electron states at $\bar{M}$. Numbers are the percentage of the Co-d component inside the Co muffin-tin spheres.

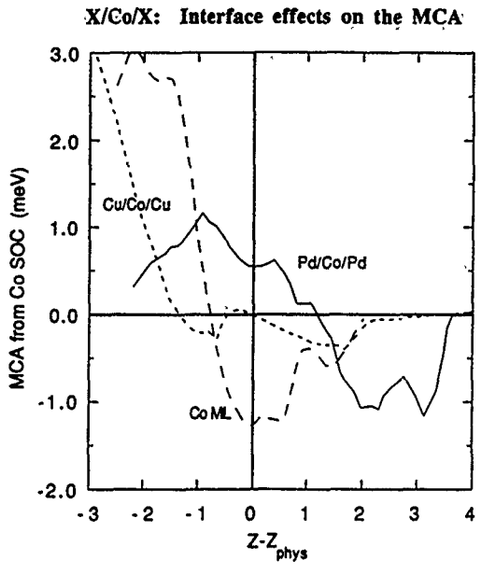

FIG. 2. Comparison of the effect of the Co–Pd and Co–Cu interface on the MCA contribution calculated when only the SOC inside the Co muffin-tin spheres is included. Results are plotted as a function of the number of valence electrons by employing a rigid band approximation. Long-dashed, short-dashed, and solid lines are for Co ML, Cu/Co/Cu, and Pd/Co/Pd sandwiches, respectively. (A Gaussian broadening with full width of 40 meV was employed.)

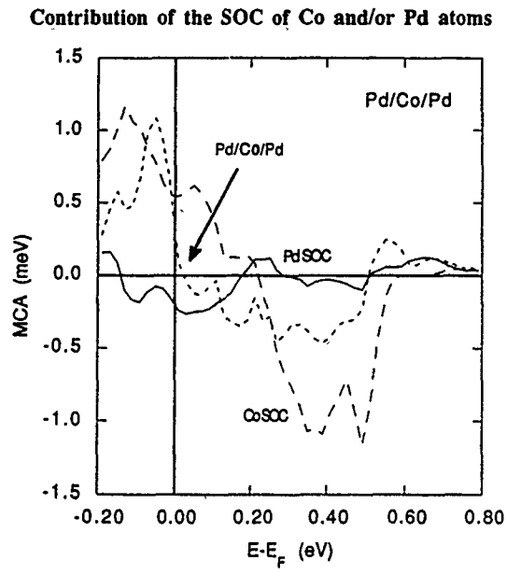

FIG. 3. MCA of the Pd/Co/Pd(001) sandwich (solid line), and the contribution of the Co SOC (long dashed line) and the contribution (per Pd atom) of the Pd SOC, plotted as a function of the highest occupation energy. (A Gaussian broadening with a full width of 40 meV was employed.)

negative peak at about half-occupation of the spin-down d band and a change of the MCA sign at a slightly smaller occupation.

Obviously, for Pd/Co/Pd the negative peak of the MCA is still as strong as for a free-standing monolayer, but its position has been largely shifted to the larger band filling region. This behavior is caused mostly by the change of the upward shift of the out-of-plane $d_{xz,yz}$ bands (cf. Fig. 1) into the empty part, and thus the reduction in the negative MCA energy results from the SOC (through L_x) between the Co-d_{z^2} and Co-$d_{xz,yz}$ states. As a result, a positive MCA energy for Pd/Co/Pd, 0.55 meV (only SOC for a Co atom), is achieved at the physical value of band filling. This behavior is in some sense very similar to the origin of the positive MCA energy for a free standing Fe monolayer[8] according to the relative position of the $d_{xz,yz}$ states, with respect to E_F. In the case of a free standing Fe monolayer, the $d_{xz,yz}$ is empty because there is one less electron/atom, but for the Co/Pd interface, it is due to the upward shift of the bonding Co-$d_{xz,yz}$ states.

This behavior is in clear contrast to the behavior of the Co–Cu interface, where only the magnitude of the negative MCA energy peak is greatly reduced, and the change of MCA sign is shifted to the region with lower band filling (short dashed line in Fig. 2) due to the downward shift of the out-of-plane bonding bands. This is expected, since, as shown in Fig. 1, the Co-$d_{xz,yz}$ state is drawn down by the lower-lying Cu-d bands, while the Co-d_{z^2} state remains almost unaffected.

Now it is clear that the effects of the nonmagnetic substrates on the MCA in the Co layer arise mainly from the hybridization with the Co-d_{z^2} and Co-$d_{xz,yz}$ states. Obviously, also as revealed in an effective ligand interaction model (ELIM),[5] (i) the energy separation between the Co and substrate d bands; and (ii) the strength of the interfacial hybridization play the key roles in determining the MCA energy. The stronger the hybridization, the more the perpendicular MCA prevails. This explains the difference between two groups of substrates on the Co MCA (i.e., perpendicular MCA with Pd, Au, and Ir, and in-plane MCA with Cu and Ag).

Finally, beyond the effects of the chemical interaction discussed above, the SOC in the substrate may also affect the MCA in the magnetic layer. In the Cu/Co/Cu sandwich, the spin-polarization of the Cu bands is small, and thus the effects of the SOC in Cu muffin-tin spheres are negligible.[5] However, in the case of Co–Pd, the strong exchange interaction produces an appreciable spin-polarization at the Pd sites ($M=0.20-0.37\mu_B$). Meanwhile, as is known, the SOC constant, ξ, of the heavier Pd atom is about three times larger than that for Co. Therefore, the contribution to the MCA of the substrate Pd atoms becomes comparable with that from the SOC in the Co layer.

The results of the MCA contribution (per Pd atom) calculated with only the SOC of the Pd atoms is given in Fig. 3. Although the magnitude of this contribution is still smaller than that from the Co SOC, it is obviously not negligible, as in the case of the Cu substrate. Since in the structure employed each unit cell contains four Pd atoms (versus one Co atom), the contribution from the Pd SOC becomes even more prominent in determining the total MCA (per unit cell). The total MCA calculated with the SOC in both Co and Pd muffin-tin spheres is also shown in Fig. 3. It is seen to be not simply the sum of the two contributions obtained by including the Co or Pd SOC separately, because the MCA comes

from the second-order SOC perturbation, and so cross terms should also exist. Note that the general trend of the variation of the total MCA with respect to the band filling follows approximately the curve of the contribution from the Co SOC only. This shows that the magnetic Co layer plays the most important role in determining the MCA behavior of this interface, although inclusion of the Pd SOC does make a difference. The resultant MCA becomes 0.23 meV (per unit cell) compared to 0.55 meV when only the Co SOC is considered.

We have grown face-centered cubic (FCC) (111)- and (001)-oriented Co_xPd_{1-x} alloy films ($x \approx 0.20-0.25$) by molecular beam epitaxy on (111)Si and (001)MgO substrates, respectively, with thicknesses ≈200–1000 Å. Magnetization (SQUID) measurements show that both (111) and (100) films present a perpendicular easy axis, indicating that a strong magnetic anisotropy overcomes the demagnetizing field favoring the in-plane orientation. We have studied this magnetic anisotropy by combining SQUID and torque measurements. Our experimental results cannot be accounted for by only invoking the magnetocrystalline anisotropy of a disordered solid solution of Co in FCC Pd, and rather indicate an anisotropic distribution of Co in the Pd host.

There has been significant interest in the use of Co/Pd multilayers for magneto-optic recording, due to the observed perpendicular magnetization of ultrathin Co layers, and the large magneto-optical Kerr rotation measured in these materials.[1] More recently, it has been found that Co–Pd alloys, deposited by evaporation, electrodeposition, or sputtering with a (111) texture, also display perpendicular anisotropy and a large magneto-optical constant.[2–5] Whereas the origin of perpendicular anisotropy in Co/Pd multilayers is usually attributed to magnetic interface anisotropy, the source of anisotropy in Co–Pd alloys has not been fully explained. In this paper, we present the fabrication and study of Co–Pd alloys fabricated, for the first time, using molecular beam epitaxy (MBE). The advantage of the MBE approach is to allow the simultaneous study of films prepared in various orientations, using different single-crystal substrates. In this manner, the dependence of the magnetic anisotropy on crystalline orientation can be explored.

Samples were grown by MBE onto single-crystal (111)Si or (100)MgO substrates, with substrate temperatures $T_S \approx 80$ °C, using separate effusion cells for Pd and Co. The growth rate of the alloy films was ≈6 Å/min. (111)Si substrates were cleaned chemically prior to their introduction in the vacuum, and deoxidized by heating above 800 °C in ultrahigh vacuum (UHV). Prior to the deposition of Co–Pd, a 75 Å-thick buffer layer of (111)Ag was deposited, primarily to prevent a chemical reaction of the alloy with the substrate. In the case of (100)MgO, substrates were cleaned in UHV by heating to 450 °C for 20 mins. A 15 Å Fe buffer layer was then deposited at 80 °C, to provide a flat (100) surface for the growth of the alloy.

Figure 1(a) shows the 10 keV reflection high-energy electron diffraction (RHEED) pattern obtained after growth of a 600 Å-thick nominal $Co_{0.25}Pd_{0.75}$ sample on (111)Si. This pattern, which upon rotation is found to be sixfold symmetric in the plane of the sample, is characteristic of epitaxial growth, at least over lateral distances greater than the electron coherency length (a few hundred Å). The broadening of the lines and slightly diffuse background indicates contributions from misoriented regions in the sample. The θ–2θ x-ray diffraction pattern of this sample is shown in Fig. 2(a), where it can be seen that the main contribution to the diffraction (besides the Si substrate) is the face-centered cubic (FCC) (111) peak of the alloy. The peak shape is slightly asymmetric, suggesting a slight distribution of Co concentrations within the area sampled by the x-ray beam, or a distribution of lattice constants due to epitaxial strain near the Ag/CoPd interface. The position of the peak maximum yields a lattice spacing of $a = 3.826$ Å, which corresponds to a Co concentration of 19 at. %, assuming a linear deviation from the bulk Pd parameter (3.890 Å) toward the bulk FCC Co parameter (3.544 Å). The electron diffraction pattern of this sample, obtained in cross section, is shown in Fig. 1(b). In addition to the bulk Si contributions, one clearly sees a strong contribution (#1) along the growth axis, which is related to the (111) FCC peak of the Co–Pd alloy. We also observe additional weak off-axis contributions (#2) from (200) and (111) peaks. Their existence and position indicate that part of the sample is well crystallized with its ⟨110⟩ FCC axis parallel to the ⟨110⟩ axis of Si. A detailed analysis of these contributions reveal that this part of the alloy is twinned along the ⟨111⟩ FCC growth axis. Finally, a close examination of the pattern reveal other contributions (#3), which are randomly located in a circle corresponding to the

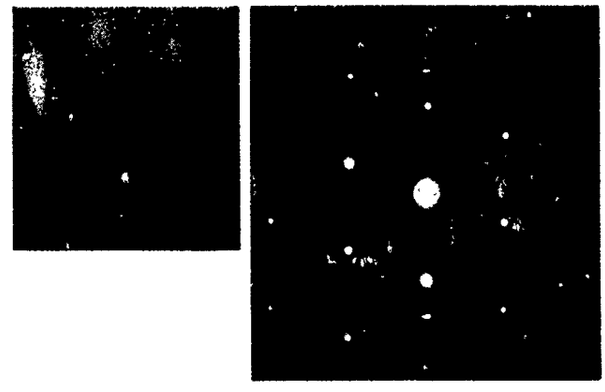

FIG 1. (a) RHEED pattern obtained after deposition of a 600 Å film of $Co_{0.25}Pd_{0.75}$ on (111)Si with a Ag buffer layer. (b) Electron diffraction pattern of the same sample, obtained in a cross section, along the (110) axis of Si. The strongest peaks originate from the substrate, while the weaker ones are related to the alloy (see the text for details).

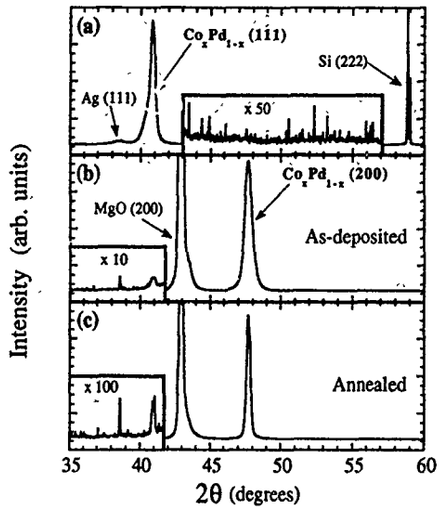

FIG. 2. (a) The θ–2θ x-ray diffraction pattern of a (111)-oriented $Co_{0.25}Pd_{0.75}$ alloy, using Cu K_α radiation. The Ag(111) peak comes from the Ag buffer and cap layers. (b) X-ray diffraction pattern of as-deposited (001)-oriented $Co_{0.25}Pd_{0.75}$ alloy film grown on (100)MgO. The shoulder to the right of the MgO peak is due to unfiltered substrate scattering due to the Compton effect. (c) The same (001)-oriented film after vacuum annealing at 600 °C for 2 h and rapid quenching to room temperature. The expanded views in (b) and (c) show (111) contributions, which are negligible. The other small sharp peak is due to the substrate.

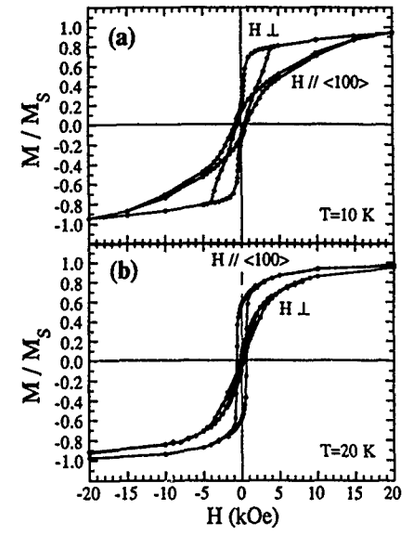

FIG. 4. (a) Hysteresis loops, with the applied field H parallel (∥, open circles) and perpendicular (⊥, filled circles) to the plane of the film, of (a) an as-deposited 800 Å-thick (001)-oriented $Co_{0.25}Pd_{0.75}$ alloy film, and (b) the same film after vacuum annealing at 600 °C for 2 h and rapid quenching to room temperature.

(200) FCC contribution. This demonstrates that, in addition to the epitaxial structure, regions in the sample display a polycrystalline character. This may be related to the average grain size, which is only 500 Å in diameter, as observed in cross-sectional TEM imaging of the sample.

Figure 3 shows the magnetic hysteresis loops obtained at $T=15$ K for the same (111) $Co_{0.25}Pd_{0.75}$ alloy, with the field applied both in plane and out of plane of the sample. It is clear that the easy direction of magnetization is oriented out of the plane, with an anisotropy field of about 15 kOe. The coercive field is about 2 kOe, the saturation magnetization is 630±30 emu/cm^3, and the perpendicular remanence is about 88% of saturation.

The origin of this anisotropy, which is stronger than the demagnetization energy $2\pi M_s^2 \approx 2.5\times10^6$ erg/cm^3, can be tentatively explained in several ways. At low Co concentrations, Co–Pd alloys are known to have large negative anisotropy constants K_1 and K_2, resulting in a ⟨111⟩ easy axis.[6] However, in a (111)-oriented single-crystal film there are, in addition to the perpendicular ⟨111⟩ axis, three other equivalent ⟨111⟩ axes at an angle of about 70° with the vertical axis, which are favored because they also reduce the shape anisotropy energy. Therefore, the expected remanence in a perfect single-crystal sample would be only about 34%. However, as shown in the electron diffraction [Fig. 2(b)], we have observed twinning of the crystal, as well as some polycrystalline contributions. In samples where the grains are small enough and oriented differently from grain to grain, exchange stiffness does not allow the magnetization to be ori-

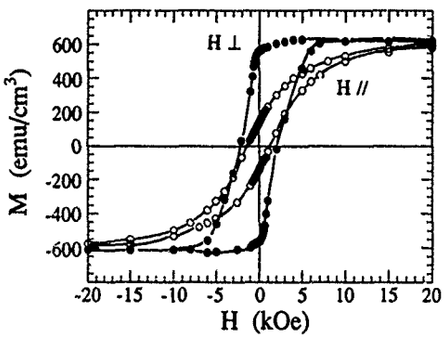

FIG. 3. Hysteresis loop at $T=15$ K of a 600 Å-thick, (111)-oriented $Co_{0.25}Pd_{0.75}$ alloy film, with the applied field H parallel (∥, open circles) and perpendicular (⊥, filled circles) to the plane of the film.

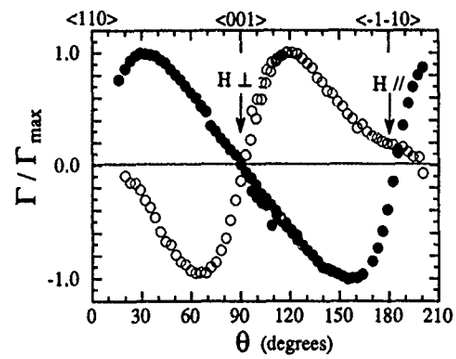

FIG. 5. Variation of the torque Γ as a function of the angle Θ between the applied field and the ⟨110⟩ axis, with rotations about ⟨−1,1,0⟩, for as-deposited 800 Å-thick (001)-oriented $Co_{0.25}Pd_{0.75}$ alloy film (filled circles), and the same film after vacuum annealing at 600 °C for 2 h and rapid quenching to room temperature (open circles). Note tha positive (negative) Γ for $0<\Theta<90°$ corresponds to perpendicular (in-plane) anisotropy.

ented differently from grain to grain, thus favoring the ⟨111⟩ axis which is perpendicular to the film plane. With grain sizes of about 500 Å in the present sample, we cannot exclude such a possibility.

A second possible explanation for the perpendicular anisotropy is the combination of growth-induced strains, together with large magnetostriction coefficients λ_{111} reported for Co–Pd alloys.[7] It is difficult to accurately determine the residual strains, and it is unlikely that significant strains can be sustained in these thick epitaxial films. A generous estimate may be made by considering the epitaxial strain due to the Ag/CoPd interface (8% mismatch), and assuming the classical (i.e., inversely proportional to the distance from the interfaces) relaxation to the expected bulk structure. This yields an average strain of 0.32%, which results in a significant strain-induced anisotropy energy $\approx 2.3\times10^6$ erg/cm^3, but that is still less than one-quarter of the magnitude of the anisotropy that we have obtained from torque experiments ($\approx 9\times10^6$ erg/cm^3).

The formation of ordered phases in Co–Pd and Co–Pt alloys has also been extensively discussed. In particular, the tetragonal $L1_0$ phase of $Co_{0.50}Pd_{0.50}$ (Ref. 8) or $Co_{0.50}Pt_{0.50}$ (Ref. 9) is uniaxial and can be at the origin of a uniaxial magnetic anisotropy, but the compositions of our samples are far from such a 50–50 alloy. The ordered phase of $Co_{0.25}Pd_{0.75}$ (close to the composition of the films studied here) is of the cubic $L1_2$ type, and cannot, by itself, produce an uniaxial anisotropy. However, this ordered phase has recently been identified in $Co_{0.25}Pt_{0.75}$ alloys with perpendicular anisotropy, suggesting that interfaces between ordered and disordered phases may provide the required symmetry breaking.[10] The $L1_2$ phase has also been suggested as responsible for the perpendicular anisotropy in (111) Co/Pt multilayers, by taking into account the occurrence of atomic slip planes and the subsequent formation of oriented Co pairs.[11] We have thus far found no experimental evidence for the existence of the $L1_0$ or $L1_2$ phases in our samples. The final possible explanation is the existence of uniaxial short-range ordering of the Co atoms induced by the MBE growth (an explanation also suggested in the work of Weller *et al.*[2]). As discussed below, results obtained on (001)-oriented films are most easily explained in terms of short-range ordering of the Co–Pd alloys.

For (001)Co–Pd alloy films on (100)MgO, RHEED patterns again indicate a fully epitaxial growth mode, with the cubic axes of the alloy parallel to those of the MgO substrate and rotated by 45° with respect to the Fe seed layer. The x-ray diffraction spectrum obtained is shown in Fig. 2(b), where only the Co–Pd (200) FCC peak is observed, in addition to those due to the MgO substrate and the Fe seed layer. Furthermore, in-plane electron diffraction patterns (not shown) demonstrate the epitaxial growth of the alloy. In Fig. 4(a) we show magnetization curves for an as-deposited 800 Å-thick (001)$Co_{0.25}Pd_{0.75}$ film. The magnetization can be saturated more easily when the applied field is perpendicular to the film along the ⟨001⟩ axis. The perpendicular anisotropy is confirmed by torque measurements in which the field is rotated around the ⟨−110⟩ axis, from ⟨110⟩ to ⟨−1−10⟩, as shown in Fig. 5. The angular dependence of the torque is approximately what is expected for uniaxial anisotropy, with an easy axis along the ⟨001⟩ perpendicular axis. The main point of the above results is that the perpendicular ⟨001⟩ axis is easier than the in-plane ⟨100⟩ and ⟨010⟩ axes, and this in spite of the additional demagnetizing field energy for the perpendicular orientation. Thus, our experimental results cannot be accounted for by the magnetocrystalline anisotropy of a perfectly disordered solid solution of Co in a non-distorted FCC Pd matrix.

As discussed above, if we rule out significant effects from lattice distortions, we have to consider some deviation from a disordered distribution of the Co atoms. To check that a disordered CoPd alloy does behave differently, we have vacuum annealed our (001) films at 600 °C for 2 h, and then quenched them rapidly to room temperature, which is the classic method to obtain disordered solutions.[12] The x-ray diffraction pattern [Fig. 2(c)] is essentially unchanged, except for a somewhat narrower linewidth. As can be seen from the magnetization curves after annealing [Fig. 4(b)], the magnetization is now saturated more easily by in-plane fields. Also, as shown in Fig. 5(b), there is an inversion of the torque curve, which is characteristic of the crossover from perpendicular to in-plane anisotropy (for the annealed sample, the in-plane anisotropy fields are about 7 kOe, consistent with a contribution from the demagnetization energy only). These experiments thus demonstrate that disordered alloy films do not exhibit perpendicular anisotropy, and that the results for the as-deposited samples are due to some short-range ordering of the magnetic Co atoms in the Pd matrix. Such anisotropic distributions can result from the in-plane mobility of the impinging atoms during the growth.

In conclusion, we have found a significant perpendicular anisotropy in both (111)- and (001)-oriented films of Co_xPd_{1-x} ($x\approx0.25$) alloys grown by MBE. For (001)CoPd, the only possible explanation resides in short-range ordering of the Co atoms in the Pd matrix. For the (111) films, we cannot rule out that the perpendicular anisotropy arises from a large magnetocrystalline energy intrinsic to the disordered FCC phase (with $K_1<0$), but, in view of our results on (001) films, we are inclined to ascribe that anisotropy in this case also to short-range atomic ordering.

In situ measurement of stress and surface morphology for Co/Pd multilayer films fabricated by rf sputtering

H. Takeshita, K. Hattori, Y. Fujiwara, K. Nakagawa, and A. Itoh
Department of Electronic Engineering, College of Science and Technology, Nihon University, Funabashi, Chiba 274, Japan

In this paper, we report the results of *in situ* measurements of stress and surface morphology for Co/Pd multilayer films deposited on glass substrate by rf sputtering. For the multilayer film sputtered in low Ar gas pressure at 10 mTorr, after more than 20 periods of Co/Pd deposition, the film is subjected to compressive stress, however, during the Co layer deposition, the value of the compressive stress is decreasing. For the film sputtered in high Ar gas pressure at 40 mTorr, the film is always subjected to tensile stress, and the value of the tensile stress in the film is increasing during the deposition of the Co layer. These changes in the stress during the Co deposition can be explained qualitatively by the difference in the lattice constants of Co and Pd at the interfaces. The surface morphology of the films observed by an atomic force microscope (AFM) in air shows that the surface of both films become rougher with increasing total film thickness. The surface roughness of the films deposited at 10 mTorr is smaller than that of the films deposited at 40 mTorr.

INTRODUCTION

Co based metallic multilayer films such as Co/Pt and Co/Pd with perpendicular magnetic anisotropy are currently investigated as a magneto-optical recording media.[1–6] One of the origins of the perpendicular magnetic anisotropy is stress-induced magnetic anisotropy.[4]

In this report, the results of *in situ* measurement of stress depend on the gas pressure for Co/Pd multilayer films deposited by rf sputtering, and the surface morphology observed by an atomic force microscope (AFM) are reported.

EXPERIMENTAL PROCEDURES

Films were deposited at room temperature on 150 μm thick, 3 cm long, and 0.8 cm wide glass substrates by rf sputtering. On the backside of the substrate, a reflecting Al layer (1000 Å) was deposited and an optical noncontact displacement detector[7] was employed to measure the bending of the substrate, as shown in Fig. 1. The following sputtering conditions were used; back pressure is 4×10^{-7} Torr, Ar pressures are 10 and 40 mTorr, and applied rf power is 100 W. The purities of Co and Pd targets are 99.9%. Deposition rates are 0.39 Å/s for Co, 0.42 Å/s for Pd at Ar gas pressure 10 mTorr, and 0.66 Å/s for Co, 0.73 Å/s for Pd at 40 mTorr, respectively.

Assuming the thickness of the glass substrate is much larger than that of the whole film, and film structure is continuous, the average internal stress $\langle\sigma_{\text{int}}\rangle$ can be expressed by the following equation:

$$\langle\sigma_{\text{int}}\rangle=\frac{E_s\times t_s^2}{3(1-\nu_s)L^2}\frac{d}{h}, \tag{1}$$

where E_s, ν_s, and t_s are Young's modulus, Poisson's ratio, and the thickness of the substrate, respectively. L is the length of the cantilever and h is the total film thickness. The displacement d is measured by using the optical noncontact displacement detector. Positive and negative values of d/h means that the film already deposited was subjected to a tensile and compressive stress, respectively.

EXPERIMENTAL RESULTS

The changes of the bending d and $\langle\sigma_{\text{int}}\rangle$ of the Co(4 Å)/Pd(30 Å) multilayer film with total thickness for $N=55-58$ periods during fabrication in low Ar gas pressure at 10 mTorr is shown in Fig. 2, where N means the number of periods of Co/Pd. The case of the film sputtered in high Ar gas pressure at 40 mTorr are also shown in Fig. 3.

For the multilayer film sputtered at 10 mTorr, d at the beginning of the film deposition is quite different from that at $N=55-58$. At the beginning of the deposition, Co/Pd film is subjected to tensile stress. After more than 20 periods, it changed to compressive stress. Even in the case for the total average stress is compressive, the change of d during Co deposition is positive for the case $N>20$. It means that $\langle\sigma_{\text{int}}\rangle$ tends to change toward the tensile one by an incremental deposition of the Co layer. During Pd deposition for $N>20$, the compressive stress increases over only a monoatomic layer of Pd, and it changed to decrease over a few monoatomic layers, and then it increases again, as shown in Fig. 2(b).

For the film sputtered in high Ar gas pressure at 40 mTorr, the film is always subjected to tensile stress and the change of $\langle\sigma_{\text{int}}\rangle$ during Co deposition is always positive, which means that the tensile stress has been enhanced by the

incremental deposition of Co layers, as shown in Fig. 3(b). During the Pd deposition, $\langle\sigma_{int}\rangle$ decreases over a monoatomic layer of Pd.

The dependence of the surface morphology on the total film thickness observed by AFM in air. The results for the Co(4 Å)/Pd(30 Å) multilayer films deposited under different Ar gas pressure (10 and 40 mTorr), are shown in Fig. 4 and Fig. 5, respectively. Structures like particles or columns can be observed at the surface of the films, and the average size of the particles is about 10 nm in diameter. The diameter becomes larger with increasing the total film thickness. These structures may be due to the influence of the initial island growth at the beginning of the deposition. It is observed that the surface roughness of the films deposited at 10 mTorr is smaller than that of the films at 40 mTorr. The surface of both films, however, become rougher with increasing the total film thickness.

DISCUSSION

One of the origins of the difference in the dependence of the stress on Ar gas pressure seen in Figs. 2(b) and 3(b), may be due to the structural difference caused by the energy difference of the sputtered atoms and/or the sputtering gas ions.

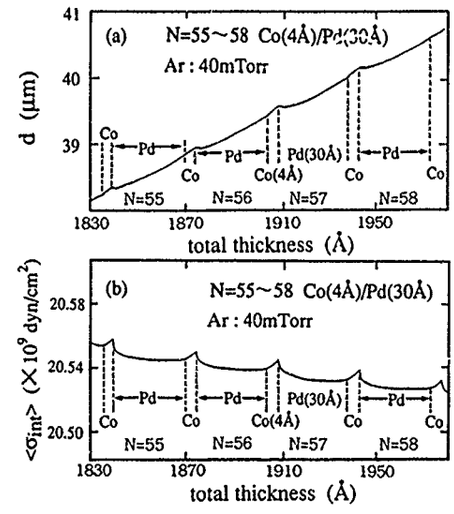

FIG. 3. (a) Substrate bending and (b) $\langle\sigma_{int}\rangle$ derived from Eq. (1), during the fabrication of Co(4 Å)/Pd(30 Å) multilayer films at the periods $N=55-58$, by rf sputtering in high Ar gas pressure at 40 mTorr. Deposition rates: Co=0.66, Pd=0.73 Å/s.

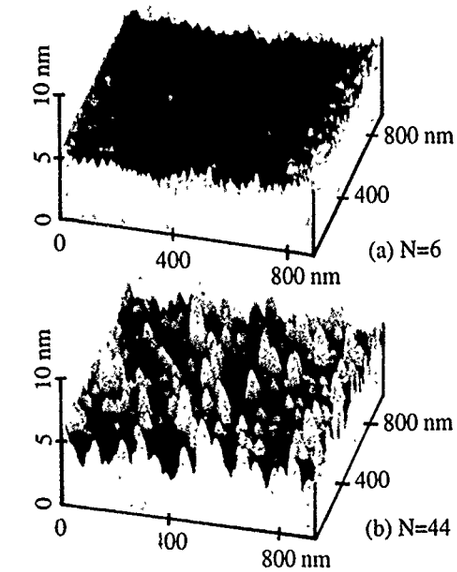

FIG. 5. AFM images for the different thickness of the Co(4 Å)/Pd(30 Å) multilayer films deposited on a glass substrate in Ar gas pressure at 40 mTorr.

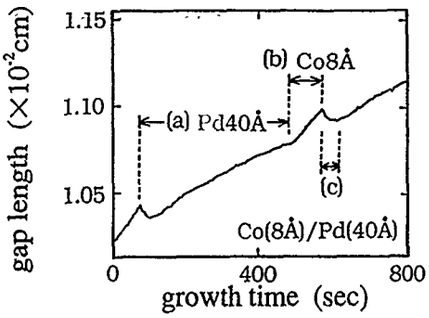

FIG. 6. Substrate bending during fabrication of the Co(8 Å)/Pd(40 Å) multilayer by ultrahigh vacuum evaporation. Deposition rates of Co and Pd are 0.1 Å/s.

In the case of the rough surface, such as the film deposited in a high Ar gas pressure at 40 mTorr, as seen in Fig. 5, surface tension is caused by the increase in the surface area compared with a perfectly flat surface. The surface tension makes tensile stress to the film. Bending of the substrate caused by the surface tension is presented by the following formula:

$$\Delta d = \frac{3L^2}{E_s \times t_s^2} \gamma \frac{\Delta S}{S}, \tag{2}$$

where γ is surface free energy of the film, S is the area of the flat surface, and ΔS is the amount of the difference in the area from the flat surface, respectively. In Eq. (2), the constriction of the substrate caused by Poisson's ratio was neglected, and it was assumed that the γ of the Co(4 Å)/Pd(30 Å) multilayer film is roughly equal to that of the Pd single crystal, because the difference in their layer thickness is large enough ($h_{Pd} \gg h_{Co}$).

The increase in the surface area compared with a perfectly flat surface, obtained from the AFM images of the films ($N=44$) deposited in Ar gas pressure at 10 and 40 mTorr, are about 0.3% and 10%, respectively. However, the values of bending estimated by Eq. (2) for the films are ten times smaller than the experimentally obtained ones.

An example of the *in situ* observation of d for the film deposited by the UHV evaporation method[5,6] is shown in Fig. 6. The film thickness is about 1000 Å. Comparing Fig. 3(a) with Fig. 6, it is seen that the change of $\langle \sigma_{int} \rangle$ during the fabrication by sputtering at high Ar pressure (40 mTorr) is similar to that of the case for the films deposited by UHV evaporation.

The changes of the $\langle \sigma_{int} \rangle$ during the deposition of each Co layer, and also in each one monoatomic layer of Pd just on Co deposited by using sputtering and UHV evaporation methods, are very similar to each other, as shown in Figs. 2(b), 3(b), and 6. The changes of $\langle \sigma_{int} \rangle$ by the incremental deposition of Co and Pd layers can be explained qualitatively by the difference in the lattice constants of Co and Pd at the interfaces.

CONCLUSION

By an incremental deposition of the Co layer, $\langle \sigma_{int} \rangle$ increases its tensile component for the both films deposited by sputtering and UHV evaporation, and it can be explained qualitatively by the difference in the lattice constants of Co and Pd.

The AFM observation shows that the surface of both films become rougher with increasing total film thickness. The surface roughness of the films deposited at 10 mTorr is smaller than that of the films at 40 mTorr. The difference in surface morphology should be connected to the difference of energy of atoms and may cause internal stress difference, however, the stress estimated from the surface free energy is much smaller than that obtained from this experiments.

We report on the temperature dependence of the magnetic properties and interface magnetism of Co/Pt multilayers. The magnetic properties including magnetization and anisotropy change substantially as the temperature varies from 300 to 10 K for samples with Co layer thickness in the range from 3 to 7 Å. The interface anisotropy of about 0.38 erg/cm^2 is nearly independent of temperature. The magnetization reversal is dominated by domain wall motion for the thinner Co layers and dominated by nucleation for the thicker Co layers.

INTRODUCTION

Co/Pt multilayers have attracted much attention as possible magneto-optical recording media because of their large perpendicular anisotropy, large Kerr rotation at short wavelength, and high corrosion resistance.[1–5] However, aside from the study of magnetization by Bloemen *et al.*,[6] very little work on the temperature dependence of the magnetic properties of this system has been presented. Recently, we have studied these properties and the magnetization reversal of Co/Pt, Co/Au, and Co/Pd multilayers. In this paper we report our studies on Co/Pt, and the results for Co/Au and Co/Pd will be published elsewhere.

EXPERIMENT

Co/Pt multilayers of the form X ÅCo/15 ÅPt (X=3, 4, 5, 7, 9, 12, 15, and 20) were fabricated by sputtering on Si(111) substrates with a 200 ÅPt buffer layer. The sputtering rate and power for Co (DC gun) were ~0.6 Å/s and 20 W and for Pt (RF gun) were 1.1 Å/s and 40 W, respectively. The vacuum prior to sputtering was 1×10^{-7} Torr and the Ar pressure during sputtering was 5×10^{-3} Torr. All eight samples were prepared in one vacuum run to ensure the same preparation conditions.

Measurements of the hysteresis loops were carried out using an alternating gradient magnetometer (AGM) and SQUID from 300 to 10 K. The measured magnetic anisotropy was determined from the area between the perpendicular and parallel (in-plane) magnetization curves. The time decay of Kerr rotation was measured on the apparatus described in Ref. 7. Structural properties were analyzed with both small and large angle x-ray diffraction.

STRUCTURE

A small angle x-ray diffraction scan [see Fig. 1(a)] showed that the peaks corresponding to the multilayer structure appeared at the right positions and up to the fourth superlattice peak was observed for the thinnest Co layer sample (X=3 Å). Therefore all samples have distinct interfaces. Large angle x-ray diffraction [see Fig. 1(b)] showed a pronounced FCC (111) texture, with the main peak falling between the pure FCC Co(111) and Pt(111).

MAGNETIC PROPERTIES

Both perpendicular ($\mathbf{H}_\perp$ film plane) and parallel ($\mathbf{H}_\parallel$ film plane) hysteresis loops were measured from 300 to 10 K for all samples. The temperature dependences of magnetization, anisotropy, and polarization of Pt atoms are summarized as follows.

A. Temperature dependences of magnetizations

The temperature (or Co layer-thickness) dependences of saturation magnetization for X=3, 4, 5, 7, 12, and 20 Å (or T=10, 100, 200, and 300 K) are illustrated in Fig. 2(a) [or Fig. 2(b)]. The magnetization here is defined as the ratio of the measured moment to the Co mass, assuming that all the moment is from Co atoms. It is seen that (1) The samples with thinner Co layers show the stronger temperature dependence. As the temperature varies from 300 to 10 K, the saturation magnetization increases by 30, 20, 13, 6.7, and ~2.4% for X=2, 4, 5, 7, and 12 Å, respectively. We notice that the X=12 and 20 Å samples have essentially the same magneti-

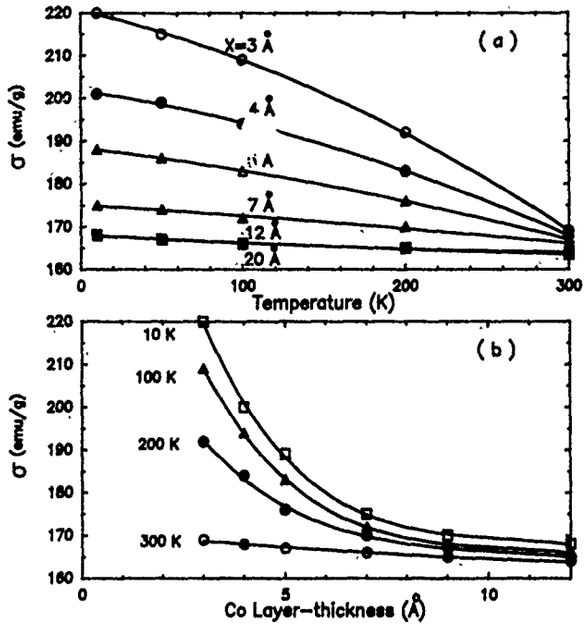

FIG. 2. Temperature dependence of Co saturation magnetization for (a) different Co layer-thickness and (b) layer-thickness dependence of Co saturation magnetization at different temperatures.

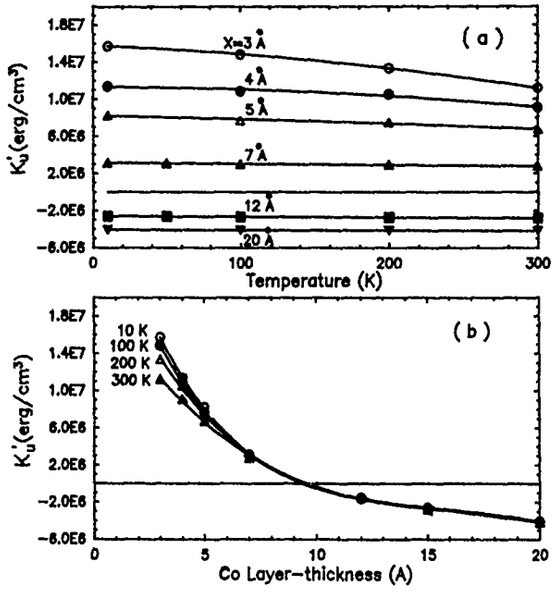

FIG. 3. Temperature dependence of measured anisotropy for (a) different Co layer thickness and (b) layer-thickness dependence of measured anisotropy at different temperatures.

zations. (2) The Co layer-thickness dependence of magnetization becomes much stronger at the lower temperature [see Fig. 2(b)].

It is well known that the magnetization of pure Co is only weakly temperature dependent (σ_{Co} only increases ~1% as the temperature decreases from 300 to 4.2 K). The enhancement of magnetization in Figs. 2(a) and 2(b) thus originates from the multilayer structure and interface magnetism. Because of the interdiffusion or mixing between Co and Pt atoms at the interface region, as the Co layer becomes very thin, e.g., one to three atomic layers, the interfaces may approximately be regarded as a disordered Co–Pt alloy. Then the polarization of Pt atoms and the temperature dependence of magnetization of the interfaces can be calculated in terms of the mean-field theory, as has been done for Co–Pd and Co–Cu alloys in Refs. 8 and 9. We will not give a detailed discussion of the mean-field calculation to save space, and only point out the main result here: Co–Pt alloys with smaller Co concentration have a lower ordering temperature and show a stronger temperature dependence of magnetization. Thus one might expect that thinner Co-layer samples, whose interfaces correspond to Co–Pt alloys with smaller Co concentration, manifest the stronger temperature dependence of magnetization.

B. Temperature dependences of anisotropy

A summary of the temperature (or Co layer-thickness) dependencies of measured anisotropy for X=3, 4, 5, 7, 12, and 20 Å (or T=10, 100, 200, and 300 K) are shown in Fig. 4(a) [or 4(b)]. It is worthwhile to mention the following: (1) The measured anisotropy K_u is positive for $X \leqslant 9$ Å and negative for $X \geqslant 10$ Å over the whole temperature range [see Fig. 4(b)]. (2) Samples with thinner Co layers show a stronger temperature dependence of K_u [see Fig. 4(a) and 4(b)]. K_u values increase by 40%, 24%, and 22% for X=3, 4, and 5 Å as temperature decreases from 300 to 10 K. (3) We have determined the interface anisotropy K_i for these samples using the standard method of plotting "λK_u vs d_{Co}," as described in Refs. 9 and 10. We found K_i to be ~0.38 (erg/cm^2). K_i is also nearly independent of temperature. The fact that the samples with thinner Co layers (X=3, 4, and 5 Å) show stronger temperature dependences of the anisotropy, while, for samples with $X \geqslant 7$ Å the anisotropy is nearly independent of temperature, implies that the interfaces give the major contribution to the temperature dependence the of anisotropy.

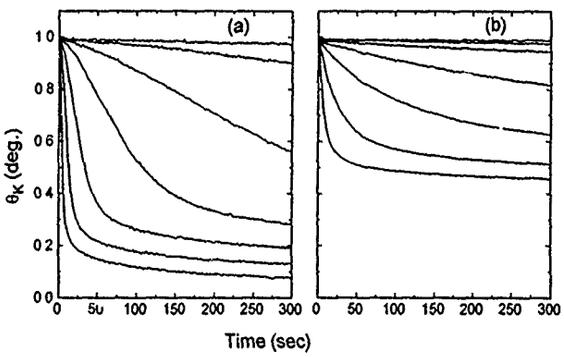

FIG. 4. Kerr rotation as a function of time after magnetization reversal for (a) 3 ÅCo/15 ÅPt and (b) 5 ÅCo/15 ÅPt. Different curves correspond to the different reversing fields ($\leqslant H_c$), with the uppermost curve corresponding to the smallest field.

To study the origins of anisotropy, Co/Pt, and Co/Au multilayers were prepared, and their temperature dependencies of the anisotropy K_u have been measured. We note that the thermal expansion coefficients of Au, Co, and Pt are 14.2×10^{-6}, 12×10^{-6}, and 9×10^{-6} ($°C^{-1}$), respectively.[11] Also, the expansion coefficient of Au is greater than that of Co, while the expansion coefficient of Pt is less than that of Co. Therefore, if stress anisotropy were the major source of K_u, one would expect that the anisotropy of Co/Pt and Co/Au would show opposite temperature dependences: one increasing with decreasing temperature while the other decreasing with decreasing temperature. However, our experiment shows that both for Co/Pt and Co/Au multilayers, the K_u values increase with decreasing temperature for samples with thin Co layers. This may be regarded as evidence that stress plus inverse magnetostriction is a minor contribution to the anisotropy in our (111) textured samples, in comparison with magnetocrystalline anisotropy generated by spin–orbit interaction in the highly anisotropic multilayers structure.[12,13]

C. Magnetization reversal

Magnetization reversal can be studied by the time decay of Kerr rotation. The measurement procedure was described in Ref. 7, and results are given in Figs. 5(a) and 5(b) for $X=3$ and 5 Å, respectively.

Several authors[14,15] have pointed out that if the nucleation rate is small and the domain wall motion velocity is large, the decay curve will first decrease slowly by nucleation at a few isolated sites and then fall quickly through the rapid expansion of the domain walls. The decay curves in Fig. 5(a) are consistent with this behavior. On the other hand, if the nucleation rate is large and the domain wall velocity is very small, the decay curve first decreases exponentially and then decreases approximately as $\ln(t)$ (t is the time) at long times. The decay curves in Fig. 5(b) show such behavior. The $\ln(t)$ behavior can arise either as a consequence of a distribution of thermal activation energies or because part of the driving force (the demagnetizing field) for reversal is decreasing with time as the sample reverses.[16] Therefore the reversal is dominated by domain wall motion for samples with thinner Co layers, while it is dominated by nucleation for thicker Co layer samples. Presumably this difference in behavior results from details of the nanostructures (defects, interface mixing, etc.), as well as differences in demagnetizing fields, both of which must be further investigated to obtain a clear understanding of the reversal behavior.

CONCLUSIONS

It is concluded that the substantial temperature dependence of the magnetic properties of the thin Co layer multilayers originates from the alloying effect at the interfaces. As the temperature decreases, the enhancement of magnetization can be understood in terms of mean-field theory and the enhancement of anisotropy results from the interfacial magnetism, however, the detailed mechanism still remains to be solved. This is a challenging problem when interfacial mixing is present, because up to the present time the theoretical calculations of magnetic anisotropy in multilayers have assumed perfect boundaries with no atomic disorder. Some experiments were performed to probe the origin of the anisotropy. It was found that stress plus magnetostriction does not appear to play a dominant role. Magnetization reversal is dominated by wall motion and nucleation for thinner and thicker Co layers, respectively.

Structural and magnetic properties of Co/Cr(001) superlattices

W. Donner, T. Zeidler, F. Schreiber, N. Metoki, and H. Zabel
Institut für Experimentelle Festkörperphysik, Ruhr-Universität Bochum, D-44780 Bochum, Germany

Epitaxial Co/Cr(001) superlattices were prepared by Molecular-Beam-Epitaxy (MBE). The crystal structure was determined both with Reflection High Energy Electron Diffraction (RHEED) and x-ray diffraction experiments. The Co layers grow in an hcp phase with their (11.0) planes oriented parallel to the Cr(001) planes. The magnetic anisotropy was measured using the Magneto-optical Kerr Effect (MOKE) and Ferromagnetic Resonance (FMR) technique. It is found that the easy axis of the magnetization is perpendicular to the film plane below a Co thickness of about 14 Å. The value of the interface anisotropy constant K_s is determined to (0.85 ± 0.1)erg/cm^2 assuming the bulk magnetization of hcp Co.

I. INTRODUCTION

Perpendicular anisotropy in ultrathin magnetic multilayers is a highly interesting topic for fundamental studies, as well as for applications as high-density magneto-optical storage devices.[1] Usually in thin film systems the magnetization tends to be oriented parallel to the film plane because of the demagnetization energy. In ultrathin films, however, the interfacial anisotropy that is due to the symmetry breaking at the interface[2] and/or hybridization effects[3] plays an important role, so that perpendicular spin orientation has been observed in many systems.[1] In addition to the above mechanisms, crystal anisotropy and magnetoelastic interactions[4] can also contribute to the perpendicular anisotropy.

In this paper we present the existence of a strong perpendicular anisotropy in high-quality MBE-grown Co/Cr(001) superlattices studied by means of the Magneto-optical Kerr effect and FMR. We believe that the observed interfacial anisotropy has an electronic origin, since we find from our intensive studies that the magnetoelastic and crystal anisotropy contributions are not large enough to force the magnetization into the perpendicular orientation.

II. STRUCTURAL PROPERTIES

The preparation of the samples is described in detail elsewhere,[5] which is briefly summarized here: the Co/Cr(001) superlattices are grown on $Al_2O_3(1\bar{1}.2)$ substrates with Nb(001) seed layers and Cr(001) buffer layers at growth temperatures of 300 °C–350 °C. The obtained RHEED pictures (Fig. 1) show sharp streaks, implying atomically flat surfaces. We were able to observe RHEED intensity oscillations during Co growth up to a thickness of 20 atomic layers. Very small interfacial roughness ($\lesssim$5 Å) has been derived from x-ray reflectivity measurements. From the position of the in-plane diffraction spots, we find that hcp-Co(11.0) grows epitaxially on Cr(001), with the c axis of Co being oriented parallel to the Cr[110] axis. This orientation can also be recognized from the additional streaks in the RHEED pattern in [Fig. 1(b)] resulting from the Co layers. Since the substrate has a fourfold symmetry, in most of the samples we observed two equivalent crystallographic domains, which are oriented perpendicular to each other.

This orientation is similar to the Burgers relationship,[6] which is the orientational relation in the BCC-hcp Martensitic transition. We have obtained experimental evidence[7] that the Co layers in Co/Cr(001) superlattices exhibit a precursive structural transition from hcp to BCC with decreasing Co thickness. First, the shape of the in-plane unit cell changes from rectangular to nearly square, and second, the intensity of the hcp-Co$\{\bar{1}1.1\}$ spots, which are forbidden in the BCC structure, shows a continuous decrease, implying a symmetry

change of the Co layers from hcp to BCC with decreasing t_{Co}. In addition, the observed anomalous out-of-plane expansion of the Co layers is an indication for a precursive BCC-hcp structural phase transition, since it can be explained by a rigid-atom-model, assuming that the structural transition takes place.

The structural coherence length of our samples reaches about 100 Å in the film plane and several hundred Angströms in the out-of-plane direction.

III. MAGNETIC ANISOTROPY

Figure 2 shows typical p lar hysteresis curves of Co/Cr superlattices. For t_{Co}=21 Å the polar hysteresis loop exhibits a continuous change of Kerr angles θ_K as a function of the external field H without remanence. The longitudinal hysteresis curve of th sample has a perfect square shape with H_c=250 Oe. These two hysteresis curves indicate that the Co magnetization is parallel to the film plane. With decreasing t_{Co} the saturation field in the polar hysteresis curves decreases continuously, and nonzero remanence is observed below t_{Co}=14 Å. Below th critical film thickness we observed square-type hysteresis loops, indicating that the direction of the easy axis is perpendicular to the film plane. The large critical film thickness of about 14 Å is an indication of the existence of a strong perpendicular anisotropy.

The effective anisotropy energy K_{eff} can be determined by integrating the area enclosed by the polar ($H_\perp$) and longitudinal ($H_\parallel$) hysteresis curves. In this paper, however, we evaluate the effective anisotropy field $H_A=2K_{eff}/M_s$ instead of K_{eff}, because H_A can be determined[9] by MOKE experiments without knowing the magnetization of our samples M_s:

$$H_A=\frac{2}{\theta_K}\int_0^{\theta_K}(H_\parallel-H_\perp)\,d\theta_K'; \tag{1}$$

H_A can also be measured directly by the resonance field H_{res} in out-of-plane FMR measurements. From the resonance condition in perpendicular orientation we get

$$H_A=H_{res}-(\omega/\gamma), \tag{2}$$

where $\omega/2\pi$ is the microwave frequency (X and Q band in our experiments), and γ is the gyromagnetic ratio. The experimental results of H_A are shown in Fig. 3, both for MOKE and FMR. It can be readily seen that both data sets agree very well and that the anisotropy field H_A exhibits a $1/t_{Co}$ behavior. This behavior can be understood in terms of an interfacial anisotropy. The anisotropy in thin films can be described as a sum of interfacial and bulk contributions K_s and K_v, respectively,

$$H_A=2\cdot\frac{2K_s}{M_s\cdot t_{Co}}+\frac{2\cdot K_v}{M_s}. \tag{3}$$

The slope of the least-squares fit to the experimental data with Eq. (3) yields K_s=0.85 erg/cm^2, if we assume that the magnetization of the Co layers is the same as in the bulk: M_s=1430 emu/cm^3. This interfacial contribution is very large in comparison with other $3d$ systems like in Co/Cu (K_s=0.1–0.5 erg/cm^2) or Co/Ni (K_s=0.1 erg/cm^2), and is comparable with Co/Pt, Au ($K_s\cong$1 erg/cm^2).

The intercept of the fitting gives us $2\cdot K_v/M_s$=17 KOe. We argue below that this anisotropy field can be explained by the demagnetization field $4\pi M_s$ and the crystal anisotropy energy $F_{Ani.}$. By taking into account the crystallographic domain structure, the crystal anisotropy energy can be expressed as follows:

$$F_{Ani.}=-\tfrac{1}{2}(K_1+2K_2)\sin^2\theta+\tfrac{3}{8}K_2\sin^4\theta+\tfrac{1}{8}K_2\sin^4\theta\cos(4\Phi), \tag{4}$$

where θ is the polar angle from the film normal and Φ is the azimuthal angle from the c axis of the Co layers. This expression is valid when the magnetic domains are larger than the crystallographic ones, which has been confirmed by both

the MOKE (static method) and FMR (dynamic method) experiments: longitudinal hysteresis loops with the magnetic field along the hard axis yielded a $\sqrt{2}$ fraction of the remanent signal of the easy axis loops, as is expected from a fourfold symmetry. In FMR experiments we observed only one resonance (at a fixed orientation) due to the *coupled* excitation of the two domains.

For out-of-plane MOKE measurements the difference of the anisotropy energy from perpendicular to parallel spin orientation, $F_{\text{Ani.}}(\theta=90°, \Phi=45°)-F_{\text{Ani.}}(\theta=0°, \Phi=45°)$ is important for K_v,

$$\text{MOKE:} K_V^{\text{MOKE}}=2\pi M_s^2+\tfrac{1}{2}K_1+\tfrac{3}{4}K_2, \tag{5}$$

while K_v for FMR is slightly different from the one obtained from MOKE, because $\sin^4\theta$ terms in $F_{\text{Ani.}}$ have no influence on the resonance condition in out-of-plane FMR signals:

$$\text{FMR:} K_V^{\text{FMR}}=2\pi M_s^2+\tfrac{1}{2}K_1+K_2 \tag{6}$$

Despite the slight difference in the crystal anisotropy energy, it makes no significant difference in K_v because the demagnetization factor [the first term in Eqs. (5) and (6)] is most dominant. Assuming bulk anisotropy constants we get $2\cdot K_v/M_s \cong 22$ KOe, which is close but not in perfect agreement with our experimental results. The reason could be a reduced anisotropy due to stepped surfaces[10] or slightly tilted crystallographic directions, but this has not been investigated in detail.

The origin of the large surface anisotropy is thought to be of the Néel type (symmetry breaking at the surface). Furthermore, electronic effects at the interface of these two $3d$ metals should play an important role. Our calculations show that magnetoelastic (at least *linear*) effects are not sufficient to explain the magnitude of K_s. We determined the magnetoelastic energy using a model developed in Ref. 11. According to Mason, the difference in magnetoelastic energy of a hexagonal system with the spin perpendicular to the (11.0) plane and parallel to this plane (for the case of two-domain samples) can be expressed as

$$\begin{aligned} K_{ME}^{\perp}-K_{ME}^{\parallel}=&[(-\lambda_B+\tfrac{1}{2}\lambda_A)\cdot c_{11}+(-\lambda_A+\tfrac{1}{2}\lambda_B)\cdot c_{12} \\ &+(-\tfrac{1}{2}\lambda_C)\cdot c_{13}]\cdot e_1[(-\lambda_B+\tfrac{1}{2}\lambda_A)\cdot c_{12} \\ &+(-\lambda_A+\tfrac{1}{2}\lambda_B)\cdot c_{11}+(-\tfrac{1}{2}\lambda_C)\cdot c_{13}]\cdot e_2 \\ &\times[(-\lambda_B+\tfrac{1}{2}\lambda_A)\cdot c_{13}+(-\lambda_A+\tfrac{1}{2}\lambda_B)\cdot c_{13} \\ &+(-\tfrac{1}{2}\lambda_C)\cdot c_{33}]\cdot e_3, \end{aligned} \tag{7}$$

where λ_i are the magnetostriction constants and c_{ij} are the elastic constants of bulk hcp Co. Substituting the measured values for the in-plane strain, $e_1=-4\%$ and $e_3=+0.2\%$, and the out-of-plane lattice expansion $e_2=+7\%$ of a sample with a Co thickness of 10 Å in this equation, we find a value for $K_{ME}^{\perp}-K_{ME}^{\parallel}$ of -3.3×10^6 erg/cm^3, which corresponds to a field of -4.6 kOe. This is not big enough to overcome the in-plane bulk contribution $2\times K_V/M_s=17$ kOe and not small enough to be neglected. It has to be remarked that using the bulk constants for hcp Co in Eq. (7) could lead to a slightly different K_{ME} because of the structural transition in our Co layers.

In a previous investigation of Co/Cr superlattices with a different orientation,[12] it was argued that the observed perpendicular anisotropy was governed by the shape anisotropy resulting from the columnar growth in those samples. In our samples this mechanism can be excluded, because in the investigated sandwich structures the in-plane structural coherence lengths were larger than the Co thickness.

It is known that interface interdiffusion or roughness reduces the magnetization of Co/Cr multilayers.[13] Since the slope of the linear fit is also determined by the "thick" samples, in which the relative fraction of the interfaces is rather small, we believe, however, that using the bulk magnetization should not alter the result in a dramatic way. As described in Ref. 7 in more detail, the interdiffusion in *our* samples is limited to a few atomic layers only.

IV. SUMMARY AND CONCLUSIONS

In Co/Cr(001) superlattices, hcp-Co(11.0) layers were found to be oriented parallel to Cr(001) planes, with their c axis aligned parallel to the Cr[110] directions. A precursive structural change to the BCC-Co phase with decreasing Co thickness is accompanied with a change of the easy axis of magnetization from in plane to the direction perpendicular to the film plane. The corresponding interface anisotropy K_s is (0.8 ± 0.1)erg/cm^2. The interface anisotropy may originate from broken symmetry, electronic effects at the interface, and from magnetoelastic effects. Since the magnetoelastic effects can be excluded, the first two effects must govern the observed anisotropic behavior.

Orientational and structural dependence of magnetic anisotropy of Cu/Ni/Cu sandwiches: Misfit interface anisotropy

R. Jungblut, M. T. Johnson, J. aan de Stegge, A. Reinders, and F. J. A. den Broeder
Philips Research, Prof. Holstlaan 4, 5656 AA Eindhoven, The Netherlands

Magnetic anisotropies and misfit strain relaxations have been investigated in Cu/Ni-wedge/Cu (100) and (111) sandwiches deposited by molecular beam epitaxy on single-crystal Cu substrates. Our results reveal a clear distinction in the nature of the measured anisotropy at Ni thicknesses below and above the critical value t_c, where the growth becomes incoherent. Below t_c, coherent lattice strain modifies only the volume anisotropy, while interface anisotropy is Néel type; above t_c, magnetoelastic effects are found to contribute to the interface anisotropy.

In recent years, one of the most intriguing properties displayed by several magnetic ultrathin films and multilayers (MLs) has been a preferential magnetization perpendicular to the film plane, called perpendicular magnetic anisotropy (PMA).[1] Phenomenologically, it appears that this effect is associated with the interfaces between magnetic and nonmagnetic layers, since the effective anisotropy constant K has been found to show the following dependence on magnetic layer thickness t:[2]

$$Kt = K_V t + 2K_S. \tag{1}$$

Here, K_V is a magnetic volume coefficient, largely composed of magnetostatic energy, favoring in-plane magnetization. The interface contribution K_S, which sometimes favors perpendicular magnetization, has usually been associated with Néel's surface anisotropy K_N originating in the broken symmetry of interface atoms.[3] On the other hand, Chappert and Bruno[4] have proposed that lattice misfit strain may, via magnetostriction, contribute not only to the *volume* anisotropy in coherent structures, but also to the *surface* anisotropy in incoherent structures, via the misfit interface anisotropy, K_λ.

Experimentally, the challenge has been to isolate these different contributions to K_S, but various research groups have come to quite opposite conclusions. In a pioneering experiment, Gradmann[5] noted that tensile stresses in the Ni layers of Cu/Ni sandwich structures were responsible for the appearance of PMA at certain Ni layer thicknesses, but could not explain the reappearance of in-plane magnetization for thinner Ni layers. Recently, Lee *et al.*[6] explained the thickness dependence of the anisotropy for Co/Au and Co/Cu MLs as being due solely to Co-layer misfit strain variation. In addition, Nakamura *et al.*[7] also considered that, in sputtered Co/Pd MLs, PMA is caused mainly by interfacial strain anisotropy of interface alloys. On the other hand, in a series of experiments on Co/Pd MLs with various crystal orientations,[8] the K_V values could be fully accounted for by magnetoelastic and magnetocrystalline anisotropy contributions, suggesting that K_S was only due to Néel-type anisotropy. This unclear situation regarding the role of K_N and K_λ is probably related to the large lattice misfit (≈8%) in the Co/Pd system, and in other systems, precipitating immediate incoherent growth, which excludes distinct identification of K_N and K_λ.

In this paper, we unambiguously demonstrate that both Néel and misfit interface anisotropies are active in determining the magnetic anisotropy in Cu/Ni/Cu sandwich structures. In this system with a relatively small lattice misfit (≈2.5%), the relaxation of misfit strain as the Ni layer changes from a coherent to an incoherent structure could be followed in samples with a Ni wedge structure and related to changes in the anisotropy. This made it possible to *quantify* the contribution of strain to both K_S and K_V.

The central concept in the understanding of the misfit interface anisotropy is the existence of a critical layer thickness, t_c. Below t_c, growth is coherent and the lattice misfit is absorbed by elastic strain. Above t_c, growth is incoherent and strain relaxes by misfit dislocations. The critical thickness can be derived from[9]

$$\frac{t_c}{b} = \frac{Gx}{4\pi|\eta|E}\ \ln\left(\frac{t_c}{b}+1\right), \tag{2}$$

with b the Burgers vector, G is the shear modulus, E is the elastic constant in the film plane, and η is the lattice misfit [$=(a_s-a)/a$, with a the overlayer and a_s the substrate-lattice constants]. In practice, $x=1$ for a single layer deposited on a substrate, whereas $x=2$ if the stressed layer is sandwiched between two equivalent thick layers, which both support coherent growth. It should be noted that for the sandwich case $x=2$ is a purely thermodynamic result, implying no barriers for dislocation motion. In the incoherent region above t_c, Chappert and Bruno[4] have shown that the residual strain ϵ can be written as $\epsilon=\eta t_c/t$. This inverse proportionality of strain to layer thickness, which has been experimentally observed in, for example, Ni overlayers on a Cu(100) substrate,[10] will have important consequences for the interpretation of the anisotropy, as outlined below.

A separate interpretation of the magnetic anisotropy must be made in the regions above and below t_c. For coherent systems, the volume anisotropy K_V incorporates shape anisotropy, magnetocrystalline anisotropy (K_{MC}) and strain anisotropy (K_{ME}), with interface anisotropy being solely Néel type. Following den Broeder,[11] we find

$$K_S = K_N, \tag{3}$$

$$K_V = -\tfrac{1}{2}\mu_0 M_s^2 + K_{MC} + K_{ME}, \tag{4}$$

with

$$K_{ME} = -\frac{3}{2}\ \lambda\sigma = -\frac{3}{2}\ \lambda\left(\frac{E\eta}{1-\nu}\right), \tag{5}$$

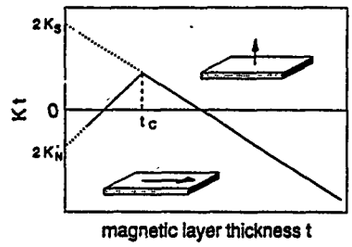

FIG. 1. Schematic dependence of Kt on layer thickness t, in the presence of negative Néel surface anisotropy K_N.

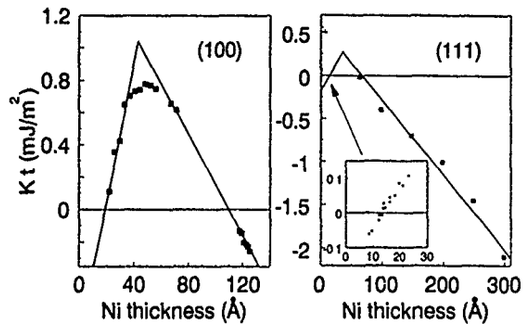

FIG. 2. The product of total anisotropy K and Ni layer thickness t, plotted as a function of t for (100) and (111) orientations.

with M_s the saturation magnetization, λ the magnetostriction constant, σ the stress, and ν the Poisson ratio. In this region, the influence of misfit strain thus appears as a volume contribution to the anisotropy.

In the incoherent region above t_c, the distinctive form of volume strain has been shown[4] to lead to an apparent interface contribution—the magnetoelastic interface anisotropy. Following Ref. 11 and Eq. (2), we find

$$K_S = K_N + K_\lambda, \tag{6}$$

with

$$K_\lambda = \pm \frac{3}{8\pi} \left(\frac{Gb\lambda}{1-\nu}\right) \ln\left(\frac{t_c}{b}+1\right), \tag{7}$$

and

$$K_V = -\tfrac{1}{2}\mu_0 M_s^2 + K_{MC}, \tag{8}$$

where the + and − signs in Eq. (7) refer to the respective cases $\eta<0$ and $\eta>0$. Figure 1 schematically illustrates the expected dependence of Kt on t, with a marked kink appearing at the critical thickness t_c. In the remainder of this paper, we will discuss how relevant this picture is by considering the Cu/Ni model system.

The majority of the structural and magnetic properties were determined from measurements on only two Cu/Ni/Cu samples: one for the (100) and one for the (111) crystallographic orientations. For both samples, the Ni layer was grown in the form of a wedge. The layers were deposited at room temperature by Molecular Beam Epitaxy (MBE), the final sample-composition being Cu(100)/Ni wedge (0–130 Å, slope: 15 Å/mm)/Cu(10 Å)/Au (25 Å); and Cu(111)/Ni wedge (0–40 Å, slope: 3.6 Å/mm)/Cu (12 Å)/Au (25 Å). More details concerning the substrate-preparation and growth technique can be found in Ref. 12. In addition, a small number of (111) oriented samples with uniform Ni thicknesses in the range 100–300 Å were prepared on Si(111)/2000 Å Cu substrates.

The established onset of strain relaxation in Ni layers on Cu crystals[10,13] was confirmed using LEED. Initially, the Ni displays a 2.5% expanded fcc surface net that was within experimental error identical to that of the Cu substrate. In-plane strain relaxation manifests itself in the LEED patterns through small changes in the position of the diffraction spots and the occurrence of additional features located close to the primary diffraction spots, possibly caused by diffraction from arrays of dislocations at large repeat intervals ($\approx a/\eta$), which have recently been imaged with TEM in the Cu(100)/Ni system.[13] In-plane relaxation starts at ≈13 Å Ni in the (111) orientation, and ≈15 Å Ni in the (100) case. The latter value agrees closely with that determined by Matthews and Crawford ($t_c = 14.6 \pm 3$ Å[10]).

To evaluate the agreement between these observations and theory, we consider Eq. (2) in the approximation $x=1$ (the single layer situation actually encountered in the LEED measurements). Using literature values for the (orientation-dependent) elastic and shear moduli for Ni,[14] and $b=2.5$ Å ([110] slip direction), we expect $t_c(111)=11$ Å and $t_c(100)=12.5$ Å. The close agreement between predicted and observed critical thicknesses in both orientations lends validity to the considerations presented above. We now consider whether elastic strain ($t<t_c$) and strain relaxation ($t>t_c$) play a role in determining the anisotropies of the samples.

The magnetic anisotropy was determined at various positions along the Ni wedges using a Kerr Effect apparatus. Providing the magnetization rotates homogeneously, anisotropies at thicknesses where the magnetization was *in plane* could be determined by forcing the sample toward saturation in a field applied along the film-normal, whereas *perpendicular* anisotropies were derived by forcing the magnetization away from the film-normal using an external field with an in-plane component.[15] The nonuniformity in magnetization rotation accounts for the absence of measurements at intermediate Ni thicknesses. For the (111) orientation, supplementary anisotropy measurements using standard vibrating sample magnetometry were carried out on the samples of uniform thickness.

The results of the study appear in Fig. 2. We immediately see that the form of both curves strongly resembles the schematic depiction in Fig. 1. Clear breaks are observed in both curves. In the spirit of Fig. 1, we can straightforwardly assert a linear dependence of Kt on t, both below and above t_c. The resulting anisotropies are also compiled in Table I. Comparing Eqs. (3) and (4) with (6) and (8), respectively, it is easy to derive values for the strain-related interface (K_λ) and volume (K_{ME}) terms, which are also compiled in Table I (assuming $K_{MC}\approx 0$ for Ni). Using the relevant magnetostriction and elastic constants in these equations ($\lambda_{111}=-24\times10^{-6}$ and $\lambda_{100}=-46\times10^{-6}$), the *theoretical* values of K_λ and K_{ME} can be determined. As shown in Table

TABLE I. Summary of Cu/Ni anisotropy data pertaining to both investigated orientations. Critical thicknesses (t_c reported for both single layers and sandwiches) and stress-induced anisotropy energies are determined both experimentally and (in parentheses) by calculation.

Orientation	t_c (Å) Layer	t_c (Å) Sandwich	K below t_c	K above t_c	Stress-induced anisotropy
(111)	13	32	$K_N=-0.08$ mJ/m^2	$K_S=+0.27$ mJ/m^2	$K_\lambda=0.35$ mJ/m^2 (0.64)
	(11)	(35)	$K_V=+0.13$ MJ/m^3	$K_V=-0.09$ MJ/m^3	$K_{ME}=0.22$ MJ/m^3 (0.36)
(100)	15	42	$K_N=-0.4$ mJ/m^2	$K_S=+0.9$ mJ/m^2	$K_\lambda=1.3$ mJ/m^2 (0.8)
	(12.5)	(40)	$K_V=+0.39$ MJ/m^3	$K_V=-0.16$ MJ/m^3	$K_{ME}=0.55$ MJ/m^3 (0.39)

I, the predicted volume and interface strain anisotropies all have the correct magnitude and sign to account for the experimental observations. Quantitatively, the uncertainty in defining magnetostriction and elastic constants for ultrathin layers, or the presence of interface Cu–Ni alloys with radically different magnetostriction may preclude closer agreement. The positions of the breaks are not in agreement with the t_c values established from LEED studies. Probably the presence of the overlayer has increased t_c for the sandwich structure, in accordance with Eq. (2). By inserting $x=2$ into Eq. (2), we expect $t_c=35$ Å for Cu(111)/Ni/Cu and $t_c=40$ Å for Cu(100)/Ni/Cu, close to the break points of Figs. 2(a) and 2(b). Previous work on Cu/Ni MLs[16] has revealed respective (100) and (111) interface anisotropies of -0.23 mJ/m^2 and -0.12 mJ/m^2 on samples with rather thin individual layers, where the growth was essentially coherent. A similar situation is encountered in the present work, with a more negative K_S being found in the (100) orientation than in the (111) orientation, in the coherent region below t_c. Concerning the crossover from perpendicular to in-plane anisotropies at larger Ni thicknesses, the present results are seen to be consistent with the work of Chang.[17] There, a reversal of the magnetic anisotropy was measured for Ni layers sandwiched between thick Cu(100) layers that occurred at a Ni thickness in between 50 Å (perpendicular remanence) and 100 Å (in-plane remanence). In their attempt to explain the anisotropy of Co/Pd MLs by magnetoelastic anisotropy of interface alloys, Nakamura *et al.*[7] found similar kinks in the anisotropy of $Pd_{67}Co_{33}$/Au and $Pd_{67}Co_{33}$/Cu MLs. We suggest that this behavior is related to the mechanism proposed in this paper.

In conclusion, we summarize why the present experiment has allowed isolation of the Néel- and misfit-type anisotropies, which have previously eluded separation. Several favorable conditions are met in the present Cu/Ni/Cu samples. First, both metals are fcc, with only a small lattice misfit. Consequently, as revealed by our LEED studies, both coherent and incoherent structures can be realized across wide ranges of Ni thicknesses accessible to anisotropy measurements. In addition, the small saturation magnetization of Ni (compared to Co or Fe) results in a domination of strain-induced anisotropies compared to shape anisotropy. Finally, magnetocrystalline anisotropies are rather small in Ni.

Magnetic anisotropy in ultrathin films grown on vicinal surfaces (abstract)

D. S. Chuang, C. A. Ballentine, and R. C. O'Handley
Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

Growth of thin epitaxial magnetic films on terraced substrates, such as Co/Cu(1 1 13) vicinal to (001), leads to unexpected magnetic anisotropy associated with the surface steps. This anisotropy remains largely unexplained and is of potential technological importance. We have studied the anisotropy of fcc Co/Cu(1 1 13) films of 3–20 ML thicknesses using *in situ* MOKE. The presence of monoatomic steps on the Cu(1 1 13) surface induces a uniaxial anisotropy favoring magnetization parallel to the steps. The strength of this anisotropy decreases with increasing film thickness. In this paper we focus on the interpretation of this anisotropy in terms of the Néel model.[1,2] Vicinal surfaces are characterized by (001) terraces separated by monoatomic steps. The Néel anisotropy energy for such a surface has the form $E^N_{\text{total}} = E_{\text{bulk atoms}} + (E_{\text{surface atoms}}/t) + E_{\text{step-edge atoms}}/td)$, where t and d are film thickness and terrace width, respectively. The last term includes contributions from sites at both the top and bottom of the step and is responsible for the step-induced anisotropy. For 10 ML of Co on Cu(1 1 13), the magnitude of this term is approximately 0.3 erg/cm^2, favoring M parallel to the steps, as we have observed. Fe/W vicinal to (001) films show a preference for in-plane magnetization perpendicular to the steps.[3] The Néel model predicts this anisotropy for a bcc Fe film provided the magnetization lies in the film plane, not in the (001) plane.

Theoretical predictions for magnetic anisotropy of superlattice defects (abstract)

R. H. Victora
Storage Technology Research and Development Division, EIPC, Eastman Kodak Company, Rochester, New York 14650-2017

J. M. MacLaren
Physics Department, Tulane University, New Orleans, Louisiana 70118

Most experimental superlattices contain numerous defects that substantially affect the anisotropy. Calculations based on two different theoretical approaches are presented for a variety of substitutional defects at the interface. The first method involves electronic structure calculations employing the local density approximation within the layer Korringa–Kohn–Rostoker technique. Defects are treated as periodic at a third nearest-neighbor spacing. Large in-plane contributions to the anisotropy are found for a substituted atom within the (111) Co layer of both the Co/Pd and Co/Pt systems. For example, -203 uRy is obtained for a single defect in the 1Co/1Pt superlattice: this is -4.2 times the interface anisotropy. This is believed to be the first *ab initio* prediction of the anisotropy energy of defects. The second method sums pair interactions using the potential $(\mathbf{M}\cdot\mathbf{R})^2$, where $\mathbf{M}$ is the magnetization and $\mathbf{R}$ is the vector connecting the two atoms. This method has been previously demonstrated[1] to be accurate in comparison both to electronic structure calculation and to experiment. For the fcc (111) interface, it is predicted that the anisotropy (in units of interface anisotropy) of a substitution in a monolayer is -4, the anisotropy of an adatom is -2, and the anisotropy of a one-atom recess that does not penetrate the magnetic layer is -2. These predictions are found to aproximately match the electronic structure theory in those cases we have tested. Finally, the summation of a variety of randomly chosen defects to form a diffuse interface yields an anisotropy equal to that of a perfect interface times the sum over all layers i of $[P(i)-P(i+1)]^2$, where $P(i)$ is the probability of a magnetic atom in layer i. This suggests that the highest anisotropy is obtained at the sharpest interface.

Magnetoelastic coefficients at tetragonal surfaces (abstract)

Oh Sung Song, C. A. Ballentine, and R. C. O'Handley
Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

Surfaces and thin films are generally highly strained relative to their bulk structures. The magnetoelastic (ME) coefficients coupling these strains to magnetic properties must be considered in lower symmetry than the bulk values. We outline a method of analyzing the ME problem at a surface in tetragonal symmetry (assuming the bulk is cubic). Five ME coefficients are required. Two methods have been developed to extract these surface ME coefficients from the M-H behavior of films subjected to different strains. One method fits the M-H behavior with that predicted by an equation of motion derived from a free energy which includes ME, magnetostatic, crystal field, and Zeeman terms. This method is useful in certain simple cases where canonical linear M-H behavior is observed. In more complicated cases, it can be shown that the ME coefficients are related to the area $A(\Delta H,\Delta e)$ between two anhysteretic M-H curves at two different strain levels and between arbitrary field limits (see Fig.). The choice of field limits allows the M-H results near the origin, $H \leqslant H_c$, and near saturation $H \geqslant H_K$ to be omitted from the analysis. The validity of the method is illustrated with measurements on thin cobalt, nickel, and permalloy films.

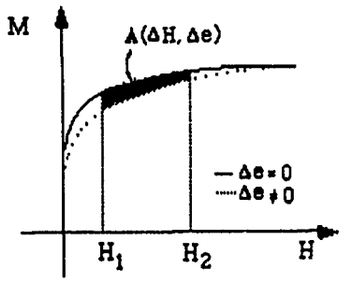

FIG. 1. ME coefficients as related to the area $A(\Delta H,\Delta e)$ between two anhysteretic M-H curves at two different strain levels and between arbitrary field units.

Magnetic anisotropy in epitaxial Ni/Cu(001) thin films: Effects of misfit strain on perpendicular magnetic anisotropy (abstract)

G. Bochi, C. A. Balentine, H. E. Inglefield, S. S. Bogomolov, C. V. Thompson, and R. C. O'Handley
Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

Several epitaxial magnetic systems, notably Fe/Ag(001) and Fe/Cu(001), exhibit perpendicular magnetic anisotropy (PMA) over a relatively narrow thickness range, approximately 2–6 ML. Recently, it has been shown[1,2] that a similar region of perpendicular anisotropy exists for Ni/Cu(001), but over a much broader range of film thicknesses extending up to approximately 40 ML. The effective anisotropy energy density can be written as $K_{\text{eff}} = -2\pi M_s^2 + 2B_1\epsilon(t) + (2K_N/t)$, which includes magnetostatic (MS), magnetoelastic (ME), and Néel (averaged over two surfaces) terms. The effective anisotropy vanishes at the perpendicular to in-plane transition thickness of about 60 Å. If we assume bulk values for M_S and B_1, the ME coupling coefficient, and use our measured strain values $\epsilon(t)$, we find that the Néel term is an order of magnitude smaller than the ME and MS terms. These large competing terms therefore control the PMA in this system. We have extended our studies of PMA in Ni/Cu(001) to include $Cu_{1-x}Ni_x$ ($0\%<x<50\%$) alloy substrates for which the misfit strain with the Ni film is reduced. We find that the perpendicular-to-in-plane transition, at $t\approx 40$ ML for Ni/Cu(001), shifts to thinner nickel layers as the misfit strain is decreased by deposition on $Cu_{1-x}Ni_x$ substrates. This further confirms the important role of ME energy in PMA for this system.

Using a microscopic and quantum approach, we study the ground state configuration and the spin-wave excitations of a model of two ferromagnetic monolayers, interacting via both bilinear and biquadratic exchange, and subject to an easy-plane anisotropy, a quartic in-plane anisotropy, and an external field. Peculiar features are found in the field dependence of the acoustic and optical frequency gaps in correspondence to the critical fields for which the canting angle between the magnetizations of the two coupled layers presents discontinuities. In particular, we suggest that a minimum in the optical gap at the saturation field could be experimentally observed by Brillouin light scattering in real systems, like Fe/Cr/Fe trilayers.

I. INTRODUCTION

Sandwich structures consisting of two ferromagnetic films separated by a nonmagnetic spacer, like Fe/Cr/Fe trilayers, have attracted wide interest since the discovery of interlayer antiferromagnetic coupling.[1] Later on, detailed investigations of wedge shaped samples revealed the existence of long- and short-period damped oscillations of the interlayer coupling with increasing Cr thickness.[2,3] Recently, magnetooptic and magnetometry techniques[4,5] provided experimental evidence for a nearly perpendicular orientation of the magnetizations of the two Fe layers. It was suggested[4] that such a configuration is due to the presence of a biquadratic interlayer exchange, in addition to the usual bilinear one. Several mechanisms were proposed for the biquadratic coupling, both of macroscopic[6] and microscopic[7] origin.

In this paper we study, within a microscopic and quantum approach, the ground state configuration and the spin-wave excitations for the simple model of two ferromagnetic monolayers, interacting via both bilinear and biquadratic interlayer exchange, and subject to an easy-plane single-ion anisotropy, a quartic in-plane anisotropy, and an external field. Whatever its origin, in our model the biquadratic coupling is assumed as a phenomenological parameter. Analytical results are obtained for the frequencies of the two spin-wave modes. Peculiar features are found in the field dependence of the acoustic and optical frequency gaps in correspondence to the critical fields where the canting angle between the magnetizations of the two coupled layers presents discontinuities. Finally, we discuss the relevance of our calculations with respect to real systems, like Fe/Cr/Fe trilayers, and suggest that a minimum in the optical gap at the saturation field could be experimentally observed by Brillouin light scattering (BLS).

II. SPIN-WAVE THEORY

We assume a model of spins localized on the sites of two parallel monolayers, with simple quadratic structure and lattice constant a, separated by a fixed distance c, with a registered (010) interface. The spin Hamiltonian reads

$$\mathcal{H}=\sum_{\mathbf{l}_\parallel,l}\left\{-\frac{J}{2}\sum_{\delta}\mathbf{S}_l(\mathbf{l}_\parallel)\cdot\mathbf{S}_l(\mathbf{l}_\parallel+\delta)+D[S_l^y(\mathbf{l}_\parallel)]^2 -\frac{K}{2}([S_l^x(\mathbf{l}_\parallel)]^4+[S_l^z(\mathbf{l}_\parallel)]^4)-g\mu_B\mathbf{H}\cdot\mathbf{S}_l(\mathbf{l}_\parallel)\right\} -A\sum_{\mathbf{l}_\parallel}\mathbf{S}_1(\mathbf{l}_\parallel)\cdot\mathbf{S}_2(\mathbf{l}_\parallel)-B\sum_{\mathbf{l}_\parallel}[\mathbf{S}_1(\mathbf{l}_\parallel)\cdot\mathbf{S}_2(\mathbf{l}_\parallel)]^2, \quad (1)$$

where $\mathbf{l}_\parallel\equiv(l_x,l_z)$ and $l(=1,2)$ denotes the plane index. We are particularly interested in the peculiar features arising from the competition between the nearest neighbor ferromagnetic intralayer exchange ($J>0$) and the antiferromagnetic bilinear ($A<0$) and biquadratic ($B<0$) interlayer couplings. We also assume a single-ion anisotropy ($D>0$), sufficiently strong to make the spins lie in the xz plane, and a quartic anisotropy (K) breaking the in-plane rotational symmetry. We take $K>0$, so that $\{100\}$ is the easy direction, and $\{101\}$ the hard one. A magnetic field is applied within the xz plane, along a high symmetry direction.

We first perform a transformation of the spin components from the crystallographic frame of reference to a local one, then the usual Dyson–Maleev transformation from spin to bosonic operators. Using the mixed representation $(\mathbf{k}_\parallel,l)$, allowed by the translational invariance in the xz plane, and retaining up to quadratic terms in the bosonic operators, the Hamiltonian (1) takes the form

 0021-8979/94/75(10)/6431/3/$6.00 © 1994 American Institute of Physics

$$\mathcal{H}=E(\varphi_1,\varphi_2)+\sum_{\mathbf{k}_\parallel}\sum_{l,m=1,2}[\mathcal{A}_{lm}a^\dagger_{\mathbf{k}_\parallel,l}a_{\mathbf{k}_\parallel,m}$$

$$+\tfrac{1}{2}\mathcal{C}_{lm}(a^\dagger_{\mathbf{k}_\parallel,l}a^\dagger_{-\mathbf{k}_\parallel,m}+a_{\mathbf{k}_\parallel,l}a_{-\mathbf{k}_\parallel,m})]. \quad (2)$$

Defining $h=g\mu_B H$, $\Delta=(\varphi_2-\varphi_1)$, $\Gamma=(\varphi_1+\varphi_2)/2$, $f_n=[1-n/(2S)]$ (with $n=1,2,3$), and $\psi=0$ $(\pi/4)$ for H applied along an easy (hard) axis, the diagonal elements are written as

$$\mathcal{A}_{ll}=4JS[1-\gamma(\mathbf{k}_\parallel)]+h\cos(\psi-\varphi_l)+DSf_1+AS\cos\Delta$$
$$-\tfrac{1}{2}BS[2S^2f_1^2(1-3\cos^2\Delta)+\cos\Delta]$$
$$-\tfrac{1}{2}KSf_1[-4S^2f_3+S-4+5S^2f_2f_3\sin^2(2\varphi_l)],$$
$$\mathcal{C}_{ll}=-DSf_1-BS^3f_1^2\sin^2\Delta-\tfrac{1}{2}KSf_1\times[3S-2$$
$$+3S^2f_2f_3\sin^2(2\varphi_l)], \quad (3)$$

where $\gamma(\mathbf{k}_\parallel)=[\cos(k_xa)+\cos(k_za)]/2$, with $-\pi\leq k_xa$, $k_za\leq\pi$. The off-diagonal elements ($l\neq m$) are

$$\mathcal{A}_{lm}=\mathcal{A}_{ml}=-AS\cos^2\frac{\Delta}{2}-BS$$
$$\times[2S^2f_1^2\cos^2\Delta-S^2f_2(1-\cos\Delta)-\tfrac{1}{2}],$$
$$\mathcal{C}_{lm}=\mathcal{C}_{ml}=AS\sin^2\frac{\Delta}{2}-BS$$
$$\times[2S^2f_1^2\cos^2\Delta-(S^2f_2+\tfrac{1}{2})\cos\Delta-S^2f_2]. \quad (4)$$

The ground state configuration is found minimizing the zero boson term

$$E(\varphi_1,\varphi_2)=(\tfrac{1}{2}B-A)S^2\cos\Delta-BS^4f_1^2\cos^2\Delta$$
$$+\tfrac{1}{4}KS^4f_1f_2f_3[\sin^2(2\varphi_1)+\sin^2(2\varphi_2)]$$
$$-hS[\cos(\psi-\varphi_1)+\cos(\psi-\varphi_2)] \quad (5)$$

with respect to φ_1 and φ_2 (i.e., the angles formed by the magnetizations of the two coupled ferromagnetic monolayers with the in-plane easy axis [100]), or equivalently with respect to Δ and Γ (i.e., the canting angle, and the angle formed by the vector sum of the two magnetizations with [100], respectively). In the classical limit $S\to\infty$ (so that $f_n\to 1\ \forall\ n$), we recover the results previously found in Ref. 4 for the $H=0$ ground state configuration.

The frequencies of the spin-wave excitations are obtained, in the framework of a Green's function method previously developed for the study of magnetic multilayers,[8] as the eigenvalues of the 4×4 real nonsymmetric dynamical matrix

$$\mathcal{T}(\mathbf{k}_\parallel)=\begin{pmatrix}\mathcal{A} & \mathcal{C}\\ -\mathcal{C} & -\mathcal{A}\end{pmatrix}. \quad (6)$$

In the limiting cases with high symmetry, such that $\mathcal{A}_{11}=\mathcal{A}_{22}$ and $\mathcal{C}_{11}=\mathcal{C}_{22}$, they turn out to be[9]

$$\omega^2_{ac}(\mathbf{k}_\parallel)=(\mathcal{A}_{11}+\mathcal{A}_{12})^2-(\mathcal{C}_{11}+\mathcal{C}_{12})^2$$
$$\omega^2_{op}(\mathbf{k}_\parallel)=(\mathcal{A}_{11}-\mathcal{A}_{12})^2-(\mathcal{C}_{11}-\mathcal{C}_{12})^2. \quad (7)$$

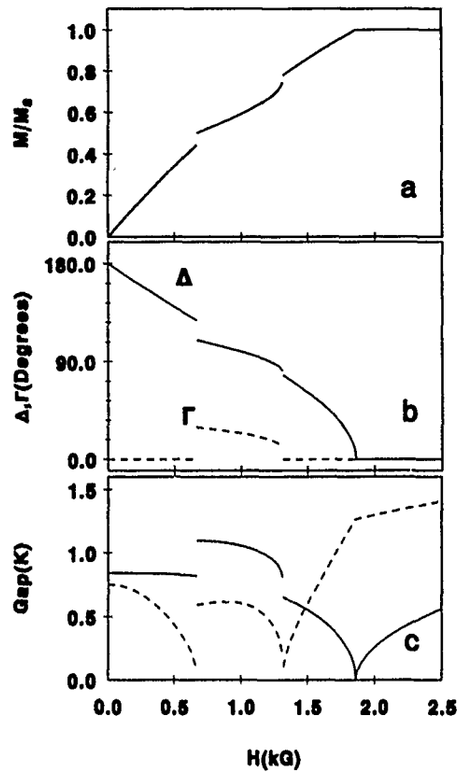

FIG. 1. 3i FIG. 1. (a) Mean of the $T=0$ magnetizations of the two coupled films versus the intensity of a magnetic field applied along an in-plane easy axis, [100]. (b) Field dependence of the canting angle Δ (full line), and of the angle Γ (dashed line), formed by the total magnetization with the field direction. (c) Field dependence of the optical (full line) and acoustic (dashed line) frequency gaps. The Hamiltonian parameters are fixed to $A=-0.06$ K, $B=-0.01$ K, $K=0.1$ K, $D=1$ K, $S=2$, $g=2$.

From the analysis of the eigenvectors of $\mathcal{T}(\mathbf{k}_\parallel)$, one finds that ω_{ac} and ω_{op} can be identified with the acoustic and the optical mode, since they are associated to in-phase and out-of-phase motion of the spins, respectively.[9]

III. RESULTS AND DISCUSSION

In Fig. 1(a) we report the mean of the $T=0$ magnetizations of the two coupled films, $M/M_s=(\cos\varphi_1+\cos\varphi_2)/2$, versus the intensity of a magnetic field applied along the in-plane easy axis [100]. We choose Hamiltonian parameters such that for $H=0$ the ground state is antiferromagnetic,[10] as experimentally observed by Köbler *et al.* in Fe/Cr/Fe sandwiches.[5] In agreement with previous calculations,[5] four different phases are clearly distinguishable with increasing field.[11]

From Fig. 1(b), where the field dependence of the canting angle Δ and of the angle Γ are reported, one can see that in correspondence to the two lower critical fields separating the first three phases, one has a first order transition since both angles undergo abrupt changes. Instead, at the saturation field $H_s=[B(1-4S^2f_1^2)-2A-2KS^2f_1f_2f_3]S/(g\mu_B)$, one has a second order transition.[5] Moreover, we notice that in the second phase, characterized by an almost perpendicular mutual orientation of the magnetizations of the two

coupled layers, $\Delta \simeq 90°$, the total magnetization is not directed along the field, $\Gamma \neq 0$: these two features result in an almost half-saturation value for the mean of the magnetizations [see Fig. 1(a)].

In correspondence to the critical values of H, for which the magnetization undergoes a first-order phase transition, also the acoustic and optical frequency gaps, $\omega(\mathbf{k}_\parallel=0)$, present discontinuities: see Fig. 1(c). The most interesting feature is the vanishing of the optical gap at the saturation field H_s, even in the presence of a finite in-plane anisotropy, $K \neq 0$. This can be explained, by inspection of the explicit analytic expressions for the frequency gaps,[9] in terms of a field-induced mechanism of isotropization of the in-plane motion of the spins. In fact, we find that while the energy barrier for deviations of the spins out of the film plane is constant with respect to H, its in-plane counterpart does depend on the field. More precisely, upon H approaching H_s, the energy barrier for in-plane deviations from the canted ground state decreases (i.e., the system becomes more and more isotropic) until, when the field increases further, it constitutes itself an energy barrier.

We suggest that the peculiar features, predicted in the field dependence of the acoustic and optical frequency gaps, could be experimentally observed by BLS in sandwich structures made of ultrathin ferromagnetic films separated by a nonmagnetic spacer. However, for our theory to be applicable, two conditions have to be satisfied. First, the intraplane exchange interaction should be much greater than the interlayer ones, so that the low frequency modes measurable by BLS are determined only by the feeble bilinear and biquadratic interlayer couplings. Second, the system should be able to jump between monodomain stable configurations (with respect to which the spin-wave excitations have been calculated) without forming domains. Both conditions seem to be satisfied in the case of Fe/Cr/Fe trilayers.[12]

In conclusion, our microscopic spin-wave study of the magnetic excitations, in sandwich structures coupled by bilinear and biquadratic exchange, provides analytical expressions for the spin-wave dispersion curves, which could be useful for the determination of the interlayer coupling constants from BLS data in real systems. In particular, by this technique one could detect the peculiar features predicted in the field dependence of the acoustic and optical frequency gaps, in correspondence to the critical fields for which the canting angle between the magnetizations of the two coupled layers presents discontinuities.

[10] With an appropriate choice of the Hamiltonian parameters, one can obtain (see Refs. 4,9) a *canted* ground state configuration at $H=0$, as experimentally observed by Rührig *et al.* (see Ref. 4).
[11] Upon reducing the biquadratic exchange constant, one finds that the third phase disappears (see Refs. 5,9).
[12] In the light of the experimental results by Köbler *et al.* (see Ref. 5) the multi-domain state observed in Fe/Cr/Fe wedge shaped samples (see Ref. 4) appears to be a very unstable intermediate state between monodomain stable configurations.

Temperature dependence of interlayer exchange coupling in Co/Ru/Co trilayer structures

Z. Zhang, L. Zhou, and P. E. Wigen
Department of Physics, The Ohio State University, Columbus, Ohio 43210

K. Ounadjela
Institut de Physique et Chimie des Matériaux de Strasbourg, Groupe d'Etudes des Matériaux Metalliques, 4 rue Blaise Pascal, 67070 Strasbourg, France

The temperature dependence of the interlayer exchange coupling field H_{ex} and the effective anisotropy field H_{eff} within ferromagnetic layers was investigated for Co/Ru/Co trilayer structures using the angular dependence of ferromagnetic resonance (FMR). It was found that both H_{ex} and H_{eff} increase with decreasing temperature. The dependence of H_{ex} on temperature follows roughly the relationship $H_{ex} \propto (T/T_0)\ \sinh(T/T_0)$ predicted by Edwards *et al.*, and the characteristic temperature T_0 decreases with increasing Ru spacer thickness as predicted.

Since the first discovery of antiparallel exchange coupling in the Fe/Cr system,[1] a lot of work has been done to evaluate the interlayer exchange coupling strength in various magnetic multilayer systems using ferromagnetic resonance (FMR) and Brillouin light scattering (BLS).[2–5] For a trilayer system consisting of two ferromagnetic layers separated by a nonmagnetic spacer, the interlayer exchange coupling energy per unit surface area is generally assumed to have the form

$$A_{12}\frac{\mathbf{M}_1\cdot\mathbf{M}_2}{M_1M_2}, \tag{1}$$

where A_{12} is the exchange coupling coefficient and $\mathbf{M}_1$ and $\mathbf{M}_2$ are magnetization vectors in ferromagnetic layers 1 and 2, respectively.

While many of the FMR and BLS experiments were performed at room temperature, limited research has been devoted to the temperature dependence of the magnetic properties in the magnetic multilayer system. Using a polarized one-band model and an analogy with the de Haas–van Alphen effect, Edwards *et al.*[6] predicted that the exchange coupling coefficient A_{12} decreases with increasing temperature and follows the relationship

$$A_{12} \propto \frac{T}{T_0} \Big/ \sinh\left(\frac{T}{T_0}\right). \tag{2}$$

For multilayer films, the characteristic temperature given by

$$T_0 = \hbar v_F/2\pi k_B L, \tag{3}$$

is on the order of 100 K. Here v_F is the Fermi velocity and L is the spacer thickness. Celinski *et al.* performed FMR measurements at several low temperatures on Fe/Pd/Fe and Fe/Cu/Fe trilayer structures and found that the exchange coupling strength at 77 K is almost twice as large as the value at room temperature.[7] However, the data are too limited to draw any systematic conclusions.

The temperature dependence of the interlayer exchange coupling is readily obtained if both the acoustic mode and the optic mode can be observed in the trilayer system.[8] However, for the samples in which the two ferromagnetic layers are identical, only the acoustic mode can be observed. In this case, a sensitive experimental method must be developed. The angular dependence of the dispersion relation for a symmetrical trilayer system was calculated by adding an exchange field $H_{ex}=2A_{12}/dM_s$, where d is the thickness of the magnetic layer to the standard single-layer model.[9] One important result from the calculation is that for an antiparallel coupled system, even the resonance position of the acoustic mode is significantly modified from that of the noncoupled system if the magnetic layers are not saturated at resonance. Furthermore, the angular dependence of the acoustic mode in the unsaturated region is very sensitive to small changes in the exchange coupling strength or to the internal anisotropy energies for certain frequencies.[9] This provides another way to study the temperature dependence of the interlayer exchange coupling.

Both methods were used to investigate the temperature dependence of the interlayer exchange coupling for a series of Co(32 Å)/Ru(t_{Ru})/Co(32 Å) trilayer structures, where 6 Å$<t_{Ru}<$80 Å. These trilayer films were prepared in ultrahigh vacuum by evaporation on freshly cleaved mica substrate. Transmission electron microscopy (TEM) studies have shown that the layers are epitaxially grown with good crystalline features and relatively sharp interfaces.[10] From the previous FMR and magnetization measurements,[8] oscillations in the exchange coupling between the Co layers have been found as a function of the Ru spacer at room temperature. The magnetization vectors of the two Co layers are strongly antiparallel coupled for $t_{Ru}\leqslant$12 Å, parallel coupled for $t_{Ru}\sim$16 Å and antiparallel coupled for $20\leqslant t_{Ru}\leqslant$24 Å. Insignificant coupling was found for samples with a Ru thickness greater than 28 Å.

The three samples reported here have a Ru thickness of 9 Å (S1), 20 Å (S2), and 24 Å (S3). The Co layers are antiparallel coupled and have easy plane anisotropy energy. Sample S1 is in the first antiparallel coupled region while samples S2 and S3 are in the second antiparallel coupled region.[8] FMR measurements have been performed at X-band (9.2 GHz) and K-band (23 GHz) frequencies with the temperature ranging from 50 K to 300 K. At each temperature, the external field is rotated from the orientation parallel to the film plane, $\theta_H=90°$, to the orientation perpendicular to the film plane, $\theta_H=0°$, in 10° steps.

Figure 1 shows the angular dependence of the FMR spectra for the $t_{Ru}=9$ Å (S1) sample at K-band frequencies

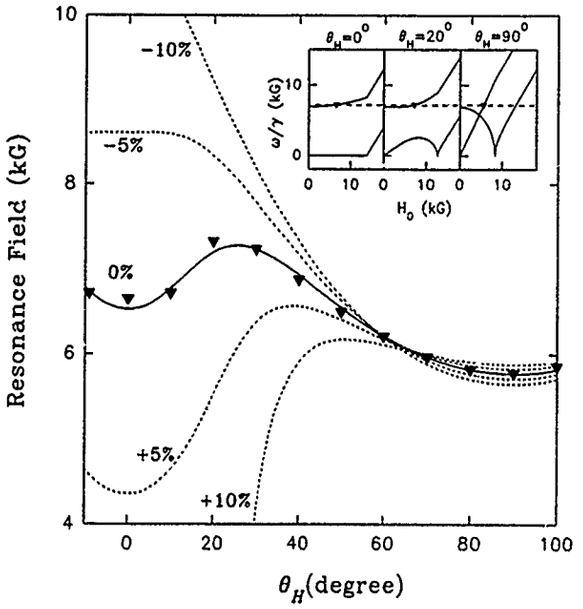

FIG. 1. The angular dependence of the resonance field at K-band frequency (23 GHz) for the Co(32 Å)/Ru(9 Å)/Co(32 Å) sample at room temperature. The solid line is the theoretical curve using the parameters. H_{ex}=8.74 kG, H_{eff}=−5.80 kG, and g=2.22. The dashed lines are the predictions corresponding to a 5% and 10% variation in the exchange field H_{ex}. The inset figures are the predictions of the dispersion relations for this sample at the angles θ_H=0°, 20°, and 90°. The dashed line in the inset figures indicate the position of the K-band frequency.

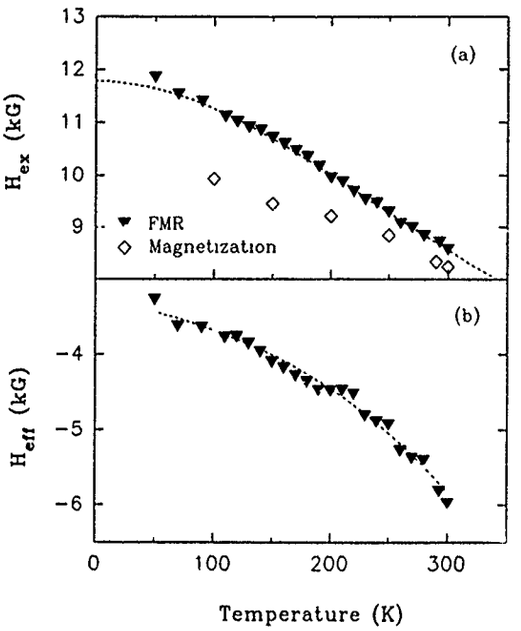

FIG. 2. (a) The interlayer exchange coupling field H_{ex} and (b) the effective anisotropy field H_{eff} as a function of temperature for the sample Co(32 Å)/Ru(9 Å)/Co(32 Å). The dashed lines are the best fit using Eq. (4).

and room temperature. The resonance field increases as the external field is rotated away from the parallel orientation (θ_H=90°) until it reaches a maximum value at some intermediate angle. The resonance field then decreases as the applied field continues to rotate toward the perpendicular orientation (θ_H=0°). In contrast to the case of a single-layer system, this behavior is not due to a large higher-order anisotropy energy term, but rather related to the nonparallel orientation of the magnetization vectors in the two Co layers due to the large antiparallel interlayer exchange coupling as expected from the magnetization measurement which shows an in-plane saturation field $H_{sat,\parallel}$>8 kG. Using the exchange coupled resonance theory,[9] the experimental data can be fitted as shown by the solid line in Fig. 1. The same fitting parameters account for the resonance data at X-band frequencies as well.

If the internal anisotropy field is constant but the exchange coupling field H_{ex} varies by 5% or 10%, Fig. 1 shows that the angular dependence of the resonance spectra changes significantly (dotted line). The agreement between the experimental data and the theoretical calculation indicates that the uncertainty of H_{ex} and the contribution from the biquadratic exchange coupled term should be less than 1% for this sample. With the increase of H_{ex}, it can be seen that (1) the angle, θ_H^{max}, at which the resonance field reaches its maximum value increases; (2) the resonance field in the perpendicular orientation decreases; and (3) the change of resonance fields in the parallel orientation is insignificant.

From the temperature dependent FMR spectra for this sample at K-band frequencies, it was found that θ_H^{max} increases from about 20° at 300 K to nearly 80° at 50 K, due to an increase of the interlayer exchange coupling with decreasing temperature. These results are consistent with the in-plane magnetization measurements which show an increase of $H_{sat,\parallel}$ from 8.3 kG at 300 K to 9.9 kG at 100 K. The resonance field in the perpendicular orientation does not change significantly over the temperature range (decreases from 6.5 kG at T=300 K to 6.15 kG at T=50 K) even though the magnetization measurement indicates a 20% increase in the exchange coupling field as the temperature decreases from 300 to 100 K. The changes in the internal anisotropy field within each Co layer over this temperature range nearly compensates for the increasing in the exchange coupling at the perpendicular orientation but gives a significant increase to the parallel resonance field, from 5.6 kG at room temperature to 6.6 kG at 50 K.

From the FMR results, the g value, H_{ex}, and the effective anisotropy field $H_{eff}=H_u-4\pi M_s$ were evaluated. The g value from this fitting is between 2.18 and 2.26 through the whole temperature range. Both H_{ex} and H_{eff} decrease with increasing temperature (as shown in Fig. 2). The variation of H_{ex} with temperature follows the relationship

$$H_{ex}=H_{ex}^0\left(\frac{T}{T_0}\right)\Big/\sinh\left(\frac{T}{T_0}\right)+H_{ex}^{\infty}, \tag{4}$$

which is shown as the broken curve in Fig. 2(a). In comparison with Eq. (2) predicted by Edwards *et al.*,[6] a temperature-independent term, H_{ex}^{∞}, is added in order to get a better fit. The characteristic temperature T_0 for this sample is about 150 K. Also shown in Fig. 2(a) are the in-plane saturation fields $H_{sat,\parallel}=H_{ex}$ from the magnetization measurements. The trend of H_{ex} with temperature agrees with the FMR results; however, the values of H_{ex} are noticeably different, which is

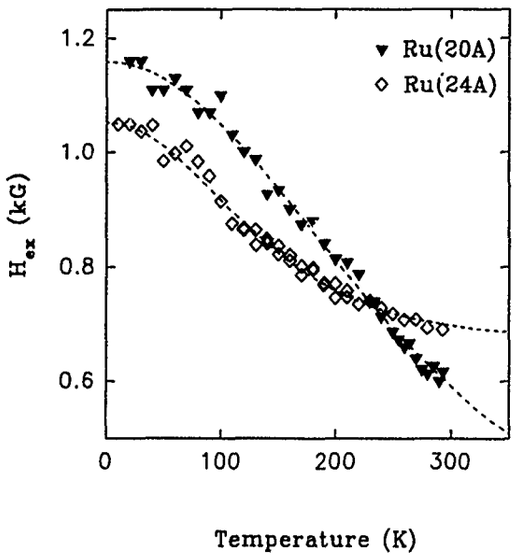

FIG. 3. H_{ex} as a function of temperature for the samples Co(32 Å)/Ru(20 Å)/Co(32 Å) and Co(32 Å)/Ru(24 Å)/Co(32 Å). The dashed lines are the best fit using Eq. (4).

probably due to the inaccurate measurement from the magnetization curve.

For the t_{Ru}=20 Å (S2) and 24 Å (S3) samples, the exchange coupling strength is about 0.5 kG at room temperature, much smaller than that in sample S1. Therefore, the magnetization vectors of the Co layers are saturated at resonance. There is a small difference in the internal anisotropy field between the two Co layers in these two samples due to different growth quality.[8] As a result, both the acoustic mode and the optic mode can be observed. The field separation between the acoustic mode and the optic mode is equal to the exchange field H_{ex} plus the contribution due to the difference in the effective anisotropy field between the two Co layers, $|H_{eff,1}-H_{eff,2}|$. However, the analysis shows that the contribution of the latter term is insignificant for these two samples when the external field is applied parallel to the film plane at X-band frequencies; therefore the field separation in the parallel FMR spectra is used as the exchange coupling field H_{ex}.

Similar to sample S1, H_{ex} in samples S2 and S3 increases with decreasing temperature and can be fitted to Eq. (4) as shown by the dashed lines in Fig. 3. However, T_0 was found to be about 110 K and 60 K for samples S2 and S3, respectively, smaller than that for sample S1 as expected for the thicker Ru layers from Eq. (3).

In these two samples, the parallel resonance field of the acoustic mode increases while the perpendicular resonance field decreases with decreasing temperature, suggesting a decrease in amplitude of the effective anisotropy field H_{eff} at low temperatures. At 100 K $|H_{eff}|$ is observed to decrease by 2–3 kG from the value at room temperature, similar to the result obtained in sample S1, shown in Fig. 2(b).

From the results obtained for the three Co/Ru/Co trilayer structures, it was found that the variation of H_{ex} with temperature follows roughly the relationship predicted by Edwards *et al.*[6] The characteristic temperature T_0 decreases with an increase of the Ru layer thickness—from 150 K at t_{Ru}=9 Å to 60 K at t_{Ru}=24 Å. However, T_0 does not seem to follow the $1/t_{Ru}$ relation predicted in the Edwards model which would give T_0~70 K at t_{Ru}=20 Å, a value much smaller than the 110 K observed in sample S2.

Oscillatory exchange coupling in Fe/Au/Fe(100)

J. Unguris, R. J. Celotta, and D. T. Pierce
Electron Physics Group, National Institute of Standards and Technology, Gaithersburg, Maryland 20899

Scanning electron microscopy with polarization analysis was used to investigate the interlayer exchange coupling in Fe/Au/Fe(100) sandwich structures. The films were epitaxially grown on single-crystal Fe(100) substrates. Electron diffraction measurements revealed that the Au spacer film grew with a surface reconstruction consistent with that observed for bulk Au crystals. The exchange coupling oscillates between primarily ferromagnetic and antiferromagnetic coupling for Au spacer layers up to 65 layers (13 nm) thick, but a significant biquadratic coupling component was also observed. The oscillatory coupling exhibited two components with periods of 2.48±0.05 layers (0.506±0.010 nm) and 8.6±0.3 layers (1.75±0.06 nm). The measured periods are in excellent agreement with those calculated from spanning vectors of the Au Fermi surface.

I. INTRODUCTION

Magnetic measurements from atomically well-ordered magnetic multilayer structures are essential in order to make meaningful evaluations of various models of oscillatory exchange coupling. Thickness variations due to deviations from ideal layer-by-layer growth can obscure important features of the magnetic coupling. For example, in Fe/Cr/Fe multilayers it has been shown that a Cr spacer roughness of only a quarter layer can completely obscure the short, two-layer period, exchange coupling oscillations.[1-3]

In this work we have investigated the interlayer exchange coupling in epitaxially grown Fe/Au/Fe(100) sandwich structures. Au(100) rotated by 45° is a very close lateral match to the Fe(100) surface and should therefore be a possible candidate for atomically well-ordered growth. In previous work, where the Fe/Au/Fe multilayer was deposited on a Ag(100) substrate, Celinski and Heinrich[4] did not observe any well-defined oscillatory behavior of the exchange coupling through the Au(100). Using GaAs(100) substrates to grow Fe(100) and a wedge-shaped Au spacer layer, Fuss *et al.*[5] observed oscillatory coupling consisting of a long-period component of 6.9 layers and a weaker short-period oscillation of about two layers. We have used single-crystal Fe whisker substrates in our studies and have observed very well-defined short- and long-period coupling oscillations that extended over a large Au thickness range.

II. EXPERIMENT

The experimental procedures used to investigate the exchange coupling in Fe/Au/Fe have been described in detail elsewhere.[2,6] Briefly, the chemical composition and the structural order of the samples were measured using scanning Auger spectroscopy and reflection high-energy electron diffraction (RHEED), respectively. Scanning electron microscopy with polarization analysis (SEMPA) was used to make *in situ* measurements of the sample's magnetization during and following film growth. The films were grown on Fe(100) single-crystal substrates that were cleaned by Ar-ion sputtering followed by 750 °C annealing cycles. Scanning tunneling microscope images of similar whiskers show high-quality surfaces with only about one single atomic height step per square μm.[7] RHEED patterns from the bare whiskers showed sharp diffraction spots distributed along Laue arcs as expected for a perfect crystal. The Auger spectra established that contamination levels were below 0.05 monolayers.

In order to measure the Au thickness dependence of the exchange coupling, wedge-shaped Au spacer layers were grown by moving a shutter in front of the Fe substrate during Au deposition. The geometry of the wedge is shown schematically in Fig. 1. The slope of the Au wedge was small, about 0.001°, which is less than the 0.01° average slope of the Fe whisker substrate. Au spacer layers were grown at Fe substrate temperatures between 80 and 100 °C, and at an evaporation rate of about 8 layers/min. The direction of the interlayer exchange coupling was determined by measuring the magnetization of the top Fe film with SEMPA. Fe whisker substrates with the simple two-domain structure shown in Fig. 1 were used in order to check for and eliminate any instrumental offsets in the SEMPA measurement.

III. RESULTS

The crystalline order and thickness of the Au films were measured using spatially resolved scanning RHEED. Figure 2 shows the specular RHEED intensity as the incident electron beam was scanned along the wedge and a RHEED pattern from a 10-layer-thick Au film. The RHEED intensity oscillations were used to determine the Au thickness con-

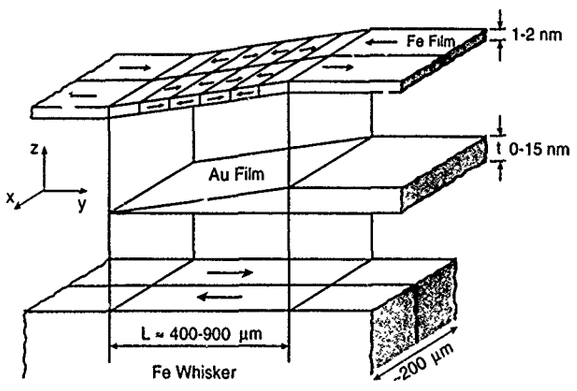

FIG. 1. An exploded schematic view of the sample structure showing the Fe(100) single-crystal whisker substrate, the evaporated Au wedge, and the Fe overlayer. Arrows in the Fe show the magnetization direction.

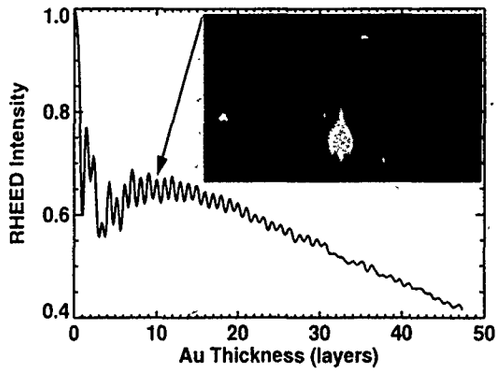

FIG. 2. The specular RHEED intensity as a function of the Au thickness obtained by scanning the electron beam along the wedge. A RHEED pattern from a 10-layer-thick film is shown in the inset.

tours along the wedge. For Au films less than three layers thick, the RHEED patterns were similar to those for clean Fe, but after three layers the diffraction spots stretched into sharp streaks and superlattice streaks began to form. The four extra streaks that appeared between the primary diffraction beams were characteristic of a fivefold surface reconstruction. Both (5×1) and (5×20) surface reconstructions have been observed for bulk Au.[8] While the presence of streaks in the diffraction patterns indicates some disorder, the surface reconstruction suggests that the Au films have bulklike structural order. In fact the sharpness of the streaks indicates that the Au grows in patches that are internally well ordered but slightly misaligned with respect to one another.

The direction of the magnetic coupling was determined by measuring the magnetization of the top Fe film using SEMPA. A SEMPA image of a Au wedge coated with five layers of Fe is shown in Fig. 3. The component of the magnetization along the whisker direction is M_y and the orthogonal component of the in plane magnetization is M_x. Oscillations between ferromagnetic and antiferromagnetic "bilinear" coupling are most clearly visible in the M_y component. The M_x component, on the other hand, emphasizes the perpendicular "biquadratic" coupling between the Fe film and substrate. The thickness scale on these images is not linear, because of a gradual drift in the Au evaporation rate. This nonlinearity, as well as any other spatial variations in the Au thickness, was accounted for by using scanning RHEED images from the same region. The scanning RHEED images were correlated with the SEMPA images by aligning topographic features in the RHEED images with the same features in intensity images that were acquired at the same time as the magnetization images.

Averaged, linearized line scans of M_y taken from the data in Fig. 3 and from a different Fe/Au/Fe(100) wedge are shown in Fig. 4. One can see from these data that the periodicity of the coupling is very reproducible, but the amplitude of the oscillations and the thickness at which they eventually vanish vary among samples grown under slightly different conditions.

In order to measure the coupling periods precisely, we followed a previously described procedure[6] and modeled the bilinear coupling J by the sum of two sine waves such that

$$J=A_1 \sin(2\pi t/d_1+\phi_1)+A_2 \sin(2\pi t/d_2+\phi_2), \qquad (1)$$

where t is the Au thickness, and A, d, and ϕ are adjustable amplitudes, periods, and phases, respectively. To simulate the SEMPA data, this continuous function was first discretized with the Au lattice so that each monolayer was assigned a single coupling strength. The thicknesses at which the coupling switched sign were then determined by taking the weighted average of the coupling from adjacent layers. Finally, all positive coupling values were set to the same magnetization level and all negative coupling to the equal but opposite magnetization. Figure 4 shows the results of a calculation that gave the best fit of the model to the data. The parameter values for this model were $A_1/A_2=2.1$, $d_1=2.48$ layers, $\phi_1=0.44$, $d_2=8.60$ layers, and $\phi_2=3.14$.

In addition to the bilinear coupling, biquadratic coupling was also observed in these films. While SEMPA cannot directly measure the absolute strength of the magnetic coupling, the magnetization direction is roughly proportional to the ratio of the biquadratic to bilinear coupling.[9] The M_x

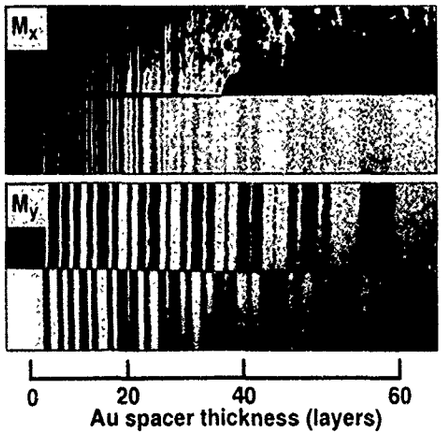

FIG. 3. SEMPA images from the five-layer-thick Fe overlayer, showing the in-plane magnetization components along the wedge, M_y, and orthogonal to the wedge, M_x.

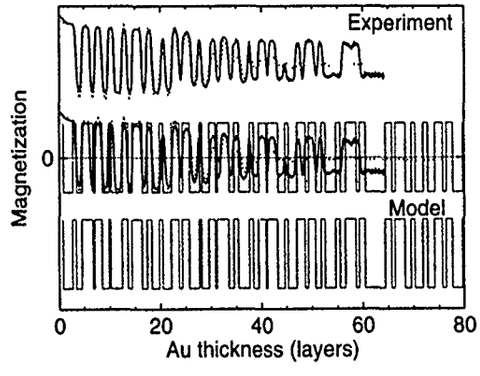

FIG. 4. The results of the model calculation described in the text are compared with an averaged, linearized line scan of the M_y data from Fig. 3 and from a SEMPA measurement from a different wedge (dotted line). For comparison, the calculated (bottom) and measured (top) curves are shown both seperately and overlaid.

image in Fig. 3 shows that in the thin part of the wedge the biquadratic coupling is only significant at the transitions between the ferromagnetic and antiferromagnetic regions. As the Au thickness increases, the relative strength of the biquadratic coupling also increases, so that for thicknesses greater than about 20 layers, the biquadratic coupling is always present, and the coupling oscillations are no longer between purely ferromagnetic or antiferromagnetic states, but between some intermediate angles. For thicker Au films the coupling also tends to break up randomly into islands with different M_x magnetization components but the same M_y component. The formation of these regions is not understood, but the length scales involved suggest that it is related to the details of the Au growth.

IV. DISCUSSION

Qualitatively, the Au results are similar to SEMPA measurements of the coupling in Fe/Cr/Fe(100) (Ref. 2) and Fe/Ag/Fe(100) (Ref. 6). In each case, oscillatory coupling was observed that consisted of two periodic components, and the oscillations persisted for spacer layers greater than 10 nm thick. Another common feature of these films grown on Fe whisker substrates is that the short-period oscillations are more pronounced and the oscillations extend over a greater thickness range than in multilayers grown on more conventional substrates. Fe/Au/Fe sandwiches grown on Ag substrates show no oscillatory coupling.[4] Fe/Au/Fe sandwiches grown on GaAs substrates only reveal weak short-period modulations in the long-period antiferromagnetic coupling.[5]

The ability to observe many coupling oscillations over a large interlayer thickness range allows the coupling periods to be measured with sufficient precision to provide a stringent test of current theories of multilayer exchange coupling. Currently, there are two quantitative predictions of Fe/Au/Fe coupling periods available. In both theories the oscillatory coupling periods are determined by wave vectors that are perpendicular to the surface and span nearly parallel faces of the spacer layer's bulk Fermi surface. Stiles[10] used a tight-binding fit to a local-density approximation of the Au band structure to compute coupling periods of 2.50 and 9.36 layers. Bruno and Chappert[11] used a nearly-free-electron fit to de Haas–van Alphen and cyclotron resonance measurements of Fermi surface extremals and predicted coupling periods of 2.51 and 8.60 layers for Au(100). Both calculations are in good agreement with our measured Au coupling periods of 2.48 ± 0.05 and 8.6 ± 0.3 layers, although the Bruno and Chappert calculation matches the long period better. The general agreement between our measurements and these theories further supports the hypothesis that the oscillatory exchange coupling periods in atomically well-ordered materials are determined by Fermi surface spanning vectors.

ACKNOWLEDGMENTS

We wish to thank M. D. Stiles for many helpful discussions. The whiskers were grown at Simon Fraser University under an operating grant from the National Science and Engineering Research Council of Canada. Oscillation of the interlayer coupling in Co/Au(111)/Co

An oscillatory interlayer coupling in Co/Au(111)/Co has been obtained from polar Kerr hysteresis loop measurements on a molecular-beam-epitaxy-grown 50 Å Au/2 Å Co/0–40 Å Au wedge/7 Å Co/20 Å Au sample deposited on a Cu(111) single crystal. The period of the coupling is seen to increase from 11 to 14 Å with increasing Au thickness, indicating a preasymptotic behavior. The asymptotic period of 14±1 Å is larger than the theoretically expected period of 11.4 Å. The observation of coupling up to 40 Å Au will be discussed in relation to the general absence of coupling in evaporated Co/Cu(111)/Co samples.

I. INTRODUCTION

Lately, much attention has been given to the antiferromagnetic (AF) interlayer coupling and its oscillation period in evaporated Co/Cu(111)/Co samples.[1–5] In general, experiments failed to reveal AF coupling[1] or an oscillation period,[2] except for recent measurements by Schreyer *et al.*[3] and Howson *et al.*,[4] who only detect a small fraction of AF-coupled Co, and Kohlhepp *et al.*,[5] who found full AF coupling when using Co layers only one monolayer thick. The difficulty in obtaining interlayer coupling at thicknesses larger than that of the first AF maximum was suggested by Bruno and Chappert[6] to originate from a cutoff length for the interlayer coupling, whereas others[7] propose formation of magnetic links through a granular interlayer.

In the former suggestion, the cutoff length results from a loss of translational invariance along the interfaces between the interlayer and the magnetic layers. Consequently, destructive interference in the oscillating interlayer interaction suppresses the coupling at interlayer thicknesses typically larger than the cutoff length. Loss of translational invariance, in turn, can have various origins: mixing at the interfaces, roughness, grain boundaries, or dislocations associated with the incoherent growth present in lattice-mismatched systems. Specifically for the (111) orientation, the expected effect of suppression is dramatic, because of the large angle between the Fermi velocity and the film normal. Assuming only incoherent growth, Bruno and Chappert[6] have evaluated the cutoff length in the case of Co/Cu(111)/Co to be 52 Å Cu; for Co/Au(111)/Co only 9 Å Au was predicted. The shorter cutoff length in the latter case follows from the large lattice mismatch of approximately 14% compared to about 2% in the case of Co/Cu, as the cutoff length originating from incoherent growth is proportional to the inverse of the lattice mismatch.[6] If incoherent growth due to a lattice mismatch is to be responsible for the absence of interlayer coupling in various coupling experiments on evaporated Co/Cu(111)/Co samples, then certainly no interlayer coupling is expected in Co/Au(111)/Co. In this article the above hypothesis is tested.

II. EXPERIMENT

In the present experiments, the interlayer was deposited in a wedge shape by translation of a shutter along the sample during evaporation. The Co layers were chosen to be thin, in order to be able to measure even weak antiferromagnetic coupling (2 Å Co) or to have a perpendicular anisotropy[8] in order to obtain a large coercive field (7 Å Co). Unequal thicknesses for the two Co layers were used to obtain different coercivities.[9] This allows measurement of both AF coupling and small ferromagnetic (F) coupling as described in the following section.

The composition of the sample, prepared by molecular beam epitaxy (MBE) in a VG Semicon V80M system, was 50 Å Au/2 Å Co/0–40 Å Au wedge/7 Å Co/20 Å Au. A Cu(111) single crystal of 1 mm thickness and 12 mm diameter was used as a substrate. All layers were deposited at room temperature, at pressures of 10^{-9} Pa and with deposition rates of typically 0.1 Å/s. Layer thicknesses were controlled by a vibrating quartz crystal monitor and checked with *in situ* Auger electron spectroscopy (AES). The wedge start was also determined with AES and its slope was obtained using the quartz crystal (4.1 Å/mm) and confirmed with AES (4.0 Å/mm). Low-energy electron diffraction (LEED) investigations revealed that incoherent growth of the Au base layer resulted in an almost complete relaxation to the bulk Au lattice spacing. Deposition of the ultrathin 2 Å Co layer decreased the sharpness of the LEED spots. The spots remained at their position, which can be interpreted as coherent growth of the Co on Au or as due to the Au layer below the ultrathin, perhaps incoherent, Co layer. Upon deposition of the Au wedge the spots became still more diffuse. Deposition of the thicker upper Co layer clearly proceeded by incoherent growth, with the Co layer assuming bulk lattice spacings. The sixfold symmetry of all LEED photos is ascribed to either a twinned fcc(111) structure or possibly hcp(0001) structure in the case of Co. The presence of incoherent growth establishes that the conditions are met for which the occurrence of the cutoff length has been predicted.

In a perpendicularly applied field, polar Kerr hysteresis loops were measured at various positions along the Au wedge and hence at various Au interlayer thicknesses.

III. RESULTS AND DISCUSSION

In Fig. 1 schematic hysteresis loops are given in case of weak and strong, F and AF coupling. A large and small arrow

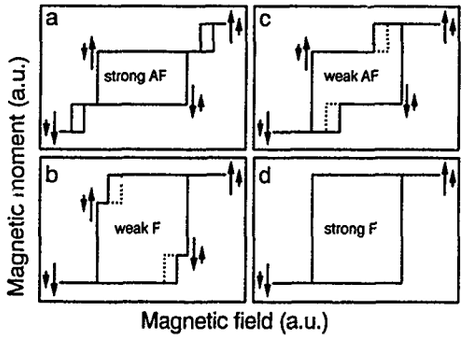

FIG. 1. Model hysteresis loops in case of (a) strong AF, (b) weak F, (c) weak AF, and (d) strong F interlayer coupling. A small and a large arrow indicate a thin and thick layer, respectively. The path indicated by the dotted lines appears if an inner loop is measured.

indicate the magnetic moment of a thick layer (layer 1) with a large coercive field and that of a thin layer (layer 2) with a smaller coercive field, respectively. Both layers are assumed to have a perpendicular easy axis, along which the external field is applied. In case of F [AF] interlayer coupling, the moment of layer 2 is oriented [anti] parallel to that of layer 1 at zero field and does not flip until the coupling is overcome by a large enough negative [positive] magnetic field, as is visible in Fig. 1(b) [1(a) and 1(c)]. As a result the hysteresis loop of layer 2 will be shifted to negative [positive] magnetic fields, although measurement of an inner loop, indicated by the dotted lines, may be required to reveal the full hysteresis loop of this layer. However, the finite coercivity of layer 1 puts an upper limit to the maximum F coupling to be measured. In the case of strong F coupling, the flipping of the moment of layer 1 at its coercive field ends the pinning of the moment of layer 2 via the F coupling against the external field. As a consequence, both moments simultaniously flip and a square hysteresis loop results as shown in Fig. 1(d). Regions of AF coupling can be identified in a straightforward way via a decrease in remanent magnetization.

A compilation of measured Kerr loops obtained at the indicated thickness of the Au interlayer is shown in Fig. 2. First, note that in the loops that show two transitions [2(e)–2(h)] one transition is large and steplike (perpendicular anisotropy), whereas the other is small and gradual (in-plane easy axis). In view of the thickness of the Co layers as well as their position below the top layer, the large steplike transition in the Kerr effect originates from a flipping of the perpendicular moment of the 7 Å Co layer, and the small gradual transition from a rotation of the in-plane moment of the 2 Å Co layer. A clear correspondence between the loops in Figs. 1 and 2 is visible. However, the steplike transition of layer 2 in Fig. 1 has become a gradual transition instead, as can be seen if one compares loop 1(c) with loop 2(h) where an inner loop was measured. An inner loop could not be measured in all cases as the AF state was not always completely reached before the transition of layer 1 took place, e.g., loop 2(f). Nevertheless, a shift of the remaining branch of the transition of layer 2 can still be seen. Comparison with Fig. 1 shows that the loops in Figs. 2(e), 2(g), and 2(h) reveal AF coupling, whereas the loop in Fig. 2(f) indicates weak F

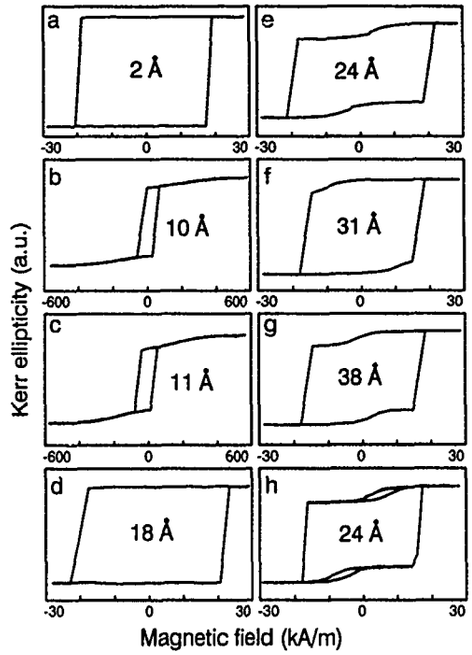

FIG. 2. Kerr hysteresis loops measured at the indicated Au interlayer thickness. Note that the magnetic field range of loops (b) and (c) is much larger than the range of the other loops.

coupling. The square loops in Figs. 2(a) and 2(d) indicate a strong F interlayer coupling. In Figs. 2(b) and 2(c) the magnetic transition of the 2 Å Co layer also indicates AF coupling, but the transition extends over a much larger field range than for example in Fig. 2(e). This can be partly understood from numerical absolute minimum energy calculations as discussed in a more extensive article,[10] in which also the transition fields as observed in Fig. 2, containing the strength of the interlayer interaction, will be analyzed. However, since the main point of this article is the oscillatory behavior of the interlayer coupling, an analysis of the remanence is sufficient.

In Fig. 3, the remanence is plotted against the Au interlayer thickness. Three minima corresponding to maximum AF coupling are visible at 12.6, 23.8, and 38.0 Å Au. The period increases with increasing spacer thickness from 11.2 to 14.2 Å (with an estimated error of ±1 Å due to wedge slope uncertainties), which indicates preasymptotic behavior. Although a decreasing period was predicted by Zlatic[11] an increasing period was also found by Shintaku, Daitoh, and

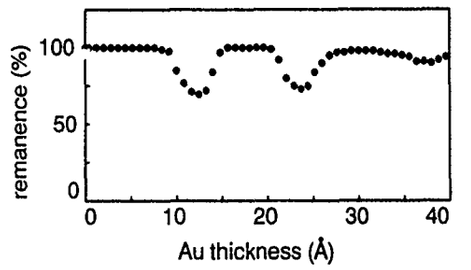

FIG. 3. Plot of the remanence against Au interlayer thickness.

Shinjo[12] for Fe/Au(100). The period at large Au thicknesses is significantly larger than the predicted[13] asymptotic period of 11.4 Å. The origin of this discrepancy is not clear, but a similar discrepancy was observed for Co/Cu(100).[14] The analysis of the transition fields[10] corroborates these results.

It has thus been established that a clear oscillatory interlayer coupling across Au(111) layers separating (partly) incoherent Co layers can be observed up to 40 Å Au. This result must be confronted with the discussion of Bruno and Chappert,[6] who argue that, in Co/Au(111)/Co, the interlayer coupling would be suppressed typically above 9 Å, being the cutoff length due to lattice mismatch. Apparently, the suppression is not strong enough to obscure the interlayer coupling at larger Au thicknesses. In view of the considerably smaller cutoff length due to lattice mismatch in the present system as compared to the cutoff length in Co/Cu(111)/Co (52 Å), one is tempted to conclude that the controversial behavior in evaporated Co/Cu(111)/Co cannot be due to this suppression. The observation of an oscillation of the coupling strength in sputtered incoherent Co/Cu(111)/Co samples[15] supports this. Still, other sources of loss of translational invariance, such as interface mixing, could be responsible for the different behavior of the Co/Cu(111) and the Co/Au(111) systems.

IV. CONCLUSIONS

From magnetization remanence data the interlayer coupling oscillation period for Au(111) between Co layers is deduced and is found to increase with spacer thickness, reflecting a preasymptotic behavior. The period of 14 ± 1 Å at large Au thickness is larger than the predicted[13] period of 11.2 Å.

Note added in proof. After completion of this work, we were informed of a similar investigation of the F and AF interlayer coupling in Co/Au(111)/Co by Grolier *et al.*[16]

The analytic theory of Brillouin light scattering from dipole-exchange spin waves (SW) in single magnetic films is extended to the case of perpendicularly magnetized exchange-coupled magnetic double layers. It is shown that the influence of the interlayer exchange coupling on the SW spectrum of a symmetric double layer can be taken into account by renormalizing the pinning parameter at the interface between the magnetic film and the spacer for the antisymmetric SW modes (the symmetric modes are unaffected). Using a Green's-function formalism for light scattering from magnetic films, we calculate the light-scattering cross sections from the dipole-exchange discrete SW branches of the double layer. Numerical examples are presented.

I. INTRODUCTION

In our previous papers[1,2] we have developed a simple analytical formalism for Brillouin light scattering from dipole-exchange spin waves (SW) in ferromagnetic films with arbitrary surface anisotropies. The aim of the present paper is to extend this theory to the case of layered structures consisting of two ferromagnetic films separated by thin nonmagnetic layers. The complete theory should account for dipole-dipole and exchange interactions within each ferromagnetic layer as well as the dipole-dipole and exchange couplings between different films (layers).

The problem of SW excitations in double-layer systems has been addressed by several authors and, although theoretical curves obtained adequately describe the existing experimental data, the theory involves lengthy numerical calculations of a rather cumbersome system of initial equations. Here we develop a more simple, analytic approach to the theoretical description of this system, and we make applications to Brillouin light scattering.

II. SPIN-WAVE SPECTRUM FOR THE DOUBLE-LAYER SYSTEM

Let us consider a perpendicularly magnetized layered structure consisting of two ferromagnetic films (labeled 1 and 2) of thicknesses L_1 and L_2, separated by a nonmagnetic layer of thickness b. The pinning constants $d_1^{s,i}$ and $d_2^{s,i}$ characterize pinning on the outer surface (s) and interface (i), respectively, of each film. The z axis is taken to be perpendicular to the planar surfaces and interfaces.

We assume that the interlayer exchange interaction is characterized by a phenomenological parameter $\beta_j = A_{12}/A_j$, j and A_j being the film number and the corresponding exchange constant, respectively, and A_{12} is the interlayer exchange constant as defined in Refs. 3 and 4. The parameter β is a function of the spacer thickness b. The typical experimental behavior of β as a function of b is discussed elsewhere.[5,6] It can be positive, negative, or oscillatory, being generally of the order of magnitude 10^6 cm^{-1}. In our theory we use β as an empirical parameter already known either from microscopic calculations or from experiment.

The procedure of obtaining the SW spectrum for the multilayered system has been developed in Ref. 7 for the case of purely dipolar coupling between the layers. It is based on the expansion of the variable part of magnetization $\mathbf{m}_j(\mathbf{r},t)$ and the dipolar field $\mathbf{h}^{\rm dip}(\mathbf{r},t)$ of the film j into the Fourier series of the following kind:

$$\mathbf{m}_j(\mathbf{r},t)=\sum_{\mathbf{k}}\sum_{n}\mathbf{m}_{\mathbf{k}jn}\phi_{jn}(z)\exp[-i(\mathbf{k}\boldsymbol{\rho}-\omega t)], \quad (1)$$

$$\mathbf{h}_j^{\rm dip}(\mathbf{r},t)=\sum_{\mathbf{k}}\sum_{n}\mathbf{h}_{\mathbf{k}jn}^{\rm dip}\phi_{jn}(z)\exp[-i(\mathbf{k}\boldsymbol{\rho}-\omega t)], \quad (2)$$

where $\mathbf{k}$ and $\boldsymbol{\rho}$ are the in-plane wave vector and radius vector, respectively, and the functions $\phi_{jn}(z)$ for the case of two layers should be taken in the form:

$$\begin{aligned}\phi_{1n}(z)&=A_{1n}\cos\kappa_{1n}\left(z+\frac{b}{2}+L_1\right)\\&\quad+B_{1n}\sin\kappa_{1n}\left(z+\frac{b}{2}+L_1\right),\\\phi_{2n}(z)&=A_{2n}\cos\kappa_{2n}\left(z-\frac{b}{2}-L_2\right)\\&\quad+B_{2n}\sin\kappa_{2n}\left(z-\frac{b}{2}-L_2\right),\end{aligned} \quad (3)$$

where κ_{jn} are the transverse discrete wave numbers. To incorporate the effects of the interlayer exchange coupling into the theory[7] we require that the eigenfunctions (3) satisfy the linearized Hoffmann boundary conditions:[5]

$$\begin{aligned}&-\frac{\partial\phi_{1n}}{\partial z}+d_1^s\phi_{1n}\Big|_{z=-(L_1+b/2)}=0,\\&\frac{\partial\phi_{2n}}{\partial z}+d_2^s\phi_{2n}\Big|_{z=(L_2+b/2)}=0,\\&\frac{\partial\phi_{1n}}{\partial z}+(d_1^i+\beta_1)\phi_{1n}\Big|_{z=-b/2}-\frac{M_{01}}{M_{02}}\beta_1\phi_{2n}\Big|_{z=b/2}=0,\end{aligned} \quad (4)$$

 0021-8979/94/75(10)/6443/3/$6.00 © 1994 American Institute of Physics

$$-\frac{\partial\phi_{2n}}{\partial z}+(d_2^i+\beta_2)\phi_{2n}\Big|_{z=b/2}-\frac{M_{02}}{M_{01}}\,\beta_2\phi_{1n}\Big|_{z=-b/2}=0,$$

where M_{0j} is the static magnetization in the film j. In particular, for a symmetric structure with two identically magnetized layers (i.e., $L_1=L_2\equiv L$, $d_1^{i,s}=d_2^{i,s}\equiv d^{i,s}$, $\beta_1=\beta_2\equiv\beta$, $M_{01}=M_{02}\equiv M_0$, $\kappa_{1n}=\kappa_{2n}\equiv\kappa_n$), Eqs. (4) lead to

$$(\kappa_n^2-d^s d^i)\tan\kappa_n L=\kappa_n(d^s+d^i) \tag{5}$$

for the *symmetric* modes, i.e., the modes with the variable magnetization in the both layers distributed similarly, and

$$[\kappa_n^2-d^s(d^i+2\beta)]\tan\kappa_n L=\kappa_n[d^s+(d^i+2\beta)] \tag{6}$$

for the *antisymmetric* modes.

Equation (5) is the same as that for a single (uncoupled) layer of thickness L (see, e.g., Refs. 8 and 9). Equation (6) has a similar form but with a modification of the interface pinning due to the interlayer exchange β, i.e., $d^i\rightarrow d^i+2\beta$. Thus we conclude that the interlayer coupling affects only antisymmetric modes. This conclusion is in agreement with the results of Ref. 3. In particular, in the case of unpinned surface spins ($d^i=d^s=0$) we recover from Eq. (6) all the results for transverse wave numbers of antisymmetric modes obtained in Ref. 3. It also follows from the results of Refs. 8 and 9 that when $d^i=d^s=0$ for $\beta>0$ we get only real solutions for κ (bulk modes), while for $\beta<0$ along with the infinite number of bulk solutions we obtain one (lowest) surface solution with imaginary κ_n. By making the replacement $d^i\rightarrow d^i+2\beta$, we can apply all the conclusions of our previous papers[1,2] to describe quantitatively the SW dispersion in exchange-coupled magnetic double layers.

Using Eqs. (5) and (6) to calculate the transverse SW wave numbers κ_n in a double layer with exchange coupling, and the formalism developed in Ref. 7 for dipolar coupling of magnetic layers we can derive an approximate dispersion relation for SW propagating in a magnetic double layer consisting of two identical magnetic films coupled by both dipole-dipole and exchange interactions. In a particular case of coupling of two identical (nth) modes in both films we get the following dispersion relation for a double layer:

$$(\omega_n^{\pm})^2=\Omega_n(\Omega_n+\omega_M P_{nn})\pm(\omega_M\Omega_n P_{nn}^{12})^2, \tag{7}$$

where the + sign corresponds to antisymmetric modes, the − sign corresponds to symmetric modes, $\omega_M=4\pi\gamma M_0$, and γ is the gyromagnetic ratio. $\Omega_n=\Omega(\kappa_n)$ is the eigenfrequency of the nth SW mode of a single film in the purely exchange limit (see Refs. 7 and 8); it depends on $\omega_H=\gamma(H_e-4\pi M_0)$, where H_e is the external bias magnetic field. We do not reproduce here the lengthy expressions for the diagonal $P_{nn}=P_{nn}^{11}=P_{nn}^{22}$ and off-diagonal P_{nn}^{12} dipole matrix elements in coupled magnetic films as the procedure of their analytical evaluation is well developed (see, e.g., Refs. 7 and 8). We note that, as the expressions for P_{nn} and P_{nn}^{12} depend on the values of the transverse wave numbers κ_n (and therefore on the value of the exchange coupling coefficient β), so does the splitting of the spectral branches. This leads us to the conclusion that the dipole-dipole and exchange splitting of the dispersion branches should not be considered separately. Both types of splitting influence the spectrum and, though interlayer exchange mainly affects the frequencies of antisymmetric SW modes near $k=0$ [see Eq. (6)], it will also significantly change the dipole-dipole branch repulsion in the short-wavelength ($kL\gg1$) region.

III. BRILLOUIN LIGHT SCATTERING

The Green's-function formalism for Brillouin light scattering from multilayered magnetic structures is well established (see Ref. 10 and references therein) and can be considered as a direct generalization of our earlier work[1,2] for thin films. Basically, the scattering cross section can be expressed in terms of a weighted summation over magnetization-dependent Green's functions $\langle\langle m_{n\mathbf{k}}^{\mu};m_{n'\mathbf{k}}^{\nu}\rangle\rangle$ with $\mu,\nu=x,y$. The weighting factors depend on the temperature, magneto-optical coupling, electric field polarizations, scattering geometry, and the optical transmission coefficients at the various surfaces and interfaces. Hence, since the appropriate Green's functions have been calculated from the formalism described earlier, it is straightforward in principle to determine the light-scattering intensities associated with the various SW modes. In the general case it is necessary to take account of the various internal multiple reflections of the incident and scattered light at the surfaces and interfaces of the sample. In the present paper we avoid this difficulty by restricting attention to the case when the optical penetration depth of the light in the sample is smaller than L (e.g., as would be typically in the case of Fe films), thereby making the multiple reflection effects negligible.

IV. DISCUSSION OF NUMERICAL RESULTS

We are interested here in surface SW modes of a double layer that correspond to the solutions of Eqs. (5)–(7) for imaginary κ_n. The numerical analysis shows, that, depending on the values of d^i, d^s, and β, there exist two, one, or no such solutions. When both of the effective pinning parameters d^i and d^s are negative and sufficiently large, there are two imaginary solutions for κ_n, while for non-negative values of one of these parameters a single solution exists only if the second parameter is negative. The same kind of analysis can be applied to the dependence of the κ values on the exchange coupling coefficient β. As the symmetric modes are not affected by the interlayer exchange, the κ_n values for the symmetric modes remain the same for all values of β. Contrary to that, for the antisymmetric modes the effective interface pinning changes with β and so do the κ_n values.

We calculated the dependence of the imaginary transverse wave numbers (corresponding to surface SW modes) on the interlayer exchange parameter β for the system Fe/spacer/Fe. We used the following set of parameters:[1] exchange parameter[1,2] $\alpha=A/(2\pi M_0^2)=1.15\times10^{-13}$ cm^{-1}, film thickness $L=200$ Å, $4\pi M_0=21$ kG, the external bias magnetic field $H_e=22.5$ kOe, and the pinning parameters $d^s=d^i=d=K_s/A=-1\times10^6$ cm^{-1}. The values of β were taken to vary from -5×10^5 to 1×10^5 cm^{-1}. The results are presented in Fig. 1. For the given set of parameters there exist one surface branch for the symmetric mode (horizontal line A) and two surface branches for the antisymmetric mode

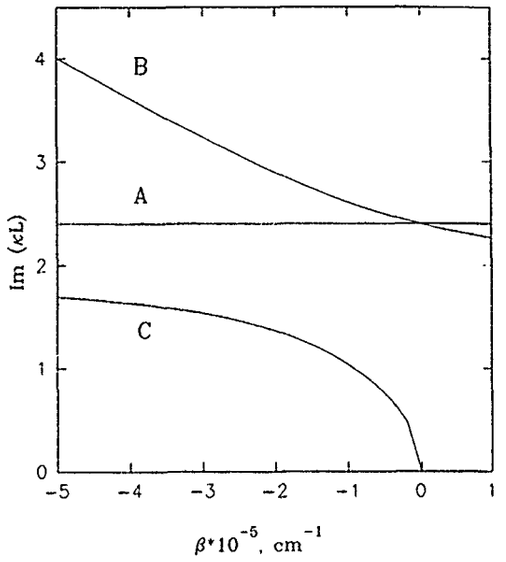

FIG. 1. The dependencies of imaginary perpendicular SW wave numbers on the interlayer exchange coefficient β for the Fe/spacer/Fe structure (see text for the parameters and details).

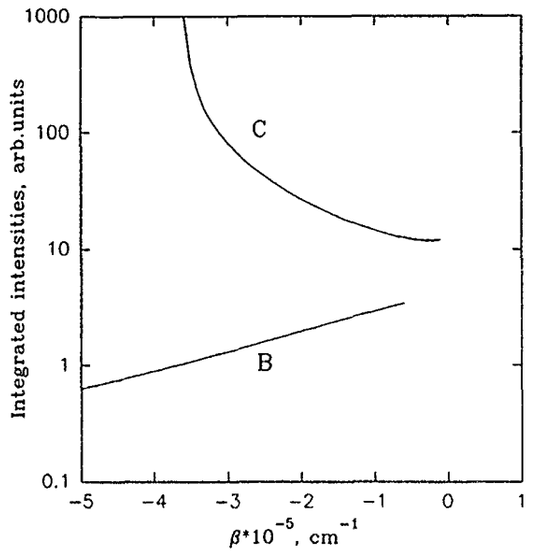

FIG. 3. The dependencies of the integrated intensities of Brillouin light scattering from the surface SW on the interlayer exchange coefficient β for the Fe/spacer/Fe structure (see text for the parameters and details).

(curves B and C). Curve C ends at the point $\beta=0$, where the corresponding branch of the SW spectrum meets the bulk continuum.

The existence of the imaginary solutions for κ_n, however, does not guarantee the existence of the corresponding branches in the SW spectrum. This becomes clear from the analysis of the dispersion equation (7). The dipole matrix elements P_{nn}^{ik} are always positive. However, the sign of the Ω_n depends on the values of $|\mathbf{k}|$ and κ_n, sometimes becoming negative. In this case if P_{nn}^{ik} are sufficiently large, the right-hand side of Eq. (7) becomes negative.

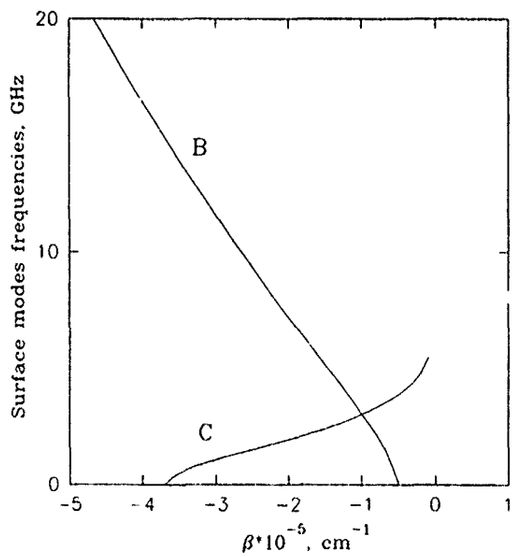

FIG. 2. The dependencies of surface SW frequencies on the interlayer exchange coefficient β for the Fe/spacer/Fe structure (see text for the parameters and details).

The above conclusions are confirmed by the results of our calculations of the SW spectrum and the integrated intensities of the light scattering from the system Fe/spacer/Fe for the given values of the parameters. We used the same 180° backscattering geometry as previously,[1,2] taking the complex refractive index $\eta=2.72+2.86i$, incident light wavelength $\lambda=488$ nm, and the scattering angle $\Theta=\pi/4$. This provides for the in-plane wave number of the SW to be $|\mathbf{k}|\cong 1.8\times10^5$ cm^{-1}. In Fig. 2 we display the dependencies of the surface modes frequencies on β. It can be seen that though the imaginary κ for symmetric mode exists, there is no corresponding branch in the SW spectrum. As well, branch C in Fig. 2, corresponding to curve C in Fig. 1, appears only when the β values are in the interval from about -3.6×10^5 to 0 cm^{-1}. In the same way, branch B ceases to exist when $\beta\geqslant-0.5\times10^5$ cm^{-1} while the corresponding κ dependence (curve B in Fig. 1) still shows the existence of the solution. Basically the same characteristic features can be seen in Fig. 3, where the integrated intensities of the Brillouin light scattering are depicted.

Self-stabilization of domain walls in antiferromagnetically coupled multilayered magnetic films

Hideo Fujiwara, Tomohiro Ishikawa, and W. D. Doyle
The University of Alabama, Center for Materials for Information Technology, Tuscaloosa, Alabama 35487-0209

In our previous work, it was shown that in antiferromagnetically coupled multilayered films there is the possibility of the appearance of both Bloch-type walls and Néel-type walls at the center of which the magnetizations point parallel (PB,PN) or antiparallel (AB,AN) to each other between the adjacent layers when a high field is applied in one direction and then removed. Here it is shown that the shift of the walls in each layer from their vertical alignment will give substantially lower energy for the AB walls and for the PN walls, giving rise to self-stabilization, and that the effect is greater for the latter than the former for $[Co/Cu]_N$ systems with the thickness ratio $t_{Co}/t_{Cu}=2$. This will result in a greater possibility of the PN walls formation than was expected in the previous work. In the region where the number of layers and the coupling field are of practical interest, Néel walls are favored, and AN walls have lower energy than PN walls. In this case, it is likely that the transition of the wall types from PN to AN and vice versa will occur during the magnetization process, which will cause noise in sensor applications.

INTRODUCTION

The giant magnetoresistance effect in antiferromagnetically coupled multilayered films has raised great interest both from the viewpoint of physics and from the viewpoint of its applications to magnetic sensors, such as read heads in magnetic recording. Domain wall behavior is one of several important properties that should be investigated thoroughly, especially for applications. Although there have been extensive studies on domain walls in multilayered films, they were mostly on ferromagnetically and/or magnetostatically coupled films (see, for instance, the first reference[1]). Our previous work[2] showed that in antiferromagnetically coupled multilayered films, such as $[Co/Cu]_N$ films, when a high field is applied in one direction and then removed, both parallel and antiparallel magnetization configurations with respect to the magnetization direction at the center of the walls of adjacent layers will become stable, both for Bloch-type and for Néel-type walls, depending on the film geometry and the strength of antiferromagnetic exchange coupling between the layers. In this paper we report on the effect of the shift of the walls from their vertical alignment on the wall energy, which reveals that the formation of parallel Néel (PN) walls is more favored by the shift than parallel Bloch (PB) and antiparallel Bloch (AB) walls for some cases of multilayered films of interest. A probable occurrence of the transition from PN to AN (antiparallel Néel) walls and vice versa during the magnetization processes will also be discussed.

DOMAIN WALL MODELS

Figure 1 illustrates the magnetization configurations in parallel (PB) and antiparallel (AB) Bloch walls and parallel (PN) and antiparallel (AN) Néel walls when no external field is applied. It is evident that for AB walls and PN walls, a shift of the center of the domain walls with respect to that of the adjacent layers, as shown in the figure, gives lower energy through the reduction in magnetostatic energy, while for PB walls and AN walls, it will not. The shift will make a zig–zag configuration for AB walls, while, for PN walls, it will result in a step-type configuration, because the magnetostatic interaction between the next nearest neighbors is attractive for the AB walls, while that for PN walls is repulsive.

DOMAIN WALL SHIFT

For simplicity, it is assumed that the magnetization direction in the wall changes linearly in the width direction, x, in a way, as given by

$$\phi=\pi x/\delta \quad \text{and} \quad -\pi x/\delta, \quad \text{for parallel walls,} \tag{1a}$$

$$\phi=\pi x/\delta \quad \text{and} \quad \pi x/\delta+\pi, \quad \text{for antiparallel walls.} \tag{1b}$$

Here, the origin of the x axis is set at the center of each wall, δ denotes the wall width, and the former and the latter formulas in each equation correspond to the magnetization direction of the odd and even numbered layers from the bottom, respectively.

The wall energy per unit area σ is expressed as a sum of the exchange energy σ_A, anisotropy energy σ_k, antiferromagnetic coupling energy σ_{AF}, and magnetostatic energy σ_s as

$$\sigma=\sigma_A+\sigma_k+\sigma_{AF}+\sigma_s. \tag{2}$$

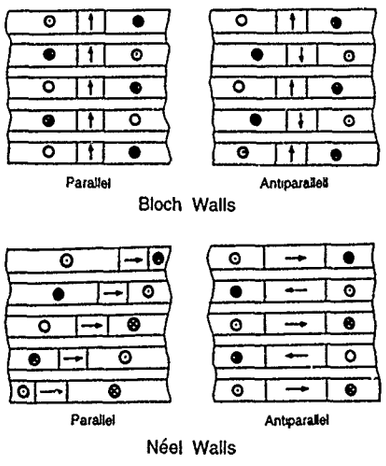

FIG. 1. Magnetization configurations in parallel and antiparallel Bloch walls and parallel and antiparallel Néel walls.

 0021-8979/94/75(10)/6446/3/$6.00 © 1994 American Institute of Physics

Among the above four energies, σ_{AF}, as well as σ_s, varies explicitly with the amount of the shift Δ, while the other two vary implicitly through the change of the wall width σ.

The antiferromagnetic coupling energy σ_{AF} is expressed as

$$\sigma_{AF}=\left(\frac{I_sH_s}{4}\right)\int_{-\delta/2}^{\delta/2+\Delta}(1+\cos\Delta\phi)dx, \tag{3}$$

where, I_s is the saturation magnetization, H_s is the effective antiferromagnetic coupling field, and $\Delta\phi$ is the difference of the angle of the magnetization between the adjacent magnetic layers. Therefore, by using (1a) and (1b), we obtain, for both AB walls and PN walls,

$$\sigma_{AF}^{AB}=(I_sH_s/4)[(\delta+\Delta)-(\delta-\Delta)\cos(\pi\Delta/\delta) -(2\delta/\pi)\sin(\pi\Delta/\delta)], \quad \text{for } \Delta\leqslant\delta, \tag{4a}$$

$$=I_sH_s\Delta/2, \quad \text{for } \Delta\geqslant\delta, \tag{4b}$$

and

$$\sigma_{AF}^{PN}=\left(\frac{I_sH_s}{4}\right)\left[(\delta+\Delta)-\left(\frac{\delta}{\pi}\right)\sin\left(\frac{\pi\Delta}{\delta}\right)\right], \quad \text{for } \Delta\leqslant\delta, \tag{5a}$$

$$=I_sH_s\Delta/2, \quad \text{for } \Delta\geqslant\delta, \tag{5b}$$

respectively.

On the other hand, the calculation of the magnetostatic energies for AB walls and PN walls, σ_s^{AB} and σ_s^{PN}, are carried out according to the method described in the previous paper.[2] The results are as follows:

$$\sigma_s^{AB}=\left(\frac{I_s^2t}{4N}\right)\sum_{m,n=1}^{N}(-1)^{n-m+1}\int_0^{\delta'}\left[(\delta'-\xi')\cos\left(\frac{\pi\xi'}{\delta'}\right)+\left(\frac{\delta'}{\pi}\right)\sin\left(\frac{\pi\xi'}{\delta'}\right)\right][L(\Delta'_{mn}+\xi')+L(\Delta'_{mn}-\xi')]d\xi', \tag{6}$$

$$L(X)=\log\{(B_{mn}^2+X^2)^2/[(B_{mn}+1)^2+X^2] \times[(B_{mn}-1)^2+X^2]\}, \tag{7}$$

$$B_{mn}=(n-m)(1+d'), \quad d'=d/t, \tag{8}$$

$$\Delta'_{mn}=\Delta'=\Delta/t, \quad \text{for } (n-m)\text{:odd},$$

$$=0, \quad \text{for } (n-m)\text{:even},$$

$$\sigma_s^{PN}=\left(\frac{\pi I_s^2t}{4N}\right)\sum_{m,n=1}^{N}\int_0^{\delta'}\left(1-\frac{\xi'}{\delta'}\right)\sin\left(\frac{\pi\xi'}{\delta'}\right)\{[(n-m)\Delta' +\xi']F[(n-m)\Delta'+\xi']-[(n-m)\Delta'-\xi'] \times F[(n-m)\Delta'-\xi']\}d\xi'. \tag{9}$$

The formulations for the other energies are the same as in the previous paper.[2]

The magnetostatic energy shown above decreases with increasing shift Δ almost monotonically, while the antiferromagnetic coupling energy increases quadratically at the beginning and linearly in the end. Therefore, at some point an equilibrium is attained.

CALCULATION OF THE EFFECT OF THE WALL SHIFT ON THE WALL ENERGY OF $[Co/Cu]_N$ MULTILAYERED FILMS

Numerical calculations were performed for $[Co/Cu]_N$ multilayered films having the thickness ratio $t_{Co}/t_{Cu}=2$, using the formulas derived above. For the calculations, the saturation magnetization I_s and the exchange constant A of the cobalt were assumed to be 1.45×10^3 emu/cm^3 and 1.3×10^{-6} erg/cm, respectively, and the uniaxial anisotropy was assumed to be negligible compared to the effective field H_s of the antiferromagnetic exchange coupling.

Figures 2(a) and 2(b) show how the wall shift at the equilibrium state Δ^* depends on H_s for PN walls and AB walls in $[Co/Cu]_N$ films ($N=4$, 16), respectively. It is noticed that with the increase in H_s, Δ^* decreases rapidly. The figures also show how the wall width δ changes with H_s. For weak H_s, Δ^* is seen to approach the wall width.

Figure 3 shows the wall energy dependence on H_s for PB, AB, and PN walls with the number of Co layers, N, as a parameter. The case of AN walls is discussed in the next section. Figure 4 illustrates the critical field at which the wall type changes from one to another as a function of N. For comparison, the critical curves obtained without taking into account the effect of the wall shift are also shown by dotted lines. It is seen that the wall shift favors PN walls more than AB walls and that the area in which PN walls are stable is substantially expanded by the shift effect.

DISCUSSION

As is evident from the results described above, PN walls will be the most likely walls to appear among the three PB, AB, and PN walls, especially for the multilayered films for practical applications such as read heads for magnetic recording, where weak antiferromagnetic coupling is required in order to obtain high field sensitivity. Of course, AN walls should have lower energy than PN walls when no external field is applied. However, during the magnetization process after the multidomain splitting from the saturated state, there is a possibility of forming PN walls before they turn into AN walls. Figure 5 shows PN and AN wall energies calculated as

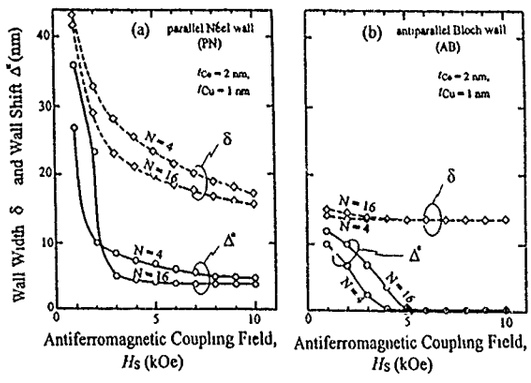

FIG. 2. Domain wall width and the amount of the wall shift at the equilibrium state estimated for [2 nm Co/1 nm Cu]$_N$ multilayered films. (a) parallel Néel walls (PN); (b) antiparallel Bloch walls (AB).

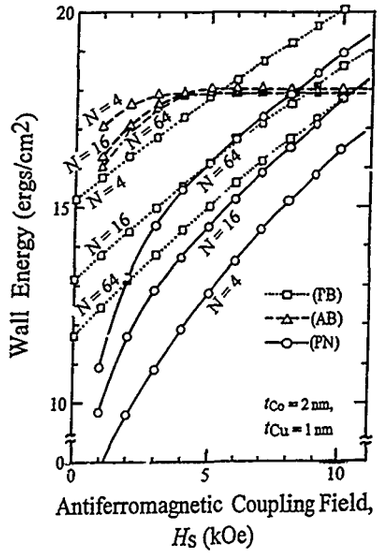

FIG. 3. Wall energy vs antiferromagnetic coupling field curves for parallel and antiparallel Bloch walls (PB and AB) and for antiparallel Néel walls (AN) in [2 nm Co/1 nm Cu]$_N$ multilayered films obtained by calculation.

a function of the applied field in the hard direction. The calculation was performed almost the same way as above, the detail of which will be presented elsewhere. Here, the film is assumed to be of the form [2 nmCo/1 nmCu]$_4$ with an anisotropy field and an effective antiferromagnetic coupling field of 20 Oe. It is seen that at the applied field of about 10 Oe, the two curves cross each other. Therefore, in this case, the type of walls will transfer from PN to AN, and vice versa, during the ascending and descending processes. The transitions will occur as indicated by the arrows in the figure, because some coercivity is likely to exist for the transition, and this will give rise to noise when such a film is applied to sensor devices.

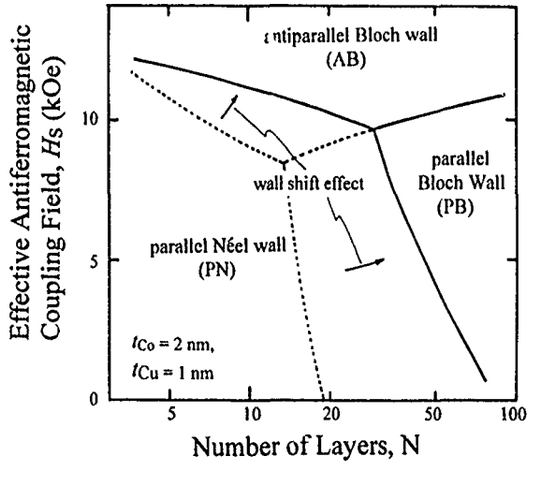

FIG. 4. Critical coupling fields for transition of the types of wall as a function of the number of layers of [2 nm Co/1 nm Cu]$_{16}$. Dotted lines are for the case where no wall shift is taken into consideration.

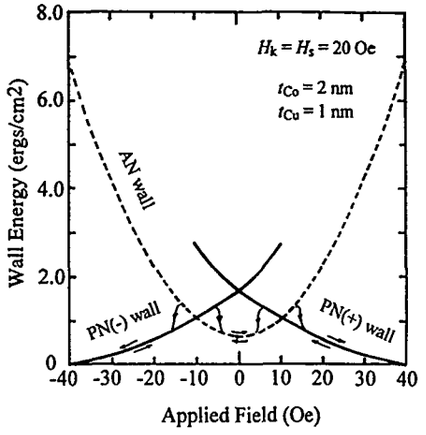

FIG. 5. PN and AN wall energies as a function of applied field calculated for [2 nmCo/1 nmCu]$_4$ multilayered films. Anisotropy field H_k and the effective antiferromagnetic coupling field H_s are assumed to be 20 Oe. PN(+) and PN(−) denote the PN walls magnetization at the center of which possess + or − polalities, respectively.

CONCLUSION

It was confirmed by energy estimation that, in antiferromagnetically coupled multilayered films, the shift of the center of the walls of the adjacent layers with respect to each other reduces their magnetostatic energy substantially for PB and AN walls, resulting in self-stabilization. This effect is especially prominent when the coupling energy is small, because the smaller the coupling energy, the more shift is allowed. It was also confirmed that for [Co/Cu]$_N$ films with the thickness ratio t_{Co}/t_{Cu}=2, this effect favors PN walls more than AB walls, leading to more of a likelihood of the PN walls' appearance than PB or AB walls. As AN walls have lower energy than PN walls when no field is applied, it may be likely that a transition from PN to AN and vice versa will occur during the magnetization process.

Short period oscillation of the interlayer exchange coupling in sputtered Co-Re superlattices

J. L. Leal
Instituto de Engenharia de Sistemas e Computadores, R. Alves Redol, 9-1, 1000 Lisbon, Portugal and Centro de Fisica Nuclear da Universidade de Lisboa, Av. Prof. Gama Pinto 2, 1699 Lisbon, Portugal

P. P. Freitas

A short period oscillation was observed in the interlayer exchange coupling of *sputtered* Co-Re superlattices, superimposed on a long period oscillation. This effect is observed on hcp-textured samples with the *c* axis perpendicular to the plane of the film. The variation of the exchange coupling strength with the spacer thickness can be described using the Bruno and Chappert theory with two oscillatory terms, with periods of 2.9±0.2 and 10.2±0.2 Å. Both magnetization and magnetoresistance measurements reflect the influence of this multiperiodic exchange.

After the discovery of antiferromagnetic (AF) exchange coupling between ferromagnetic transition-metal layers across metallic spacers[1] and the subsequent discovery of its oscillatory behavior as a function of the interlayer thickness,[2] many important details of this interaction have been reported.

Large oscillation periods were found initially (10–20 Å) for most transition-metal and noble-metal spacers.[3] More accurate measurements of the interlayer coupling on molecular beam epitaxy (MBE)-prepared samples with very good epitaxial growth have shown the presence of additional oscillations with a short period, down to 2 to 3 monolayers (ML).[4–6] The modified Ruderman-Kittel-Kasuya-Yosida theory proposed by Bruno and Chappert[7,8] provides an explanation for the occurrence of these multiperiodic oscillations. In their approach, in which the discreteness of the spacer is taken into account, the coupling is related to the topological properties of the Fermi surface of the spacer material. Quantitative predictions for the oscillation periods and relative strength in the case of noble-metal spacers could be obtained and were compared with experimental values. Good agreement was obtained for several epitaxially grown systems such as (001) Fe/Au/Fe or (001) Co/Cu/Co. The influence of structural imperfections on the coupling strength was observed experimentally, and an increase in interface roughness was shown to be detrimental for the observance of short period oscillations.[9] This explains why sputtered systems, probably due to their less perfect interfaces, did not show until now evidence of short period oscillations.

In the present study we report the observation of a multiperiodic oscillation of the interlayer exchange coupling on *sputtered* Co-Re superlattices (SL). In a previous study we have shown that high-quality Co-Re SL's can be prepared, depending on the substrate, buffer thickness, and deposition conditions.[10] Rutherford backscattering analysis indicated that chemical mixing or surface topography occurred within 2.5 Å of each side of the interface.[10,11] Anisotropic magnetoresistance (AMR) measurements confirm up to 15% Re mixed into the Co layer, leading to negative AMR, characteristic of virtual bound-state impurities such as Re, Ru, and Ir, in a Co matrix.[12]

We decided to perform a detailed study of the coupling dependence on the Re spacer thickness on these high-quality samples in order to determine if any fine structure in the coupling could be detected, apart from the well-known long period oscillation.[3,13]

Co-Re SL's were grown in a automated, load-locked, high-vacuum magnetron sputtering system (Nordiko 2000). The base pressure before deposition is 2×10^{-8} Torr. Ar pressure during deposition was maintained at 5 mTorr. Samples were deposited onto water-cooled substrate holders. The Co was deposited by dc magnetron sputtering at a rate of 1.9 Å/s while Re was deposited at rates of 0.6 Å/s. Care was taken in order to have a ±0.25-s precision control on deposition times, thus leading to an uncertainty of ±0.15 Å on the Re thickness. We should stress, however, that these are only average values. Transmission electron microscopy (TEM) pictures of sputtered SL's show that 1- or 2-Å local variations in the thickness of the spacer layers are possible. Co and Re deposition rates were calibrated by Rutherford backscattering spectrometry (RBS) and profilometer analysis. The individual Re and Co thickness of specially prepared multilayers was directly cross-checked by RBS.

We have analyzed a set of samples with the following structure: glass/$Re_{200\ Å}$/$[Co_{17\ Å}/Re_{t_{Re}}]_{\times16}$, where t_{Re} varies from 2.5 to 19 Å by 0.3-Å steps. Magnetic characterization was performed at room temperature using a vibrating sample magnetometer (VSM), with a resolution of 5×10^{-6} emu. A superconducting quantum-interference device (SQUID) setup was used to perform the magnetization measurements at 20 K. Both substrate and sample holder contributions to the total magnetization were removed. Transport measurements were done at room temperature using the standard dc four-probe technique with the current flowing in the plane of the structure and perpendicular to the external applied field.

Room-temperature magnetization results for a set of $[Co_{17\ Å}/Re_{t_{Re}}]_{\times16}$ SL's are shown in Figs. 1 and 2. Figures 1(a) and 1(b) show magnetization hysteresis loops for samples in the two main antiferromagnetic peaks (t_{Re}=5 Å and t_{Re}=16 Å). For Re thicknesses between 9.5 and 12.5 Å ferromagnetic coupling occurs. Figure 1(d) shows magneti-

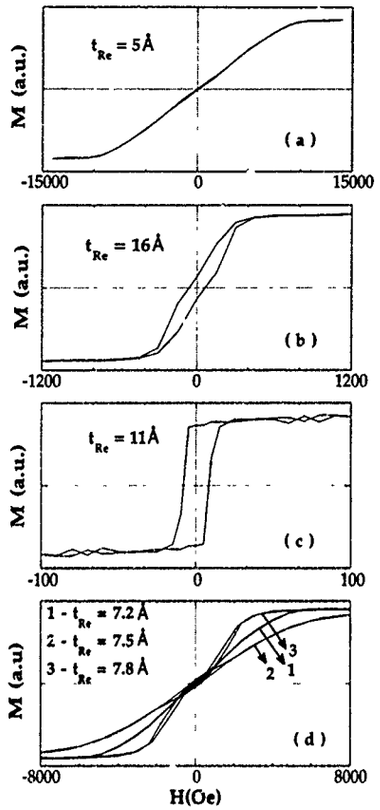

FIG. 1. Room-temperature magnetization hysteresis cycles at different Re spacer thicknesses. (a) and (b) correspond to antiferromagnetic coupling at t_{Re}=5 and 16 Å. (c) shows a ferromagnetically coupled sample. (d) shows magnetization curves for Re thicknesses of 7.2, 7.5, and 7.8 Å. Notice the peak in the saturation field at t_{Re}=7.5 Å.

zation data obtained in the region of the narrow peak at t_{Re}=7.5 Å.

In order to evaluate $J(t_{Re})$ as a function of the spacer thickness, we measured the saturation field H_S from magnetization curves taken at room temperature and at 20 K. H_S was defined as the field needed to reach 90% of the saturation magnetization. The saturation field and the total coupling are related by[5]

$$J(t_{Re}) = -t_{Co} M_S H_S/4, \tag{1}$$

where M_S is the ferromagnetic layer magnetization and t_{Co} its thickness. In Figs. 2 and 3 we plot the dependence of H_S on the Re thickness at room temperature and at 20 K, respectively. Notice the fine structure observed around t_{Re}=7.5 Å and near the second antiferromagnetic peak. Consider first the peak at t_{Re}=7.5 Å. It could arise due to a thickness-dependent anisotropy on top of the antiferromagnetic exchange. However, careful magnetization measurements in this region show no evidence of in-plane anisotropy on any of the antiferromagnetic coupled samples. Furthermore, as we will see later, the magnetoresistance also shows a maximum in this region, corresponding to a better defined antiparallel alignment between the Co layers due to stronger antiferromagnetic exchange coupling.

We will then analyze our data for the exchange constant in terms of a long period oscillation, by now well known in

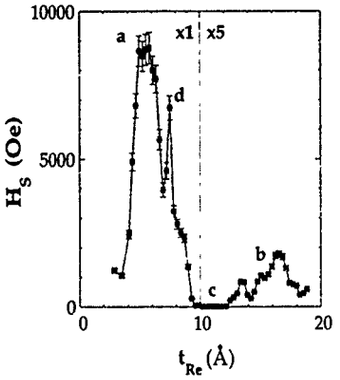

FIG. 2. Saturation field vs Re spacer thickness (t_{Re}) for the Co-Re SL's under study (300 K). The two major peaks observed at t_{Re}=5.5 and 16.5 Å correspond to the long period oscillation. The narrow and sharp peak observed at t_{Re}=7.5 Å, as well as the peaks at 13.5 and 16.5 Å, corresponds to a short period oscillation of the coupling constant with a periodicity of ≈3 Å.

Co-Re SL's,[3,13] $\Lambda_1 \approx 10$ Å, and a small period oscillation, $\Lambda_2 \approx 3$ Å, that will be responsible for the extra peaks observed. We then write $J(t_{Re}) = J_1(t_{Re}, \Lambda_1) + J_2(t_{Re}, \Lambda_2)$.

The long period component is responsible for the antiferromagnetic peaks observed at 5.5 and 16.5 Å, and the short period component is responsible for those observed at 7.5, 13.5, and also at 16.5 Å.

From the theory of Bruno and Chappert, the dependence of $J(t_{Re})$ on the interlayer thickness is given by:

$$J(t_{Re}) = -J_0 (1/t_{Re})^2 \sum \left(a_\alpha \sin(q_\alpha t_{Re} + \phi_\alpha) \times \{[t_{Re}/L_\alpha(T)]/\sinh[t_{Re}/L_\alpha(T)]\}\right), \tag{2}$$

where J_0 is a constant, the a_α are weight factors, and $L(T)$ is an attenuation length inversely proportional to the temperature. The $\mathbf{q}_\alpha$ are extremal spanning vectors of the Re Fermi surface, parallel to the growth direction of the system. The ϕ_α are phase shifts related to the topology of the Fermi surface.

Using this theory we have performed a fit to the experimental data shown in Figs. 2 and 3. For the room-temperature data, the results of this fit are shown in Fig. 4. The solid line was obtained using a two-period model (α

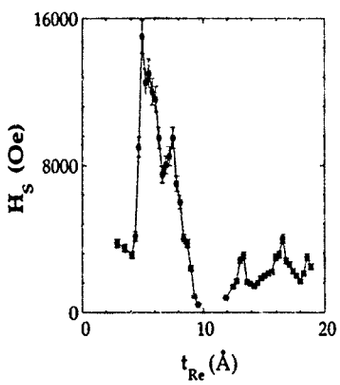

FIG. 3. Same as Fig. 2 but obtained at 20 K with a SQUID setup. Again, a multiperiodic oscillation can be observed.

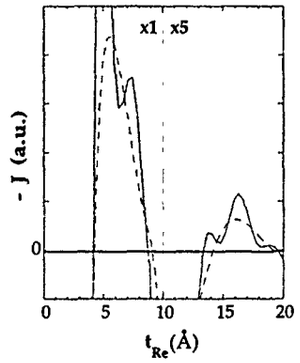

FIG. 4. Theoretical prediction for the exchange coupling constant variation with Re spacer thickness (t_{Re}), at room temperature, using Bruno and Chappert's theory. The dashed line corresponds to the long period oscillation only, while the solid line assumes two periods of 10.2±0.2 and 2.9±0.2 Å, respectively. Notice the good agreement between the experimental data and the theoretical fit..

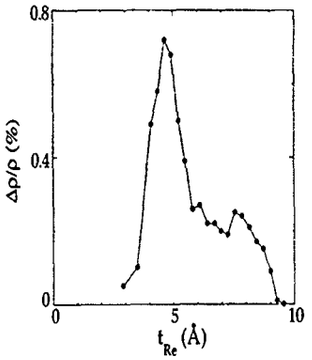

FIG. 5. Magnetoresistance vs Re thickness (t_{Re}) for Co-Re SL's with t_{Re} ranging from 3 to 9.5 Å. The magetoresistance closely follows the exchange coupling constant dependence on Re thickness, being larger at Re thicknesses where the exchange is strongest, therefore leading to well-defined antiparallel Co layers.

=1,2) with $\phi_1=\pi/6$, $\phi_2=\pi/3$, $a_2/a_1=0.3$, and shows a long period oscillation, $\Lambda_1=2\pi/q_1=10.2\pm0.2$ Å, and a short period oscillation, $\Lambda_2=2\pi/q_2=2.9\pm0.2$ Å. The main temperature-dependent parameter is $L_\alpha(T)$, which is 5–6 times larger at low temperature than at room temperature. We find $L_1(300\text{ K})=4.75$ Å and $L_2(300\text{ K})=6$ Å. The fit is in good agreement with the experimental data. The dashed line in Fig. 4 was obtained taking into account only the long period interaction ($\alpha=1$). Notice that from our magnetization data we can only measure the coupling constant for AF coupled layers [$J(t_{Re})<0$].

The Bruno and Chappert model states that experimentally measured periods are equal to $2\pi/|\mathbf{q}_\alpha|$. However, due to the discreteness of the spacer thickness, only vectors $\mathbf{q}_\alpha$ for which $|\mathbf{q}_\alpha|\leqslant\pi/d$ are relevant (d is the distance between lattice planes of the interlayer material). As a consequence the periods are expected to be at least 2 ML. Our Co-Re samples are mainly hcp with the ⟨0001⟩ axis perpendicular to the plane of the sample.[14]

It is then important to compare the observed periodicities with the Fermi surface extremal spanning vectors for the Re spacer.[15] The main spanning vector found parallel to the ⟨0001⟩ direction corresponds to observed long period oscillation. No shorter periods are predicted for this direction.[16] On the other hand, shorter period oscillations ($\Lambda\approx3$–6 Å) are predicted for spanning vectors parallel to the ⟨1120⟩ and ⟨1100⟩ directions. In the particular case of the ⟨1120⟩ direction (2 ML=2.76 Å) a short period oscillation of ≈3 Å is predicted.[16] The observed short period oscillation in our ⟨0001⟩ textured samples could then be associated with a small fraction of crystallites grown with the ⟨1120⟩ axis parallel to the growth direction. This hypothesis will have to be checked by growth of the appropriate single crystal films.

Figure 5 shows the room-temperature magnetoresistance (MR) for the set of samples used before, with t_{Re} varying from 3 to 9.5 Å. We define $\Delta\rho/\rho=(\rho_{H=0}-\rho_{H=H_S})/\rho_{H=0}$, where $\rho_{H=0}$ and $\rho_{H=H_S}$ are the resistivities measured at zero field and after magnetic saturation. Notice the sharp peak in the MR at 5 Å of Re, followed by a fast decrease, and a leveling between 6 and 8 Å of Re. This leveling of the MR value in a region where the coupling constant shows a peak can be understood by remembering that an extra damping factor, $\exp(-t_{Re}/\lambda)$, where λ is a quantity related to the electron mean free path in the ML, affects the magnetoresistance due to the interfacial nature of spin-dependent scattering in Co-Re superlattices.[17] This damping factor balances the increase in MR due to better antiparallel alignment as the coupling constant gets stronger.

Hot electron spin-valve effect in coupled magnetic layers

R. J. Celotta, J. Unguris, and D. T. Pierce
Electron Physics Group, National Institute of Standards and Technology, Gaithersburg, Maryland 20899

SEMPA observations of magnetic exchange coupling in the Fe/Ag/Fe, Fe/Au/Fe, and Fe/Cr/Fe systems reveal an intensity variation in the emitted secondary electron signal that depends only on whether the Fe layers are coupled in a ferromagnetic or antiferromagnetic sense. We ascribe this new effect to spin dependence in the transport of electrons between the two magnetic layers.

INTRODUCTION

The phenomena of exchange coupling of ferromagnetic layers and the related giant magnetoresistance effect (GMR) have been the subject of extensive recent research,[1] owing, in part, to the potential such effects have for application in a new class of devices called spin valves.[2] The GMR effect depends upon a difference in the spin-dependent transport of Fermi energy electrons between two or more ferromagnetic layers that are aligned either ferromagnetically or antiferromagnetically with each other. We have discovered a similar effect, an alignment-dependent variation in the emission of secondary electrons, in Fe/Ag/Fe, Fe/Au/Fe, and Fe/Cr/Fe sandwiches. We ascribe this new effect to spin-dependent transport of much higher energy electrons, i.e., hot electrons with energies of 5–15 eV with respect to the Fermi level.

In a series of measurements, we have applied the technique of scanning electron microscopy with polarization analysis[3] (SEMPA) to the study of the Fe/Cr/Fe,[4] Fe/Ag/Fe,[5] and Fe/Au/Fe[6] exchange coupled layers. The experimental arrangement we have used for our SEMPA studies of exchange coupling in Fe/Ag/Fe is shown in Fig. 1. Although we have obtained similar results for the Fe/Cr/Fe and Fe/Au/Fe systems, we will illustrate this new effect in this paper by concentrating on measurements of the Fe/Ag/Fe system.

An Fe single crystal whisker is used for the substrate because of its very high degree of crystalline perfection and surface flatness. A Ag film is grown epitaxially in the shape of a wedge with its thickness varying from 0 to 25 ML. Finally, an Fe overlayer is grown with a uniform thickness in the range of 3–12 ML. The domain structure of the Fe substrate is very simple; it consists of two oppositely oriented domains, as shown in Fig. 1. As a result of the periodic reversal of exchange coupling as a function of interlayer thickness, domains in the Fe overlayer will be oriented either parallel or antiparallel to the substrate domains depending on the sign of the coupling, and will form a pattern that directly reflects the periodicity of the coupling. The SEMPA instrument[3] can directly observe this magnetization pattern by measuring the polarization of the secondary electrons produced by the incident beam of a scanning electron microscope. In this way, very accurate determinations of the periods of the exchange coupling can be made and used to test the prevailing theory, in which the oscillations are correlated with the existence of nesting vectors in the Fermi surface of the interlayer material.[7,8]

In general, in SEMPA measurements the magnetization information is carried by the polarization of the secondary electrons, and is not reflected in the secondary electron intensity. However, measurements of sandwich structures with Fe whisker substrates, Fe overlayers, and Ag, Cr, and Au interlayers, reveal a very interesting secondary intensity signal, which *depends only on the relative alignment of the substrate and overlayer magnetization.* We attribute this signal to the propagation of energetic, or "hot," electrons from the substrate experiencing spin-dependent interactions during transport. Following a discussion of the specifics of the experimental procedure and results, we discuss our model for this effect.

EXPERIMENT

Complete details of the experimental procedure exist elsewhere.[3,4] The Fe(100) single crystal whiskers were cleaned with standard procedures,[9] and examined using SEMPA, reflection high energy electron diffraction (RHEED); and scanning Auger microscopy. Under inspection by scanning tunneling microscopy,[10] these Fe whisker surfaces are seen to be extremely flat with single atom high steps approximately every 1 μm. RHEED patterns of the Fe whiskers show a Laue arc of sharp spots after the whiskers are cleaned by Ar sputtering and annealed at 800 °C.

The interlayer wedge is grown by evaporating Ag at a rate between 0.07 and 0.8 monolayers/s while moving a shutter over the surface of the whisker. Growth at substrate temperatures between 60 °C and 100 °C produced RHEED patterns indicative of nearly perfect layer-by-layer growth. The observation of RHEED intensity oscillations indicated somewhat disordered growth for the first 3–4 layers, with much better growth for Ag thicknesses of 6–30 layers, followed by increasing disorder.

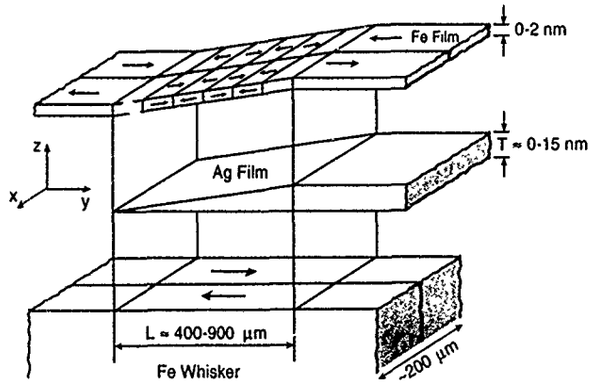

FIG. 1. Schematic diagram of Fe/Ag/Fe sandwich nanostructure showing the modulation in the sign of exchange coupling between Fe films.

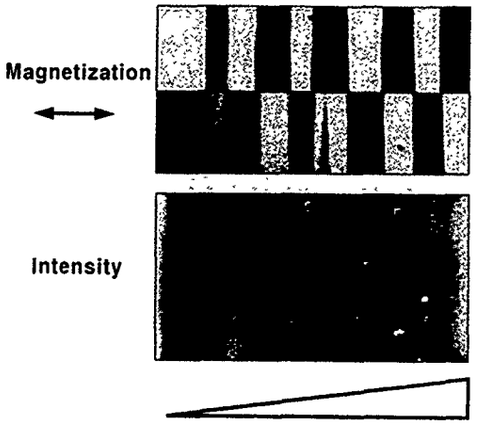

FIG. 2. Top: Magnetization image of wedge area. White (black) indicates magnetization to the right (left). Bottom: Intensity image of same region. Linear gray scale mapping with white indicating high intensity.

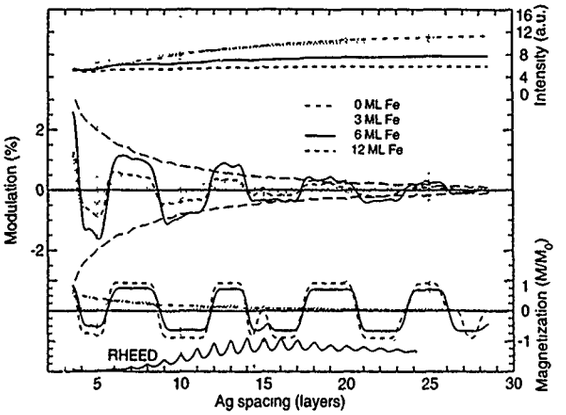

FIG. 3. Top: secondary intensity; center: modulation of secondary intensity; polarization envelope of 0 ML Fe secondaries (long dashes; see the text); bottom: normalized magnetization; RHEED intensity oscillations.

SEMPA images from the measurement of an Fe/Ag/Fe sandwich structure are shown in Fig. 2. The top image is the conventional SEMPA magnetization image, while the bottom image is the related secondary electron intensity image with its zero suppressed to better display the band-like intensity variations. Notice that while the two domain substrate structure creates a checkerboard pattern in the magnetization image, only bands are seen in the intensity. The secondary intensity image data can be reduced to a series of curves by computing, at each position along the wedge, i.e., each interlayer thickness, the secondary intensity averaged over the width of the wedge. The SEMPA magnetization image data is similarly reduced to curves, except the averaging is done within each of the two substrate domains and symmetry is invoked to correct for any instrumental zero offset in the magnetization measurement. The thickness scale can be determined very accurately by a method similar to the conventional method of monitoring RHEED intensity oscillations during evaporation. Instead, the microscope's electron beam is used to generate a RHEED image from a spot on the wedge portion of the sample. The intensity of a selected region of this image is used to form a "RHEED intensity image" as the incident beam scans the sample. The RHEED intensity image exhibits oscillations in intensity with the increasing thickness of the wedge. When correlated with the measured magnetization images by defect matching, the RHEED intensity image allows setting the thickness scale at every point of the magnetization or SEM intensity images to within ± 0.1 layers. The data are summarized in Fig. 3, where the lower curve shows the measured RHEED intensity oscillations for the first 20 layers of a wedge.

The topmost curves of Fig. 3 present the secondary electron intensity for Fe overlayer thicknesses of 3, 6, and 12 monolayers. Most notable is the rise in intensity in the 3 ML Fe curve as a function of Ag wedge thickness. This is presumably due to a greater secondary yield for Ag relative to Fe. When the background is subtracted from these curves by estimating it with a smoothly varying, low-order polynomial, a very interesting structure is revealed. These curves are replotted with their smoothly varying background subtracted in the middle of Fig. 3. The obvious modulation is presented as a percentage of the average intensity value at each Ag thickness. This modulation is seen for 3, 6, and 12 ML Fe overlayers, and closely mirrors the measured oscillation in the Fe/Ag/Fe interlayer exchange coupling. The amplitude of the modulation is greatest for a 6 ML Fe coverage, and the modulation amplitude is seen to decrease for all Fe thicknesses as the Ag thickness increases.

Below the intensity curves just discussed, we plot the magnetization measured in the positive y direction along the whisker. All magnetization values are shown normalized to the observed magnetization of bulk Fe, M_0. There are four curves here corresponding to Fe overlayer thicknesses of 0, 3, 6, and 12 ML. The 0 ML curve reflects the polarization of the Fe substrate as a function of Ag thickness, and we see an exponential falloff as the substrate polarization is attenuated by the increasing Ag interlayer thickness. The other magnetization curves display the expected[5,7] modulation of overlayer magnetization from exchange coupling. We note that it is not until an overlayer thickness of 12 ML that the full, bulk Fe magnetization is realized.

The correspondence between the modulation in the magnetization curves, with Ag thickness, and the modulation in the intensity curves, is obvious and striking. One might be led to the conclusion that the direction of magnetization of the Fe overlayer somehow affects the number of secondary electrons ejected. However, the Fe whisker substrate has two oppositely directed domains, as shown in Fig. 1, so the Fe overlayer domain structure is split into two halves with two oppositely directed magnetizations at each Ag thickness, also as shown in Fig. 1. If the overlayer magnetization from the other half of the Fe whisker were plotted, the curves would look as if they had been inverted with respect to the x axis. The intensity curves from this half of the whisker do not invert, however. Hence, *the intensity oscillations are correlated with the relative alignment of magnetization of the Fe films.*

DISCUSSION

The electrons used to form images in the SEMPA technique are secondary electrons. They are generated from the

cascade of incident primary electrons or backscattered electrons, and originate from a region within a few nanometers of the surface because of mean-free path considerations. The electrons that contribute to the signals displayed in Fig. 3 may originate in the Fe substrate, the Ag interlayer, or the Fe overlayer, depending on the particular situation. For example, the 0 ML Fe magnetization curve is seen to exhibit an approximately exponential decay with Ag thickness. This decrease in polarization corresponds to the increased number of unpolarized electrons originating in the Ag accompanied by the attenuation of the polarized secondary electrons from the Fe substrate. This 0 ML polarization curve has been scaled and replotted, with its mirror image, in the middle of Fig. 3. The envelope created suggests that the falloff in intensity modulation amplitude with Ag thickness is related to the relative abundance of secondary electrons from the substrate.

The explanation of the observed effect lies in the filtering of hot electrons due to spin-dependent scattering, and is directly analogous to explanations of the basis for the giant magnetoresistance in similar sandwich structures. Incident primary electrons, and other electrons in the cascade, generate polarized electrons in the substrate, some of which are directed toward the surface. These electrons are attenuated during their transport to the surface by spin-dependent as well as spin-independent interactions. Transport through the Ag interlayer may be presumed to occur in a spin-independent manner. However, there may be spin-dependent interactions within the Fe overlayer or at the Ag/Fe interface. For example, there have been both theoretical[11,12] and experimental[13,14] determinations of spin-dependent mean-free paths in bulk materials, as well as a discussion[15] of using the difference in mean-free path as the basis of a spin detector. The spin-dependent interactions, which depend only on the relative alignment of the magnetic layers, control the number of substrate electrons that make it to the near surface region. However, since the measured electron polarization is constant for all but the smallest Ag interlayer thicknesses, the secondary electrons ejected reflect the overlayer polarization and must originate there. The experimental results can therefore be explained by spin-dependent, hot electron transport of substrate electrons to the near surface region, followed by the ejection of polarized overlayer electrons with an intensity modulation that reflects the spin dependence of the transport.

The secondary electrons from the substrate, which must have an energy nominally greater than 5 eV above the Fermi level, experience a few percent difference in transmission probability for the two cases of parallel and antiparallel ferromagnetic layer alignment. As in the GMR effect, the transport is higher for the parallel magnetization configuration. However, the GMR phenomena is related to Fermi level electrons, while those playing a role here are obviously of a much higher energy.

We have made similar measurements in the Fe/Au/Fe and Fe/Cr/Fe systems, as shown for comparison, along with the Fe/Ag/Fe data in Fig. 4. In both cases the measured secondary intensity is modulated and the modulation correlates directly with the relative alignment between the ferromagnetic layers. As was the case in Ag, aligned ferromagnetic layers produce higher secondary electron intensities.

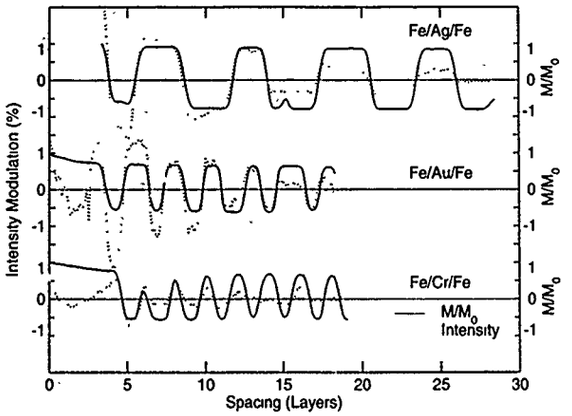

FIG. 4. Relationship between secondary intensity oscillations (dotted lines, scales to left) and magnetization direction (solid lines, scales to right).

CONCLUSION

We report a modulation in the production of near surface secondary electrons in Fe sandwich structures that depends on the relative orientation of the two Fe layers, when separated by Ag, Au, or Cr. The modulation in amplitude, of a few percent, is seen to be due to the spin-dependent transport of hot electrons between the Fe substrate and the Fe overlayer, resulting in the ejection of an overlayer electron. Parallel alignment of the Fe layers, in the cases we studied, always corresponds to a higher secondary emission current.

We studied the magnetothermopower of $Co/Cu_{1-x}Ni_x$ multilayers (with $x=0.37$ and 0.42) at various temperatures. Both systems have negative thermopower and the magnitude of the thermopower increases as the magnetic field increases. We found that as the ferromagnetic component of the magnetization becomes larger at lower temperatures, both the magnetothermopower and the magnetoresistance decrease. The inverse relationship between the thermopower and the resistance, when the field H varies, holds well at different temperatures. We interpret the results in terms of the two-current model, with an emphasis on the spin-split density of states.

The thermoelectric power has been shown to be a very useful probe of the giant magnetoresistive (GMR) mechanism in magnetic systems.[1-3] An unusually large field-dependent thermopower coexists[4-6] with the giant magnetoresistance; an inverse relationship between the field-dependent diffusion thermopower and the resistance has been found to hold for GMR systems. These experimental results were interpreted in terms of the two-current model, with an emphasis on the spin-split final density of states (DOS).[1-3] To better understand the coupling in multilayers and the origin of giant magnetoresistance, we studied the magnetothermopower of two Co/CuNi multilayer systems with different Ni concentrations.

The $Co/Cu_{1-x}Ni_x$ multilayers ($x=0.37$ and 0.42) used for the thermopower study were prepared by sputtering onto glass substrates. Both have the same Co-layer and CuNi-layer thicknesses and the structures can be represented as 50 Å Fe/{10 Å Co/16 Å $Cu_{63}Ni_{37}$}$_{15}$/10 Å Co/25 Å $Cu_{63}Ni_{37}$, and 50 Å $Cu_{58}Ni_{42}$/{10 Å Co/16 Å $Cu_{58}Ni_{42}$}$_{15}$/10 Å Co/25 Å $Cu_{58}Ni_{42}$. The magnetoresistance ratios at room temperature are 7% and 6%, respectively, and both samples are at the first antiferromagnetic peak in the exchange coupling.

Magnetic hysteresis loops were measured at various temperatures. It is found from the mutilayer magnetization curves that there is a large ferromagnetic component at temperatures for which the CuNi spacer material at these compositions does not have a ferromagnetic transition. This suggests that, by introducing Ni into Cu, the coupling between the neighboring Co layers is not completely antiferromagnetic as it is in the Co/Cu case. The reduction in the antiferromagnetic coupling is responsible for lowering the saturation fields and for decreasing the magnetoresistance ratios.

Resistance and magnetization were measured conventionally at and below room temperature. Thermoelectric power measurements were carried out using the technique described previously.[6] Narrow Pb foils were used for the electrodes, and type E differential thermocouples for detecting the temperature gradient. The field dependence of the thermopower was studied at various temperatures. The magnetoresistance decreases and the ferromagnetic component of both samples increases as the temperature is reduced. For the higher Ni concentration sample, the magnetoresistance disappears at about 100 K while the low Ni concentration sample exhibits a finite magnetoresistance over the whole temperature range ($T>4$ K).

Figure 1 shows the field dependence of the thermopower of both samples at 300 K. The zero-field thermopower for $Co/Cu_{58}Ni_{42}$ is negative (-26 μV/K), and its magnitude increases with increasing magnetic field until it saturates at about 500 Oe. The field dependence of thermopower of $Co/Cu_{63}Ni_{37}$ is qualitatively the same as that of the higher Ni concentration sample, but the saturation field is about 400 Oe and the zero-field thermopower is about -19 μV/K. Because the determination of the absolute value of thermopower depends on the closeness of the thermal EMF leads to the type-E thermocouple leads, the absolute value has some uncertainty due to the misplacement of the leads. However, the

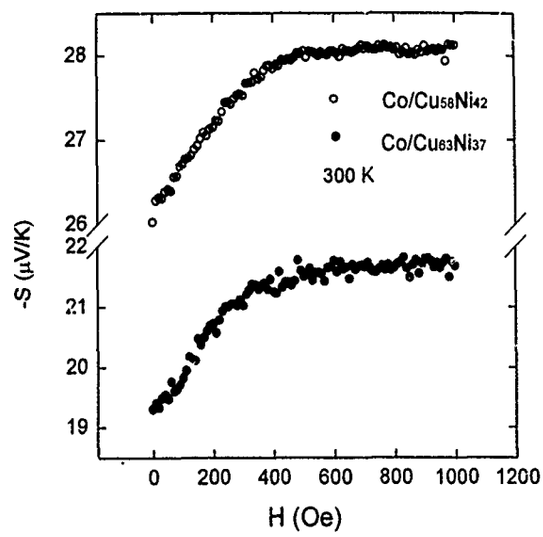

FIG. 1. Thermoelectric power as a function of magnetic field for both samples at room temperature. The open circles are for the higher Ni concentration sample, the closed circles for the lower Ni concentration sample.

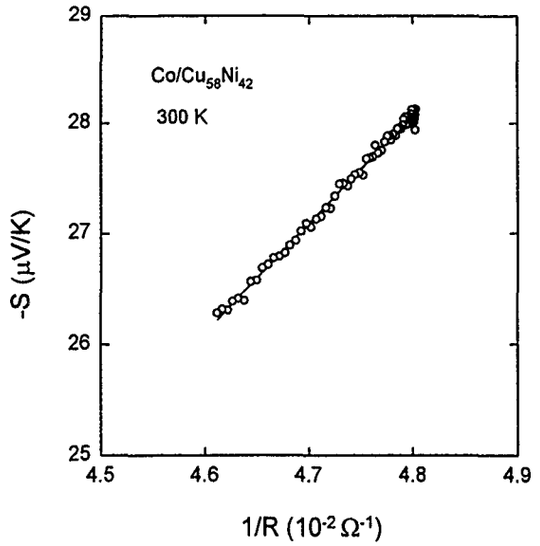

FIG. 2. $-S$ vs $1/R$ plot for the data shown in Fig. 1, in the case of the higher Ni concentration sample.

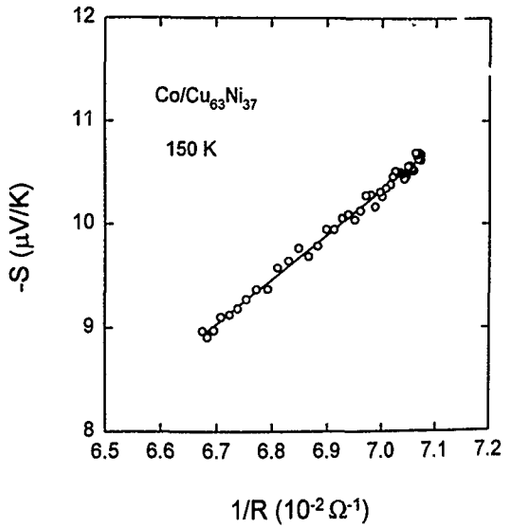

FIG. 3. $-S$ vs $1/R$ plot for the lower Ni concentration sample data at 150 K.

magnitude of the higher Ni concentration sample's thermopower is consistently larger than that of the lower Ni concentration sample. The difference may be caused by the Fe underlayer, which has a relatively large positive thermopower and is effectively in parallel connection to the Co/CuNi multilayer structure.

We demonstrate the inverse relationship between resistance and thermopower in variable fields in Fig. 2 (for the higher Ni concentration sample). The magnetothermopower $|S(H)-S(0)|$ decreases as the temperature is decreased, vanishing near 100 K for this sample. The magnetoresistance also vanishes at this temperature, indicating that a single underlying mechanism causes the coexistence of magnetothermopower and magnetoresistance. The inverse relationship also holds very well at various temperatures for the lower Ni concentration sample; the $-S$ vs $1/R$ plot at 150 K is shown in Fig. 3 for that sample.

The temperature dependence of the zero-field thermopower $S(0)$ was also measured for both samples. From the lowest temperature (4 K) to room temperature, $S(0)$ shows a linear temperature dependence, which means that the diffusion thermopower dominates. The temperature dependence of the thermopower for the low Ni concentration sample is shown in Fig. 4.

As pointed out previously,[1-3] the large field dependence of thermopower suggests that the different DOS of spin-up and spin-down d bands at the Fermi surface is essential to the scattering process. In that model, we assumed that s electrons are the main charge carriers, that the spin-flip scattering mean-free path is much longer than the spacer layer thickness, and that scattering into the d bands by the interfacial potential is the most important relaxation process. Neglecting spin-mixing scattering and applying the two-current model, we could successfully explain the following facts: the large field dependence of thermopower; the large magnitude of the thermopower and the closeness of its saturation value to the bulk thermopower of Co; the inverse relationship between the thermopower and the resistance in variable fields; and the linear temperature dependence. In applying this model to granular systems, we also included a matrix contribution because the scattering within the matrix is not negligible in that case.

There are two factors that decrease the magnetoresistance ratio, which otherwise would be determined by the magnetic layer's DOS only: scattering within the nonmagnetic layer as in the granular case,[2] and reduced antiferromagnetic coupling. In Co/CuNi samples, both contribute. The nonmagnetic layer is thicker and more resistive as compared with the Co/Cu case, and there is a significant ferromagnetic coupling component in zero magnetic field. Here

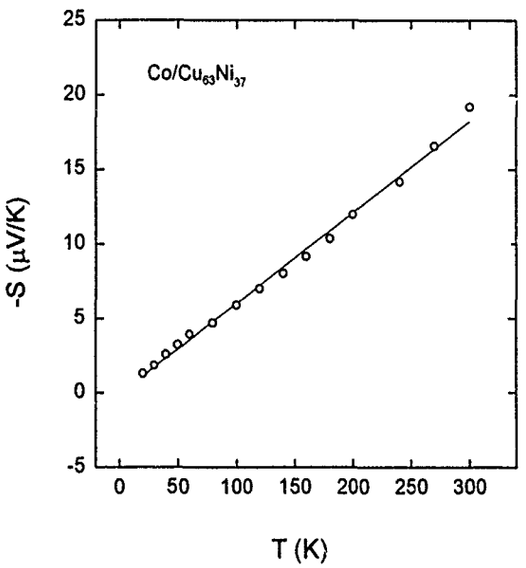

FIG. 4. Thermoelectric power as a function of temperature for the lower Ni concentration sample.

we consider only the latter. With the assumptions mentioned earlier, we can obtain an expression for the resistivity in magnetic field,

$$\rho(H)=[1-f(H)]\rho_{af}+f(H)\rho_f, \tag{1}$$

where ρ_{af} denotes the resistivity in the fully antiferromagnetically coupled state, ρ_f the resistivity in the ferromagnetically aligned state, and $f(H)=[M(H)/M_s]^2=\cos^2\theta(H)$. $\theta(H)$ is the angle between the magnetization and the applied field. If we assume that θ does not start from a right angle but from an intermediate angle between 90° and 0°, i.e., that $f(H)$ starts from a nonzero value f_0, then we will have a magnetoresistance ratio that depends on the ferromagnetic coupling parameter f_0,

$$r\equiv\frac{\Delta\rho}{\rho_f}=\frac{\rho_0-\rho_f}{\rho_f}=(1-f_0)\left(\frac{\rho_{af}-\rho_f}{\rho_f}\right). \tag{2}$$

The magnetoresistance ratio is reduced by a factor of $(1-f_0)$ from its maximum $[(\rho_{af}-\rho_f)/\rho_f]$, which is determined by the DOS of d bands at Fermi surface. As the ferromagnetic component increases, the magnetoresistance ratio decreases until $f\rightarrow 1$, where the magnetoresistance vanishes.

From Mott's formula,[7]

$$S=\frac{\pi^2k_B^2T}{3|e|}\left(\frac{\partial\ln\rho}{\partial\epsilon}\right)_{E_F}, \tag{3}$$

we can obtain the inverse relationship between resistivity and thermopower. Thermopower changes from its initial value S_0,

$$S_0=S_{af}-\frac{f_0}{1+r}\,[S_{af}-S_f], \tag{4}$$

to S_f as H is increased, where both S_{af} and S_f are determined by the DOS of d bands. Obviously, the magnetothermopower is also reduced, by a factor $[f_0r/(1+r)]$, by the existence of ferromagnetic coupling.

We compare Co/CuNi samples to the Co/Cu samples with comparable spacer-layer thickness studied previously.[6] To decrease the magnetoresistance ratio from 18% to about 7% requires that $f_0\approx 0.61$, corresponding to an initial magnetization: $M(0)\approx 0.78M_s$. This is larger than indicated by the magnetization data, for which $M(0)\approx 0.5M_s$ at room temperature. We conclude that scattering within the more resistive nonmagnetic layer also contributes to the suppression of both the magnetoresistance and magnetothermopower. Both possibilities still preserve the inverse relationship in magnetic field. Recently, there has been some discussion[8] of biquadratic coupling in multilayers in the literature, which leads to values of f_0 other than 0 and 1. The results suggest the possibility that biquadratic coupling is introduced when Ni atoms are added into Cu. An entirely different picture is that some layers are coupled ferromagnetically and others coupled antiferromagnetically, with both types connected in parallel. This scenario is not consistent with the inverse relationship between thermopower and resistance, and can be ruled out.

In summary, we studied the magnetothermopower of Co/CuNi samples at different temperatures. Thermopower values are negative in both samples, and the magnitude of the thermopower increases as the resistance decreases in magnetic fields. The inverse relationship between the thermopower and the resistance holds very well at all temperatures, which is a general consequence of the two-current model. Magnetothermopower and magnetoresistance decrease as the ferromagnetic component increases, and both vanish when antiferromagnetic coupling disappears. We emphasize again here that a spin-dependent scattering matrix element will not give rise to *both* GMR and magnetothermopower effects.

High-field polar MOKE magnetometry as a probe of interlayer exchange coupling in MBE-grown Co/Cu/Co(111) and Fe/Cr/Fe(001) wedged trilayers

A. J. R. Ives, R. J. Hicken, J. A. C. Bland, C. Daboo, M. Gester, and S. J. Gray
Cavendish Laboratory, University of Cambridge, Madingley Road, Cambridge CB3 0HE, United Kingdom

We discuss the use of room temperature polar magneto-optic Kerr effect (MOKE) measurements at high field ($\leq$7 T) in investigating antiferromagnetic (AFM) and ferromagnetic (FM) exchange coupling in MBE-grown wedged trilayers. In the case of Co/Cu/Co(111), the polar MOKE revealed the first AFM coupling peak at 9 Å Cu thickness *and* the second weaker AFM coupling peak at 20 Å. This is an important result because it helps in resolving the present controversy over whether oscillatory coupling exists in (111) oriented MBE-grown Co/Cu/Co structures. For Fe/Cr/Fe(001), polar MOKE is found to be less sensitive than in-plane MOKE for extracting the detailed form of the coupling. However, polar MOKE reveals additional variations in the perpendicular saturation fields as a function of interlayer thickness, which are not found in the in-plane MOKE saturation fields.

In-plane magneto-optic Kerr effect (MOKE) magnetometry is now a standard technique that has been used successfully to determine the antiferromagnetic (AFM) interlayer exchange coupling in a number of magnetic transition metal thin film structures. We show here that perpendicular magnetization curves obtained using polar MOKE can provide valuable information about the coupling strength and the sample homogeneity in wedged trilayer structures with a hard axis along the film normal. This information is not always obtained from in-plane MOKE measurements.

From the perpendicular magnetization curves we can measure the perpendicular saturation field $H_s^{\perp}$, and a saturation field extrapolated from the initial magnetization gradient, χ_0, defined as $H_s^{\chi\perp}=1/\chi_0$, with the magnetization normalized to unity, as illustrated in Fig. 1. Our values of $H_s^{\perp}$ are calculated from the intersection of the magnetization curve with $M/M_s=\alpha$, where α is the highest value of M/M_s at which $H_s^{\perp}$ could be accurately determined, due to the gradual approach of the magnetization to saturation. This leads to $H_s^{\perp}$ being an underestimate of the true saturation field. We consider two cubic ferromagnetic layers with thicknesses d_1 and d_2, separated by a nonmagnetic interlayer, with uniform magnetizations M_1 and M_2. We assume a bilinear exchange coupling energy per unit area given by $-2A_{12}\hat{\mathbf{M}}_1\cdot\hat{\mathbf{M}}_2$ and ignore the generally much smaller effect of biquadratic coupling. It is possible to obtain general expressions relating $H_s^{\perp}$ and $H_s^{\chi\perp}$ to A_{12}.[1] In the case of nonidentical magnetic layers with significantly different interface anisotropy fields, these expressions may be used to extract estimates of both the FM and AFM coupling strengths from the perpendicular magnetization curves, and we have used this to measure the FM coupling in an Fe/Pd/Fe(001) wedge structure.[2] For the samples presented here, which have identical magnetic layers, both the in-plane and perpendicular saturation fields have a contribution that depends on the AFM coupling strength, $-4A_{12}/\mu_0 Md$, and a contribution H_a, which depends on magnetocrystalline and interface anisotropies, and on demagnetizing effects. Thus, for AFM coupling, A_{12} can be obtained from the in-plane and the perpendicular magnetization data using $A_{12}=-\frac{1}{4}\mu_0 Md(H_s-H_a)$. We shall assume M and d are the bulk magnetization and the nominal thickness of the magnetic layers. For easy axis in-plane magnetization curves, we can usually neglect H_a and write $A_{12}^{\parallel}=-\frac{1}{4}\mu_0 MdH_s^{\parallel}$, where $H_s^{\parallel}$ is the easy axis in-plane saturation field. From the perpendicular saturation field we obtain $A_{12}^{\perp}=-\frac{1}{4}\mu_0 Md\ \Delta H_s^{\perp}$, where $\Delta H_s^{\perp}=H_s^{\perp}-H_a^{\perp}$, and from the perpendicular saturation field extracted from χ_0 we obtain $A_{12}^{\chi\perp}=-\frac{1}{4}\mu_0 Md\ \Delta H_s^{\chi\perp}$, where $\Delta H_s^{\chi\perp}=H_s^{\chi\perp}-H_a^{\chi\perp}$.

The polar MOKE measurements were made with a 7 T superconducting magnet. The samples were placed at the end of an insert tube, close to the center of the magnet, at room temperature. The laser beam was focused on to the sample and moved across it using a concave mirror mounted on a micrometer stage. This geometry was designed so that the laser light did not pass through any windows or lenses in the vicinity of the field, thus eliminating problems due to Faraday rotation or birefringence.

We have made room temperature in-plane MOKE mea-

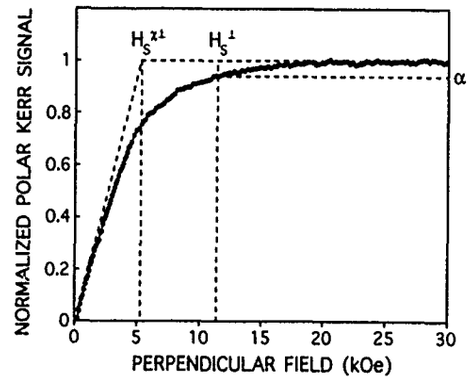

FIG. 1. A polar MOKE magnetization curve from the Co/Cu/Co(111) wedge corresponding to a Cu thickness of 7.4 Å. The dashed lines show how $H_s^{\perp}$ and $H_s^{\chi\perp}$ are defined. $H_s^{\perp}$ is obtained from the intersection of the magnetization curve with $M/M_s=\alpha$, where we have taken α=0.94 for the Co/Cu/Co wedge and 0.96 for the Fe/Cr/Fe wedge. $H_s^{\chi\perp}$ is obtained by applying a linear fit to the magnetization curve for -2 kOe$<H<$2 kOe, and then extrapolating this fit to the intersection with $M/M_s=1$.

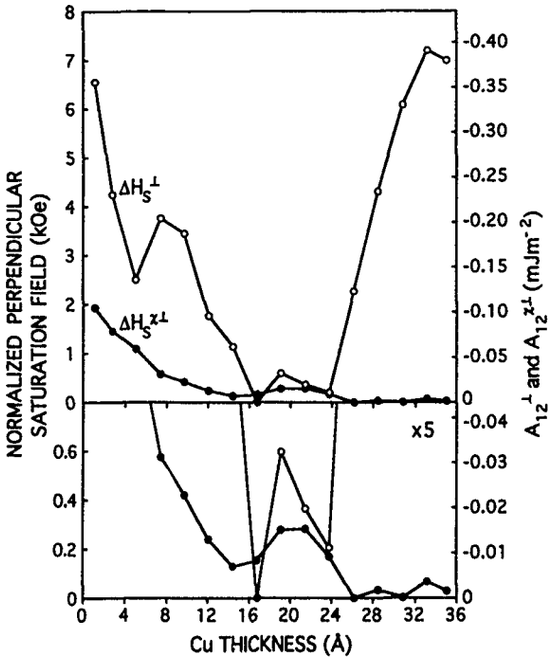

FIG. 2. $\Delta H_s^{\perp}$ (open circles) and $\Delta H_s^{\chi\perp}$ (closed circles) are plotted versus Cu thickness for the Co/Cu/Co(111) wedge sample. From the right-hand scale we obtain $A_{12}^{\perp}$ and A_{12}^{χ}

surements in fields up to 1.2 T using a conventional electromagnet, and polar MOKE measurements up to 6 T, on a wedged MBE-grown Co(111)/Cu(111)/Co(111) trilayer with structure Au(13 Å)/Cu(15 Å)/Co(15 Å)/Cu(0–35 Å)/Co(15 Å)/Cu(15 Å)/Au(200 Å)/Co(15 Å)/Ge(500 Å)/GaAs(110). The Co seed layer contributes very little to the MOKE signal due to the limited penetration depth of the laser beam. Prior to growth, the GaAs(110) substrate was cleaned by heating to 600 °C. The Ge buffer was grown at 500 °C at a rate of 0.15 Å per second. The Au, Co, and Cu layers were deposited at 150 °C at rates of 0.067, 0.2, and 0.2 Å/s, respectively, at a growth pressure of 10^{-10} mbar. RHEED, x-ray, and NMR measurements on similar samples showed that the layer growth is (111) for the Au buffer layer and subsequent layers, and that the Co/Cu layers have very smooth interfaces.[3,4]

The in-plane magnetization curves all have large remanence, even from parts of the wedge in which significant AFM coupling, and hence strongly reduced remanence, is expected. This suggests that large regions of the sample are either FM coupled or uncoupled.[5–9] The approach to saturation is gradual at all Cu interlayer thicknesses, making determination of the in-plane saturation fields difficult, and so we have been unable to deduce consistent values of A_{12} from our data. Other authors have found very similar magnetization behavior in MBE-grown Co/Cu(111) trilayers and multilayers.[6–9]

In Fig. 2 we have plotted $\Delta H_s^{\perp}$ and $\Delta H_s^{\chi\perp}$ on the left-hand scale versus Cu layer thickness, with corresponding values of $A_{12}^{\perp}$ and $A_{12}^{\chi\perp}$ on the right-hand scale. Previous workers have found oscillatory coupling in sputtered Co/Cu/Co(111) structures with first and second AFM coupling peaks at about 9 and 20 Å Cu, respectively.[10] In contrast, it has proved to be difficult to find evidence of oscillatory coupling in similar films grown by MBE.[11] While a number of groups have found the first AFM peak in MBE-grown Co/Cu/Co(111) structures,[6,8,9] only two groups have clearly seen the second peak, and conflicting values have been obtained for the coupling period.[5,7] However, our plot of $\Delta H_s^{\perp}$ shows both the 9 and 20 Å peaks. The plot of $\Delta H_s^{\chi\perp}$ shows the peak at 20 Å, but the peak at 9 Å is obscured by a steady increase in $\Delta H_s^{\chi\perp}$ toward zero Cu thickness. This increase is of even greater magnitude in the plot of $\Delta H_s^{\perp}$. Above 24 Å Cu thickness, $\Delta H_s^{\chi\perp}$ flattens out as expected, but $\Delta H_s^{\perp}$ increases rapidly. The increases in both $\Delta H_s^{\perp}$ and $\Delta H_s^{\chi\perp}$ toward zero Cu thickness, and the increase in $\Delta H_s^{\perp}$ above 24 Å Cu, may be due to variations in the interface anisotropy field along the wedge, which may occur as a result of changes in roughness and/or strain with Cu thickness. In the region 7 Å Cu–24 Å Cu, the amplitude of the oscillations in $A_{12}^{\perp}$ is clearly much greater than the amplitude of those in $A_{12}^{\chi\perp}$. This is consistent with the sample containing both AFM-coupled and FM-/uncoupled regions. An FM-/uncoupled region should have a perpendicular saturation field below that of an AFM-coupled region. The value of $\Delta H_s^{\perp}$ is representative of the saturation field of the AFM-coupled regions. However, the value of $\Delta H_s^{\chi\perp}$, being an average over both types of region, is reduced by the presence of the FM-/uncoupled regions. Since the amplitude of $A_{12}^{\chi\perp}$ is seen to decrease relative to that of $A_{12}^{\perp}$ with decreasing Cu thickness, this implies that the proportion of FM-/uncoupled regions increases with decreasing Cu thickness in our sample. This could be caused by increased pinhole coupling between the Co layers with decreasing Cu thickness.

An estimate of the maximum value of A_{12} is obtained from $A_{12}^{\perp}$ and is $A_{12}=-0.20$ mJm^{-2}. However, this is likely to be less than the true value of A_{12}, because, as stated above, $H_s^{\perp}$ is an underestimate of the true saturation field. It compares with maximum values of $A_{12}=-0.27$ mJm^{-2} (300 K) for an MBE-grown Co/Cu(111) superlattice in Ref. 7, and $A_{12}=-0.55$ mJm^{-2} (300 K) for an MBE-grown Co/Cu(111)/Co wedge in Ref. 8. The period of the coupling determined from $\Delta H_s^{\perp}$ is 11±2 Å, which compares with periods of 17 and 9 Å in Refs. 5 and 7.

We have performed room temperature in-plane MOKE measurements in fields up to 0.3 T, and polar MOKE measurements up to 4.7 T on a wedged MBE-grown Fe(001)/Cr(001)/Fe(001) trilayer with structure Cr(20 Å)/Fe(20 Å)/Cr(0–40 Å)/Fe(20 Å)/Ag(600 Å)/Fe(15 Å)/GaAs(001). Once again, the Fe seed layer contributes very little to the MOKE signal. Prior to growth, a commercially polished GaAs(001) substrate was heated to 600 °C for one hour. The Fe, Cr, and Ag layers were then grown using *e*-beam evaporators, at rates of 1 Å/min for Fe and Cr, and 0.5 Å/min for Ag, and at a growth pressure of 10^{-9} mbar. The Fe seed layer was grown at 150 °C, and the other layers were grown at room temperature. The Ag buffer layer was post-annealed at 300 °C for two hours and the first Fe layer on the Ag buffer was post-annealed at 150 °C for half an hour. LEED patterns confirmed the good epitaxial (001) growth of all layers. The situation in Fe/Cr/Fe(001) trilayers with Ag buffer layers is

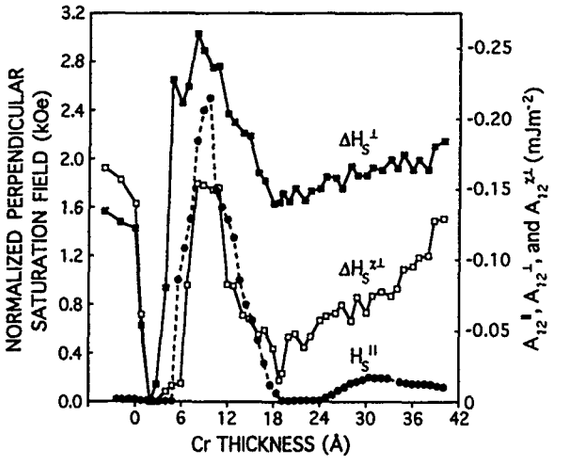

FIG. 3. $\Delta H_s^{\perp}$ (closed squares), $\Delta H_s^{\chi\perp}$ (open squares), and $H_s^{\parallel}$ (closed circles) are plotted versus Cr thickness for the Fe/Cr/Fe(001) wedge sample. From the right-hand scale we obtain $A_{12}^{\parallel}$, $A_{12}^{\perp}$, and $A_{12}^{\chi\perp}$.

quite different from that in Co/Cu/Co(111) trilayers. At Cr thicknesses where AFM coupling is obtained, the in-plane magnetization curves have almost zero remanence. This is consistent with the sample being homogeneous so that, unlike in Co/Cu/Co(111), large FM-/uncoupled regions do not occur.

In Fig. 3, we have plotted $H_s^{\parallel}$, $\Delta H_s^{\perp}$, and $\Delta H_s^{\chi\perp}$ on the left-hand scale versus Cr layer thickness, with corresponding values of $A_{12}^{\parallel}$, $A_{12}^{\perp}$, and $A_{12}^{\chi\perp}$ on the right-hand scale. The plot of $H_s^{\parallel}$ suggests that regions of FM coupling occur from 0–5 Å and from 19–24 Å Cr thickness, and that regions of AFM coupling occur from 5–19 Å and from 24–40 Å Cr thickness, in approximate agreement with previous work.[12] For the first three data points on the left-hand side of the plots of $\Delta H_s^{\perp}$ and $\Delta H_s^{\chi\perp}$ the Cr interlayer has zero thickness, so the effective Fe layer thickness is 40 Å. At subsequent points, the Cr interlayer has finite thickness, and the values of $\Delta H_s^{\perp}$ and $\Delta H_s^{\chi\perp}$ both fall abruptly by ~1.6 kOe, due to the increased interface anisotropy fields associated with the thinner separate Fe layers. In contrast, $H_s^{\parallel}$ changes only slightly from 11 to 5 Oe at the point where the Cr interlayer begins. For well-separated Fe layers we expect the variations in $\Delta H_s^{\perp}$ and $\Delta H_s^{\chi\perp}$ to have the same form as the variations seen in $H_s^{\parallel}$, and the first AFM coupling peak from 5–19 Å Cr is clearly seen in the plots of $\Delta H_s^{\perp}$ and $\Delta H_s^{\chi\perp}$. The height of the peak at 10 Å in $\Delta H_s^{\perp}$ is unexpectedly large compared with the in-plane peak, and $\Delta H_s^{\perp}$ has a much higher value than $H_s^{\parallel}$ in the region 19–40 Å Cr. $\Delta H_s^{\chi\perp}$ is smaller than $H_s^{\parallel}$ at the center of the 10 Å peak, and again has a much higher value than expected in the region 19–40 Å Cr. The large values of $\Delta H_s^{\perp}$ and $\Delta H_s^{\chi\perp}$ in this region hide the second AFM peak, which is clearly observed in $H_s^{\parallel}$ at 30 Å. A possible reason for the large perpendicular saturation field is a reduction in the interface anisotropy field in this region, due to a variation in strain or in interface roughness with Cr thickness.

The best estimate of the maximum value of A_{12} in the Fe/Cr/Fe(001) wedge is obtained from $H_s^{\parallel}$, giving $A_{12}=-0.22$ mJm^{-2}. This value is, however, much smaller than the maximum value of -0.65 mJm^{-2} (300 K) from Ref. 12. The period of the coupling obtained from $H_s^{\parallel}$ is 20 Å, which compares with a period of 19 Å in Ref. 12.

We cannot explain all the features in the perpendicular MOKE data for either the Co/Cu/Co(111) wedge or the Fe/Cr/Fe(001) wedge. However, our results show that, in addition to a thickness-dependent exchange coupling, there are changes in the magnetic properties of the wedges along their length, associated with possible variations in structure, which would not be found using in-plane MOKE measurements. Furthermore, in the case of the Co/Cu/Co(111) sample, the perpendicular data revealed both the first and second AFM coupling peaks, whereas our in-plane data did not. This shows the value of making perpendicular magnetization measurements in addition to performing in-plane magnetometry.

Note added in proof. Since we submitted this paper Dupas *et al.* [J. Magn. Magn. Mater. **128**, 361 (1993)] have also reported the observation of oscillatory coupling in a Co/Cu(111) multilayer.

We present structural and magnetic characterization of epitaxial Fe/Cr(211) and Fe/Cr(100) superlattices grown simultaneously on MgO(110) and MgO(100) substrates by magnetron sputtering. The epitaxial orientation of the Fe/Cr(211) superlattice with the MgO(110) substrate is Fe/Cr[0$\bar{1}$1]//MgO[001] and the orientation of Fe/Cr(100) is Fe/Cr[001]//MgO[011]. We find that for both orientations, that the interlayer coupling oscillates in sign with a period of 18 Å, and, furthermore, that the strength and phase of the magnetic coupling are also nearly identical for these two orientations.

Oscillatory interlayer coupling across nonmagnetic spacer layers in ferromagnetic/nonmagnetic transition-metal multilayers[1-4] has become a challenging theoretical problem.[5-13] Most theories are based on a band-structure-modified RKKY treatment of the spacer layer. Within this framework, the oscillations in the coupling arise from spanning vectors normal to the layers that join extremal points of the bulk Fermi surface. A stringent test of this approach is to study the interlayer coupling along different crystallographic directions of the spacer, since different spanning vectors should be probed for each orientation. This type of experiment has been performed most extensively for the Co/Cu system.[13-17] In this paper, we discuss the interlayer coupling of Fe/Cr(211) and (100) superlattices. We find that for both orientations that the interlayer coupling oscillates in sign with a period of 18 Å, and, furthermore, that the strength and phase of the magnetic coupling are also nearly identical.

The Fe/Cr superlattices were grown by dc magnetron sputtering onto single-crystal MgO(110) and MgO(100) substrates in an Ar pressure of 3 mTorr. The (110) and (100) substrates were mounted side by side onto the sample holder and codeposited. A 100 Å-Cr buffer layer was initially deposited at a substrate temperature of 600 °C.[18] The substrate was then cooled to 180 °C and the samples were grown by sequential deposition of the Fe and Cr layers. A similar growth sequence has been used by Kamijo and Igarishi.[19] Two series of samples were grown. The first was of [Fe(14 Å)/Cr(t_{Cr})]$_N$ superlattices with $8<t_{Cr}<70$ Å, and N was adjusted so that the total superlattice thickness was constant at ≈1200 Å.[20] A second series of samples based on the design of Parkin and Mauri[21] was grown to measure the ferromagnetic interlayer coupling. The structure was characterized by x-ray diffraction using Cu-K_α radiation. Magnetic properties were measured by SQUID magnetometry and longitudinal Kerr rotation.

The high-angle x-ray spectra of [Fe(14 Å)/Cr(46 Å)]$_{20}$ superlattices grown on MgO(110) and MgO(100) substrates are shown in Figs. 1(a) and 1(b), respectively. Figure 1(a) contains the MgO(220) peak and the Fe/Cr(211) reflections, and Fig. 1(b) contains the MgO(200) and Fe/Cr(200) reflections. Fittings of the high-angle diffraction spectra to a general structural model[22] yield Fe and Cr lattice spacings, which agree with the bulk values to better than 0.15% for both orientations.

Asymmetric diffraction scans were performed on selected samples to determine the in-plane epitaxial orientation of the superlattice. The (110) diffraction intensity was monitored as the sample was rotated by angle ϕ about the surface normal. The results of these scans are shown as the insets of Figs. 1(a) and 1(b). A two- and four-fold rotational symmetry is observed for the (211) and (100) orientations, respectively, as expected. From the position of the peaks, the following epitaxial orientations are determined: Fe/Cr[0$\bar{1}$1]//MgO[001] for the Fe/Cr(211), and Fe/Cr[011]//MgO[001] for the Fe/Cr(100). The same epitaxial relation has been observed for the MBE growth of Fe(211) on MgO(110).[23]

The in-plane magnetization hysteresis loops were measured for the superlattices with the applied field H parallel to the Fe[$\bar{1}$11] and Fe[0$\bar{1}$1] directions for the (211) orientation and to the [011] direction for the (100) orientation. For the 14-Å Fe(211) layers, there is a strong in-plane uniaxial an-

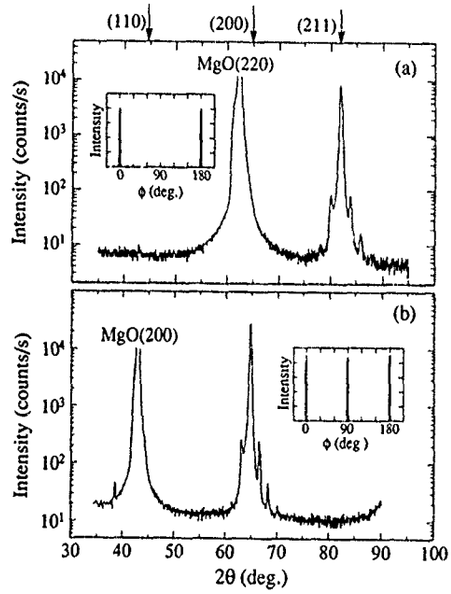

FIG. 1. X-ray diffraction results for Fe/Cr superlattices grown on MgO. High-angle spectra for [Fe(14 Å)/Cr(46 Å)]$_{20}$ superlattices grown on (a) MgO(110) and (b) MgO(100). Arrows at the top identify the position of possible Fe/Cr reflections. The MgO reflections are also identified. The insets show the Fe/Cr(110) intensity as a function of rotation angle ϕ about the surface normal for [Fe(14 Å)/Cr(17 Å)]$_{36}$ superlattices grown on (a) MgO(110) and (b) MgO(100).

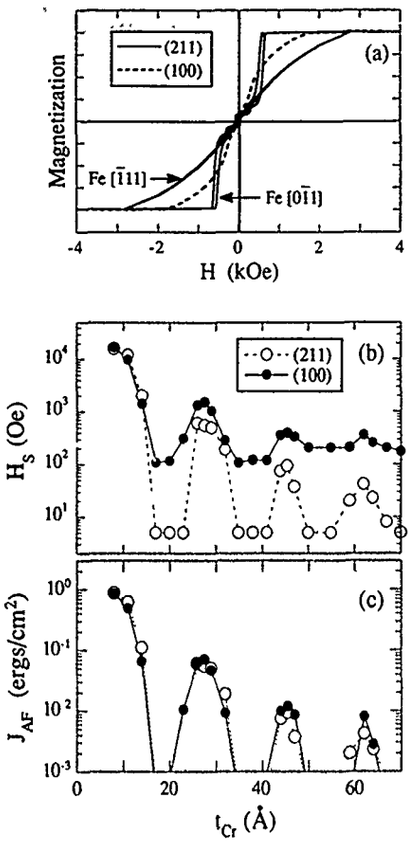

FIG. 2. (a) Room temperature magnetic hysteresis loops for (100)- and (211)-oriented [Fe(14 Å)/Cr(26 Å)]$_N$ superlattices. The applied field is along the Fe[011] direction for the (100) superlattice and along the easy Fe[01̄1] and hard Fe[1̄11] directions for the (211) superlattice. (b) Switching field H_S for (211)- and (100)-oriented Fe(14 Å)/Cr(t_{Cr}) superlattices measured at room temperature with H parallel to the Fe[011] direction. (b) Antiferromagnetic coupling strength J_{AF} vs t_{Cr} for (211)- and (100)-oriented Fe(14 Å)/Cr(t_{Cr}) superlattices determined from H_S values shown in (b).

isotropy along the Fe[01̄1]. To quantify the anisotropy, we analyze the hysteresis loop of a ferromagnetically coupled sample with H along the hard axis (Fe[1̄11]), utilizing an expression that includes a magnetocrystalline anisotropy (K_1), a uniaxial anisotropy (K_U), and a Zeeman term.[23,24] We determined $K_U \approx 9\times10^5$ ergs/cm^3 and $K_1 \approx 4\times10^5$ ergs/cm^3 for the 14-Å Fe layers at room temperature, consistent with the other studies of Fe(211) films.[23,24]

Shown in Fig. 2(a) are the room-temperature hysteresis loops for AF-coupled (100)- and (211)-oriented [Fe(14 Å)/Cr(26 Å)]$_N$ superlattices. The effect of the in-plane anisotropy is evident in the shape and saturation fields along orthogonal directions of the (211) superlattice. There is a clear spin-flop transition when the field is along the easy axis (Fe[01̄1]). When the field is along the hard axis (Fe[1̄11]), continuous rotation to saturation is observed, which is similar to the behavior in the loop for the Fe/Cr(100) sample.

The value of J_{AF} can be calculated from the saturation field H_S and the anisotropy constants for H applied along the easy and hard axis by the following equations from Refs. 25 and 26:

$$J_{AF}(211) = \begin{cases} \dfrac{(H_S+H_K)M_S t_{Fe}}{4}, & \text{for } H//\text{Fe}[01\bar{1}] \\ & \text{and } J_{AF} > K_U t_{Fe}, \quad (1a) \\ \dfrac{H_S M_S t_{Fe}}{2}, & \text{for } H//\text{Fe}[01\bar{1}] \\ & \text{and } J_{AF} < K_U t_{Fe}, \quad (1b) \end{cases}$$

$$J_{AF}(211) = \frac{(H_S-H_K)M_S t_{Fe}}{4}, \quad \text{for } H//\text{Fe}[\bar{1}11], \quad (2)$$

$$J_{AF}(100) = \frac{(H_S-H_K)M_S t_{Fe}}{4}, \quad \text{for } H//\text{Fe}[011], \quad (3)$$

$$J_{AF}(100) = \frac{(H_S+H_K)M_S t_{Fe}}{4}, \quad \text{for } H//\text{Fe}[001], \quad (4)$$

where H_K is the anisotropy field given by $2K_U/M_S$ for the (211) samples, and $2K_1/M_S$ for the (100) samples. The values of H_K are estimated from the saturation fields of the ferromagnetically coupled superlattices when the field is applied along the hard axis. Applying Eqs. (1)–(3) to the loops shown in Fig. 2 yields $J_{AF}(211)=0.061$ and 0.064 ergs/cm^2 for the hard and easy axis, respectively, and $J_{AF}(100)=0.062$ ergs/cm^2.

Shown in Fig. 2(b) are the measured saturation fields for the Fe/Cr superlattices as a function of Cr layer thickness for both orientations. Four oscillations are observed with the phase and period (18 Å) identical for the two orientations. To compare the interlayer coupling strengths requires converting H_S using Eqs. (1) and (3) into J_{AF} values. The calculated values for J_{AF} are shown in Fig. 2(c), where H_K for both orientations were determined from the saturation field of ferromagnetically coupled samples with neighboring Cr thicknesses. As can be seen in Fig. 2(c), *in addition to the phase and period of the oscillations, the strength of the AF coupling is independent of the crystallographic orientation.*

To explore the coupling of the superlattice across regions where square hysteresis loops were observed for the superlattices, we have employed the structure suggested by Parkin and Mauri shown by the lower inset in Fig. 3(a).[21] The 9-Å Cr layer was used to strongly AF couple the middle Fe layer to the thicker bottom Fe layer. Monitoring the switching of the top Fe layers allows the determination of the ferromagnetic interlayer coupling. The measured Kerr intensity for the (211)-oriented sample in which the top and middle Fe layers are separated by a 19-Å Cr layers. There are two switching fields observed that are labeled H_{S1} and H_{S2} in Fig. 3(a). H_{S1} is related to the ferromagnetic coupling across the 19-Å Cr layer, and H_{S2} is related to the AF coupling across the 9-Å Cr layer. The relationship between H_{S2} and the AF interlayer coupling for strong coupling strengths is given by[27]

$$J_{AF}(211) \approx \frac{(H_{S2}+H_K)M_S t_1}{(1+t_1/t_2)}, \quad \text{for } H//\text{Fe}[01\bar{1}], \quad (5)$$

where t_1 and t_2 correspond to the thickness of the middle and bottom Fe layers, and H_K is estimated by measuring the

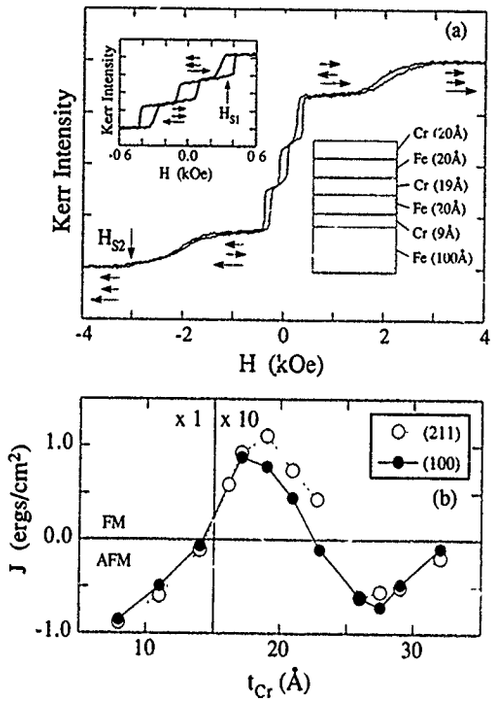

FIG. 3. (a) Room-temperature hysteresis loop measured by Kerr rotation of a (211)-oriented Fe(100 Å)/Cr(9 Å)/Fe(20 Å)/Cr(19 Å)/Fe(20 Å)/Cr(20 Å) sample. The arrows indicate the magnetization directions of the three Fe layers. The inset shows an expanded view of the low-field region. (b) Interlayer coupling J vs t_{Cr} for (211)- and (100)-oriented samples, where antiferromagnetic coupling ($J<0$) was determined from the superlattices and ferromagnetic coupling ($J>0$) was determined from the samples shown schematically in (a). Note the change in scale at $t_{Cr}=15$ Å.

difference in H_S ong both the easy and hard directions. The ferromagnetic coupling strength when H is along the easy axis is given by

$$J_F(211)=H_{S1}M_S t_{Fe},$$

$$\text{for } H \text{ /Fe}[0\bar{1}1] \quad \text{and } J_F<2K_U t_{Fe}. \qquad (6)$$

There are equivalent expressions for the (100) orientations. For the sample shown in Fig. 3(a), J_{AF} determined from Eq. (5) is 0.09 ergs/cm^2, which is consistent with the superlattice results. Shown in Fig. 3(b) is the interlayer coupling measured from 8 to 32 Å Cr, showing the coupling oscillating about zero for both orientations.

The short-period (two monolayer) oscillations observed in Fe/Cr(100)/Fe wedged samples are thought to be directly related to the nested Fermi surface of Cr, which gives rise to the spin-density wave in Cr.[3,4] The origin of the 18-Å long-period oscillation is not as easily related to the magnetic properties of Cr. Stiles[8] has shown that there are a number of spanning vectors in Cr (100), (110), and (111) orientations, which could give rise to long-period oscillations. However, it is not understood within this theoretical framework which of the many spanning vector will give rise to the coupling. In general, it is expected that the coupling should be strongly dependent on the crystal orientation. Given this expectation, the results in Figs. 2 and 3 showing no difference between the (100) and (211) oriented samples is surprising. In addition to the orientations studied in this paper, oscillations in the AF coupling has been observed with the same phase and period and similar coupling strengths in (110) textured multilayers.[28] At present, all the studies of the Fe/Cr system that show oscillatory behavior have found the same 18 Å long-period oscillation.

In conclusion, we have grown epitaxial Fe/Cr(100) and (211) superlattices on MgO(100) and (110) substrates, respectively. Both orientations show interlayer coupling, which oscillates from antiferromagnetic to ferromagnetic with a period of 18 Å. The phase, period, strength of the coupling is found to be independent of the crystallographic orientation.

We use a surface-sensitive Mössbauer spectroscopy technique to examine the spin-wave spectrum, at the Fe(110)/NM(111) interface only, of a multilayer structure with a noble metal (NM) interlayer. We find that the temperature dependence of the hyperfine field follows a Bloch law $(1-BT^{3/2})$, and use spin-wave calculations to connect the surface spin-wave stiffness parameter, B, to the interlayer exchange coupling. Films grown with Ag(111) interlayers show clear oscillations with a period of 6 ML, in good agreement with recent predictions.

I. INTRODUCTION

The phenomenon of oscillatory interlayer magnetic coupling of ultrathin magnetic films[1–3] has generated a great deal of enthusiasm in recent years from a fundamental point of view,[4–7] and, owing to the Giant Magneto-Resistance (GMR) effect exhibited by many of these coupled systems,[1,8,9] from a more device-oriented point of view as well. The origin of the coupling has been attributed[4–7] to a Ruderman–Kittel–Kasuya–Yosida (RKKY) interaction, and definite predictions of oscillation period based on Fermi surface topology are available for many interlayer materials. Experimental observations of the oscillation periods have been somewhat less forthcoming for some interlayers, in particular the (111) oriented noble metals (NM). We believe that this can be explained by the high Fermi surface curvature at the nesting Fermi wave vectors, which are responsible for the oscillations. This can result in very low-amplitude oscillations, which can be missed by traditional magnetometry techniques because of the requirement of an applied field.

In this work, we use a surface-sensitive Mössbauer spectroscopy technique to examine the spin-wave spectrum of multilayer structures Fe(110)/NM(111), with different thicknesses of the noble metal (NM) interlayer, only in the region near the Fe/NM interface. The hyperfine field due to Fe atoms in this interfacial region is found to follow a Bloch law $(1-B_S T^{3/2})$, with a surface spin-wave stiffness parameter B_S that is closely related to the interlayer exchange coupling J_1. In order to connect the two quantities, we present model spin-wave calculations. Films grown with Ag(111) interlayers show clear oscillations with a period of 6 ML, in good agreement with the RKKY model prediction[6] of 5.94 ML.

II. EXPERIMENT

The samples were prepared by molecular beam epitaxy (MBE) in a Perkin–Elmer PHI 430B MBE system equipped with *in situ* reflection high-energy-electron diffraction (RHEED) (vacuum during growth $<2\times10^{-9}$ Torr). The multilayer structures had the form $[\mathrm{Fe}(110)_x\ {}^{57}\mathrm{Fe}(110)_2\ \mathrm{NM}(111)_y]_z+\mathrm{Fe}(110)_x$, with the noble metal interlayer thickness, y, variable between 0 and 40 ML. In this arrangement, more than 90% of the Mössbauer sensitive ^{57}Fe is segregated to the interfacial region, thus allowing us to look experimentally at the interface spin-wave spectrum.

Each multilayer structure was grown on a 5000 Å thick Ag(111) single crystal, which was grown *in situ* by MBE on a V-2 quality mica substrate. Fe layer thicknesses were measured by quartz crystal microbalance, independently calibrated by profilometry; Ag layer thicknesses were monitored by electron impact emission spectroscopy (Inficon Sentinel III). For Fe(110)/Ag(111) samples, the RHEED patterns obtained during growth of the substrate and of the multilayer structure gave evidence for high quality, flat surfaces at the atomic scale, and for a highly repeatable structure. Also, the absence of line broadening and asymmetric line intensity ratios in the transmission Mössbauer spectra indicate that the surface being probed is very flat at the atomic scale and that interdiffusion between ^{57}Fe and natural Fe is negligible.[10,11] For Fe(110)/Cu(111) samples, the interdiffusion of Fe and Cu is more significant, but it can be reduced by decreasing the multilayer growth temperature to 150 °C (to be compared with 180 °C, for samples with Ag interlayer).

The multilayer structures described above can be considered three dimensional (3-D), since the thickness of natural Fe, x, was at least 20 ML. Indeed, the interface hyperfine field was found to follow a Bloch $(1-kBT^{3/2})$ law, similar to the temperature dependence of the magnetization,[12] where B is the bulk spin-wave stiffness parameter and k is related to the interlayer exchange interaction experienced by the Fe spins at the interface.

In Fe(110)/Ag(111) multilayers, k was found to increase to 1.83 with increasing y, with clear oscillations superimposed: see the full line through circles in Fig. 1(a). Actually, the minima occur at $y=6$, 11, and 18 ML, in close agreement with the 5.94 ML period predicted by the RKKY-like theory.[6] To our knowledge, our measurements provide the first evidence of oscillations in exchange coupling strength through Ag(111) interlayers, experimentally detected via a thermodynamic property. As for the sign of the interlayer coupling, vibrating sample magnetometry (VSM) measure-

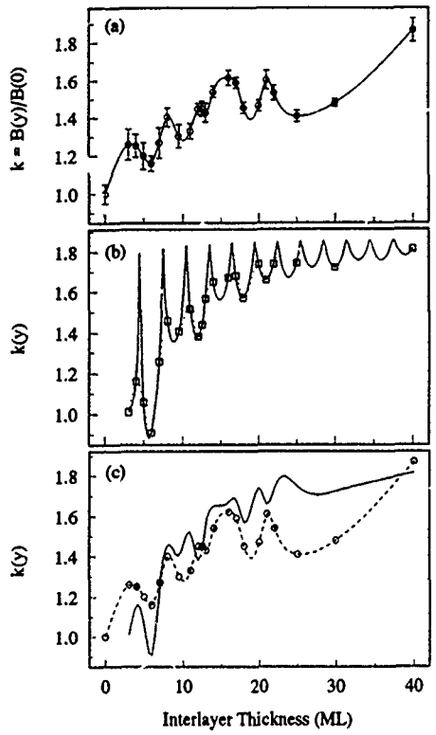

FIG. 1. Surface spin-wave stiffness parameter, $k(y)$, as a function of thickness, y, expressed in ML. (a) Circles: experimental results for Ag(111) interlayer (the full line is a guide to the eye). (b) Full line: $k(y)$ as predicted fitting RKKY theory, Eq. (4), to the data; squares: sampling of predicted $k(y)$ values at points where experimental data exist (the dotted line is a guide to the eye). (c) Comparison of a sampled fit to experimental data.

ments performed at 4.2 K suggested very weak antiferromagnetic (AF) coupling for $y=6$ ML; for all the other values of y, the hysteresis loops were found to be completely ferromagnetic (FM) in character. In Fe(110)/Cu(111) multilayers, preliminary Mössbauer data, obtained with Cu spacer thicknesses ranging between 3 and 8 ML, showed evidence for the first dip in k.

III. SPIN-WAVE THEORY

In order to connect the surface spin-wave stiffness parameter $B_S=kB$ to the interlayer exchange coupling J_1, we perform spin-wave theory calculations for the simplified model of two semi-infinite, simple cubic, Heisenberg ferromagnets, interacting through the interfacial ($l=-1,0$) planes via a nearest neighbor exchange J_1, with Hamiltonian:

$$\mathcal{H}=-\sum_{\mathbf{l}_\parallel,\mathbf{m}_\parallel}\left(\sum_{l,m\leq -1}+\sum_{l,m\geq 0}\right)J(\mathbf{l}-\mathbf{m})\mathbf{S}_\mathbf{l}\cdot\mathbf{S}_\mathbf{m}$$

$$-2J_1\sum_{\mathbf{l}_\parallel}S_{\mathbf{l}_\parallel,-1}\cdot S_{\mathbf{l}_\parallel,0}. \tag{1}$$

One has $J(\mathbf{l}-\mathbf{m})=J_0>0$ for nearest neighbor pairs within each semi-infinite part of the system, and zero otherwise; $\mathbf{l}=(\mathbf{l}_\parallel,l)$ are the lattice vectors.

We perform the usual Holstein–Primakoff transformation from spin to bosonic operators, and work in the mixed Bloch–Wannier representation to take care of the lack of translational symmetry perpendicular to the interface. For ferromagnetic interfacial exchange ($J_1>0$), we introduce the two-particle Green's function (GF) $G_{lm}(E,\mathbf{k}_\parallel)\equiv\langle\langle a_{\mathbf{k}_\parallel,l};a^\dagger_{\mathbf{k}_\parallel,m}\rangle\rangle_E$. Treating the interfacial part of the quadratic bosonic Hamiltonian as a perturbation with respect to the noninteracting part, relative to the semi-infinite system, one can obtain, via Dyson's equation, the interacting GF from the noninteracting one.[13] For antiferromagnetic interfacial interaction ($J_1<0$), a similar theoretical treatment can be developed. One must introduce two different families of bosonic operators, since the quantization directions are different for $l\leq -1$ and $l\geq 0$. Thus, one obtains *two* Green's functions, $G_{lm}(E,\mathbf{k}_\parallel)$ and $G'_{lm}(E,\mathbf{k}_\parallel)\equiv\langle\langle a^\dagger_{-\mathbf{k}_\parallel,l};a^\dagger_{\mathbf{k}_\parallel,m}\rangle\rangle_E$, coupled via *two* Dyson's equations.[14] In both cases, the local magnetization at the plane l can be expressed in terms of the trace of the two-particle GF

$$\langle S^z_l\rangle=S-\int_{-\infty}^{+\infty}dE\,f(E,T)\mathrm{Tr\ Im}\,G_{ll}(E,\mathbf{k}_\parallel), \tag{2}$$

where $f(E,T)$ is the Bose–Einstein distribution. For ferromagnetic interfacial interaction, it turns out that the effective Bloch law,

$$\langle S^z_l\rangle/S=1-k(J_1/J_0)B_{sc}T^{3/2}, \tag{3}$$

is followed for any value of the ratio $j_1\equiv J_1/J_0$, with the limits $k(1)=1$ (bulk) and $k(0)=2$ (surface),[15] in the case of a single interfacial plane ($l=0$ or $l=-1$). B_{sc} is the bulk spin-wave stiffness parameter for the simple cubic ferromagnet. For antiferromagnetic interfacial interaction, in general, we find that the local magnetization does not follow a $T^{3/2}$ law, unless the coupling is rather weak, $j_1<0.2$.

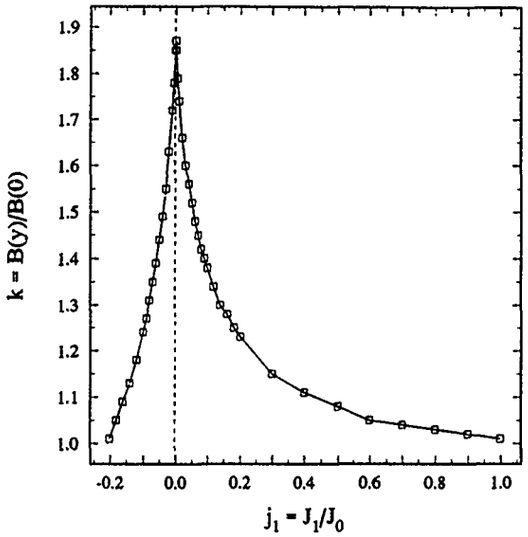

FIG. 2. Surface spin-wave stiffness parameter, $k(J_1)$, as a function of the inter-to-intralayer exchange ratio, $j_1=J_1/J_0$. The calculation is performed for the $l=0$ and $l=1$ layers of a simple-cubic biferromagnetic interface.

In Fig. 2 we report the prefactor $k(j_1)$, calculated—for the valid range of j_1 ($-0.2\leq j_1\leq 1.0$)—taking into account both the $l=0$ and the $l=1$ planes. We note that the inclusion of the $l=1$ plane, required by the experimental situation in

Fe/Ag multilayers, prevents $k(0)$ from reaching the value 2, pertinent to a free surface.[15] Actually, in the limit of zero coupling, the value $k=1.86$ is calculated, to be compared with the value $k=1.83$, experimentally found in Fe(110)/Ag(111) multilayers for $y=40$ ML. Such close agreement confirms that interdiffusion effects are negligible.

IV. DISCUSSION

We now attempt to reproduce the observed behavior of $k(y)$ by assuming an oscillating $J_1(y)$ like the RKKY function,[6]

$$\frac{J_1(y)}{J_0} = -\frac{d^2}{y^2}\frac{m^*}{m}\sin\left(\frac{2\pi y}{\Lambda}+\Phi\right)\frac{y/L(T)}{\sinh[y/L(T)]}, \quad (4)$$

where we used J_0 as the energy scale for $J_1(y)$, and took $\Phi=\pi/2$ as in Ref. 6. The oscillation period, Λ, the amplitude of the oscillations, m^*, and the temperature-dependent attenuation length, $L(T)$, have been taken as free parameters.

In Fig. 1(b) we plot $k(y)$ (full line), as obtained by performing a least square fit to our data. Owing to the steepness of k vs j_1 near $j_1=0$, $k(y)$ is very sensitive to very weak interlayer couplings: in fact, $k(y)$ must have its maximum value of 1.86 at every point where $j_1(y)$ passes through zero. It is this feature of the spin-wave stiffness that makes this surface sensitive method highly suitable for the detection of interlayer coupling in very weak antiferromagnetic multilayer structures, in addition to ferromagnetic ones. The dotted line through squares in Fig. 1(b) illustrates what happens when the $k(y)$ predictions obtained from Eq. (4) are sampled at only the interlayer thicknesses where we have data: it represents a least squares fit of this sampled function to the data. One sees that, even when sampling at 1 ML intervals, it is easy to miss the sharp peaks in $k(y)$. From the comparison with the experimental results for $k(y)$ [as shown in Fig. 1(c)], it is apparent that the qualitative agreement is quite good: at all the dips in our data up to $y=22$ ML, a corresponding dip occurs in the best fit just near the same interlayer thickness. We note that, although m^* and $L(T)$ for the best fit are not close to the theoretical predictions,[6] the oscillation period of $j_1(y)$ is about 6 ML, in good agreement with the theoretical value[6] of 5.9 ML for Ag(111) interlayers. The latter feature represents the critical test of the RKKY-like theory.[6]

In conclusion, using a surface-sensitive Mössbauer spectroscopy technique, we have found that the hyperfine field due to Fe atoms in the interfacial region of Fe(110)/NM multilayers follows an effective $T^{3/2}$ Bloch law. We have developed model spin-wave calculations to connect the spin-wave stiffness parameter to the interlayer exchange coupling through the noble metal interlayer. Films grown with Ag(111) interlayers show clear oscillations with a period of 6 ML, in close agreement with recent theoretical predictions.[6]

Ab initio study of the interlayer magnetic couplings in Fe/Pd(001) superlattices and of the polarization induced in the Fe and Pd layers

D. Stoeffler, K. Ounadjela, J. Sticht,[a] and F. Gautier
Institut de Physique et de Chimie des Matériaux (U.M.R. 46 C.N.R.S.)—Gemme, Université Louis Pasteur, 4 rue Blaise Pascal, 67070 Strasbourg, France

In this paper we present a theoretical study of the magnetic properties of $Fe_mPd_n(001)$ superlattices, (m and n being the number of Fe and Pd atomic layers). Our attention is mostly focused on the determination of both the interlayer magnetic couplings and the magnetic moments distributions as a function of the Fe layer's and Pd spacer's thicknesses. We use an *ab initio* LSDA method (ASW) to determine self-consistently the electronic structure, the magnetic moment distributions, and the total energies for the considered systems. For studying the role of the Pd spacer's structure, we consider two model structures for the Pd spacers (i) a fct structure for which the Pd atoms keep their bulk atomic volume, and (ii) a fcc structure for which the Pd atomic volume is expanded. For the first structure, the magnetic polarization in the palladium spacer is limited mostly to the Fe–Pd interfaces, and the couplings are similar to the ones obtained for nonmagnetic spacers. On the contrary, for the second atomic structure, the whole Pd spacer is polarized with a moment of about $0.15\mu_B$/atom for $n \leqslant 14$, and the couplings are ferromagnetic in a large range of Pd thicknesses. We present a detailed study of Fe_mPd_1 and Fe_3Pd_n superlattices to determine both the couplings and the polarization induced in the Fe and Pd layers.

I. INTRODUCTION

The discovery, during the last decade, of oscillating interlayer magnetic couplings between ferromagnetic (F) layers A_m (A=Fe, Co, Ni) separated by a nonmagnetic or antiferromagnetic (AF) metallic spacer B_n (Ref. 1) (m and n correspond, respectively, to the number of atomic layers) and of the related giant magnetoresistance,[2] has stimulated a lot of experimental and theoretical activity. It has been shown that (i) for nonmagnetic spacers, the period of the couplings are related to the shape of the nonmagnetic metal's Fermi surface; and (ii) for AF spacers, the couplings are due to the magnetism of the spacer and related to the compatibility of the spacer's AF order and the interlayer magnetic arrangement. The case where the spacer is a nearly F metal (Pd, Pt) can be considered as intermediate between the two previous ones. Our aim is to determine the main features of the magnetic moments distributions and of the couplings in the local spin density approximation (LSDA) framework for Fe/Pd(001) superlattices.

The Fe/Pd sandwiches and multilayers have been recently studied experimentally. $Fe(001)/Pd_n(001)/Fe(001)$ sandwiches have been first synthetized by Celinski *et al.*[3,4] The authors found that (i) the whole Pd spacer is not entirely polarized for Pd thicknesses n larger than four monolayers (ML); (ii) for $n \leqslant 12$ ML, the couplings are F and show oscillations with a period of 4 ML; (iii) for $n > 12$ ML, the couplings become AF; and (iv) they are strongly sensitive to temperature variations. Fe/Pd(001) multilayers have been realized more recently in the Thomson-CSF group[5–7] to study their magnetotransport properties. Epitaxial growth has been obtained, in agreement with the results of Celinski *et al.* The authors obtained hysteresis loops consistent with an AF coupling between the Fe layers in the same thickness range[5] as the one observed by Celinski *et al.*[4] However, by a more detailed analysis of the hysteresis loops, they found no evidence for isotropic AF couplings. Moreover, by Kerr optical microscopy, they have recently obtained a strong evidence of a F coupling for $5 \leqslant n \leqslant 25$.[7]

Theoretically, the Fe/Pd interfaces have been mostly studied[8,9] when ultrathin Pd overlayers are deposited onto a Fe substrate. However, it is not possible to split the origin of the induced Pd polarization into an Fe/Pd interfacial and a surface contribution, so that these results cannot be transposed to a multilayer situation. More recently, $Fe_5/Pd_n/Fe_5(001)$ sandwiches and $Fe_5Pd_n(001)$ superlattices have been studied using a tight binding description of the electronic structure.[10] The magnitudes for the couplings reported in these papers are very strong, as compared to the experimental data, to the results of similar calculations for Co_4Pd_n superlattices[11] and to those obtained in the present work.

II. INTERLAYER MAGNETIC COUPLINGS IN Fe_mPd_n SUPERLATTICES

We determine the couplings by calculating the difference $\Delta E_{F-AF} = E_F - E_{AF}$ between the total energies obtained for the two opposite interlayer magnetic arrangements F and AF. The F (AF) interlayer magnetic arrangement corresponds (respectively) to parallel (antiparallel) magnetizations of successive Fe layers. Here, we use the augmented spherical wave (ASW) method[12] and the LSDA formalism for treating exchange and correlation of a many electron system, which allow us to determine the electronic structure of the superlattices. More technical informations concerning the methodology used here can be found in another paper.[13]

Only the in-plane parameter is experimentally known and is found to be nearly equal to the bulk Fe one. If we assume that the (001) plane of fcc Pd when rotated by 45° matches the (001) plane of bcc Fe, a 5% in-plane expansion of the Pd parameter is obtained. Consequently, the fcc cell is

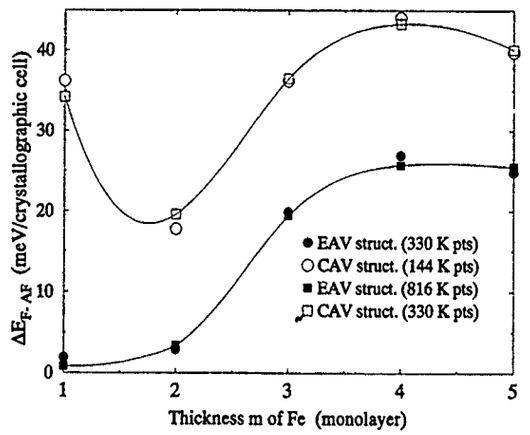

FIG. 1. Interlayer magnetic couplings $\Delta E_{F-AF} = E_F - E_{AF}$ in Fe_mPd_1 superlattices as a function of m for the CAV (full line with square symbols) and for the EAV (dashed line with circle symbols) structure obtained with the two largest number of k points used.

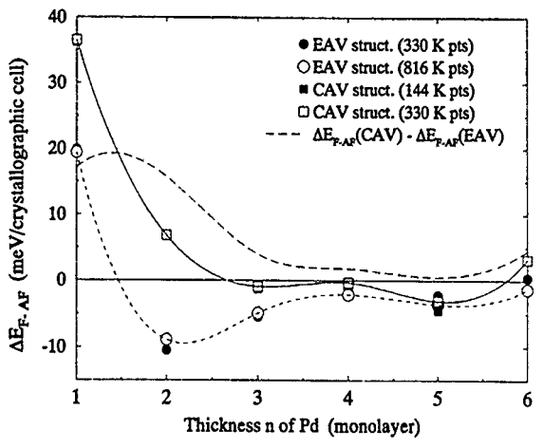

FIG. 2. Interlayer magnetic couplings $\Delta E_{F-AF} = E_F - E_{AF}$ in Fe_3Pd_n superlattices as a function of n for the CAV (full line with square symbols) and for the EAV (dashed line with circle symbols) structure obtained with the two largest number of k points used. The long dashed line corresponds to the difference $\Delta E_{F-AF}(CAV) - \Delta E_{F-AF}(EAV)$ between the couplings obtained for the two structures, which is always found to be positive. The interplanar Pd expansion introduces a contribution that always stabilizes the F state. However, we deduce that this effect is short ranged (three monolayers).

a priori tetragonally deformed, giving a fct structure for the Pd layers.

The precise value of the tetragonality, i.e., of the interplanar distances being unknown, we consider two extreme model structures: (i) the first one, for which the atomic volume of the Pd atoms is taken to be equal to the bulk one (noted CAV for constant atomic volume), and consequently induces a tetragonal deformation of the Pd fcc structure (fct); and (ii) the second one, for which the structure of the Pd layers is assumed to be fcc (noted EAV for expanded atomic volume). In the first structure the distance, $d_\perp$(Pd–Pd), between Pd planes is equal to $0.625 \times a_{Fe}$, $a_{Fe}=5.42$; the atomic unit being the experimental value of the bcc iron lattice parameter. For the second structure, $d_\perp$(Pd–Pd) is equal to $(\sqrt{2}/2) \times a_{Fe}$, so that the palladium atomic volume increase $\Delta\Omega$ from its bulk value Ω, $\Delta\Omega/\Omega$ is equal to 13%. We have verified that, for these two structures, the bulk Pd crystal is not magnetic. Finally, for the distance $d_\perp$(Pd–Fe) between a Pd plane and a Fe plane, we use the average $[d_\perp(\text{Pd–Pd}) + d_\perp(\text{Fe–Fe})]/2$ value with $d_\perp(\text{Fe–Fe}) = a_{Fe}/2$.

We have first calculated the couplings for Fe_mPd_1 superlattices (Fig. 1) to determine the smallest Fe thickness for which the results can be considered as representative of the ones that would be obtained for very large Fe thicknesses. For $m=1$ and 2, the couplings are found to be very different—mainly for the EAV structure—from the ones obtained for $m=3$–5. The couplings being nearly equal for these values, we can limit our study to Fe_3Pd_n superlattices to reduce the number of inequivalent sites in the elemental cell.

Figure 2 is a plot of the couplings versus the Pd spacer's thickness n. The couplings obtained for the CAV structure oscillate from AF ($n=1,2$) to F ($n=3,4,5$) and to AF ($n=6$) values. These oscillations can be roughly assimilated to the ones obtained with the "RKKY-like" theories. On the contrary, the couplings obtained for the EAV structure are F, except for $n=1$. The couplings are positive for both structures, i.e., the AF arrangement is the most stable one. This suggests that, for the F arrangement, the polarization of the Pd spacer costs some magnetic moment formation energy, which can be larger than the energy gain coming from the F interfacial coupling between Fe and Pd layers, these two contributions vanishing for the AF arrangement for which the Pd layer is nonmagnetic. This conjecture is consistent with the fact that the lowest AF couplings is obtained for the EAV structure, i.e., for large Fe–Pd distances, so that a given polarization of the Pd atoms costs less energy, the Pd atoms being closer from the Stoner instability.

III. INDUCED POLARIZATION IN THE Fe AND Pd LAYERS

The experimental F couplings, as measured by Celinski *et al.*[4] show a nonmonotonic behavior with n. The authors have obtained local minima for $n=6,9$ and local maxima for $n=7,11$. Unfortunately, it is not possible to determine theoretically the couplings for so large Pd thicknesses because they are certainly too small to be accurately determined and would need too large a computer time. Childress *et al.*[7] have measured the enhancement of the polarization in the superlattices, which has been found to be equal to $(3.3 \pm 1.6)\ \mu_B$ for each interfacial atom. Even if the couplings cannct be calculated for large spacer thicknesses, it is nevertheless possible to determine the magnetic moments distributions for larger m and n values by restricting our study to the F arrangement to reduce by symmetry the size of the cell by a factor of 2. This allows us to get information on the induced magnetic polarization. Therefore, we have determined the polarization in (i) the Fe layer for a $Fe_{15}Pd_1$ superlattice and (ii) the Pd spacer for large thicknesses (up to $n=20$).

In Fig. 3 we have plotted the magnetic moments distributions in the Fe layer for $Fe_{15}Pd_1$ and in the Pd spacer for Fe_3Pd_{15} for both structures.

We have verified that the magnetic moments on the Fe atoms in Fe_3Pd_n superlattices are insensitive to the thickness

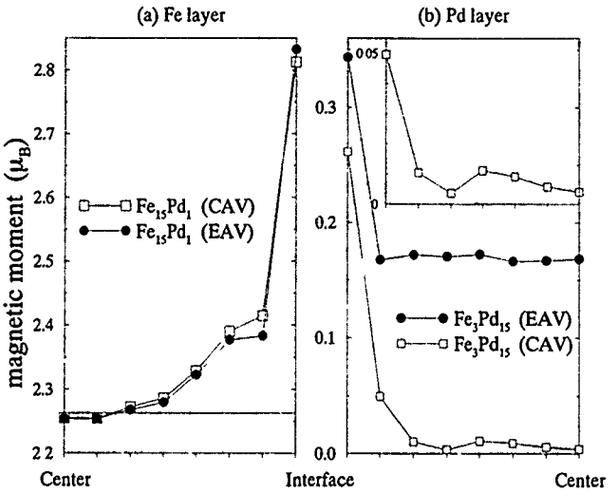

FIG. 3. (a) Polarization of the Fe layer in $Fe_{15}Pd_1$ superlattices determined with 330 k points for both the CAV and EAV structure. The horizontal line corresponds to the bulk magnetic moment. (b) Polarization of the Pd spacer in Fe_3Pd_{15} superlattices determined with 330 (108) k points for the EAV (CAV) structure. The inserts represent the same values for the CAV structure at a larger scale. The values are only given for half the sites. The others can be deduced by symmetry.

of the Pd spacer. This is why we can reasonably assume that the Fe polarization obtained for $Fe_{15}Pd_1$ is representative of the polarization obtained for larger n values. Our result also shows that the Fe polarization is nearly insensitive to the structure (CAV or EAV) of the Pd spacer. Consequently, the total polarization induced in the Fe layer is at least found equal to $0.9\mu_B$ per interfacial atom.

The polarization of the Pd spacer is nearly insensitive to the thickness of the Fe layer. However, it is strongly sensitive to the structure of the Pd spacer. In the CAV structure, the magnetic polarization of the palladium layers induced by the Fe interfacial layers is limited to the first three neighboring layers, the total induced magnetic moment being equal to about $0.35\mu_B$ per interfacial atom. However, the magnetic polarization shows a nonmonotonous decay and suggest that both interfacial polarizations are interacting. A minimum is always obtained in the magnitude of the magnetic moments on the fourth Pd layers from the interface. In the EAV structure, the whole Pd spacer remains polarized with large magnetic moments on the inner layers (0.13–$0.19\mu_B$) up to large thicknesses. This is due to the fact that, for this atomic volume, the Pd is close to the F state.

IV. DISCUSSION AND OUTLOOK

In this paper we have shown that (i) the ground states of Fe_3Pd_1 in both structures and for Fe_3Pd_2 in the CAV structure is AF. (ii) The couplings are found to oscillate in the CAV structure, whereas they are F in the EAV structure. (iii) For large Pd thicknesses values ($n>4$), the polarization of the Pd spacer is completely different for the two structures considered here: it is limited to the interfacial atoms for the CAV structure, whereas the whole Pd spacer is polarized with a magnetic moment of approximately $0.15\mu_B$/atom for the inner layers in the EAV structure. (iv) The induced polarization in the Fe layer is at least equal to $0.9\mu_B$ and in the Pd spacer is approximately equal to $0.35\mu_B$ per interfacial atom for the CAV structure.

The comparison with the experimental results shows interesting features that can be summarized as follows.

(i) The mean magnetic moment per Pd atom is estimated by Celinski *et al.* to be equal to $0.25\mu_B$ in $Fe_5/Pd_4/Fe_{10}$.[3] This result is in agreement with the one we obtain for the Fe_3Pd_4 superlattices in the EAV structure, the calculated mean magnetic moment being found equal to $0.265\mu_B$.[13] This could suggest that the experimental structure is expanded for such small thicknesses.

(ii) Childress *et al.*[7] have measured an induced polarization equal to $(3.3\pm1.6)\mu_B$ per interfacial atom. Our calculations give $1.25\mu_B$ per interfacial atom in the CAV structure, which is less than the experimental lower bond ($1.7\mu_B$).

(iii) Celinski *et al.* have also deduced that the maximum number of Pd atomic layers for which the whole Pd layer is ferromagnetically ordered is $n=4$.[3] This is not consistent with our calculations for perfect superlattices: we have shown that the Pd polarization for the CAV structure is limited to the interfacial atomic layer, while the Pd spacer is entirely polarized up to $n=15$ for the EAV structure. The present results can be consistent with experiment only if a structural change (from the EAV to the CAV structure) occurs for $n=5$. Up to now, there is no experimental evidence of such a change.

In view to clarify this point, we have recently done preliminary calculations to determine the values of the Pd interplanar distances, which minimize the total energy of the superlattice. These results show that the ground state structure is very close to the CAV one. Consequently, in contradiction with the previous conjecture, the structural change from an EAV to a CAV structure cannot be theoretically predicted. Therefore, the disagreement between theory and experiment could only be resolved if we introduce some interfacial interdiffusion. Such a study is now under progress.

Induced spin polarization on Fe/nonmagnetic metal interfaces

J. L. Pérez-Díaz and M. C. Muñoz
Instituto de Ciencia de Materiales, C.S.I.C., Serrano, 144, E-28006 Madrid, Spain

We have investigated the Fe/Au, Ag, Pt, and Al(001) single interfaces by means of an empirical tight-binding Hamiltonian within the Green's function matching formalism. The method is exact and describes equally interface states and bulk resonances. The evolution of the layer density of states indicates a rearrangement of the electronic density at the interface in form of spin polarization of the nonmagnetic layers. The induced magnetic moments in the nonmagnetic layers are only appreciable in Pt and Al, while variations of the interface Fe magnetization are predicted for all the systems.

I. INTRODUCTION

The discovery of long-range oscillatory exchange coupling between magnetic layers separated by a nonmagnetic spacer[1] has opened new perspectives in the study of magnetic layered structures. The oscillatory and long-range character of the coupling suggests that the nature of the interaction among ferromagnetic layers is indirect and associated to the Ruderman–Kittel–Kasuya–Yosida (RKKY) indirect exchange. As is well known, the RKKY interaction stems from the spin polarization induced in the spacer material by adjoining magnetic slabs. Then, the electronic interaction at the interface determines the spin polarization of the nonmagnetic material and indirectly the role of their energy bands. In multilayers, where different interfaces are simultaneously involved, the scattering at the multiple interfaces would give rise to specific modulation of the multilayer electronic structure.[2] Nevertheless, the induced spin polarization of the nearly free electrons would be identical in the one-interface case. On the other hand, overlayers and sandwiches of magnetic metals have an added interest due to their remarkable two-dimensional magnetic properties. It has been shown that the interface magnetic properties of a Fe monolayer (ML) grown on Au, Ag, or Pt single crystals differ from the bulk ones.[3] Besides the enhancement of the Fe magnetic moment (MM), an appreciable magnetization of the first nonmagnetic layer has also been predicted. The explanations for these effects are based on the variation of the coordination number of the overlayer atoms.[4] However, in multilayers and consequently in the single interfaces formed by bcc Fe and a fcc metal, the coordination number holds up throughout the interface. Then, in these systems magnetic effects are only produced by the electronic interaction between the two metal energy bands. The purpose of the paper is to investigate the interface electronic structure of Fe(bcc)/X(fcc)(001) single interfaces, where X is a nonmagnetic metal.

II. MODEL AND METHOD

The electronic structure of the interfaces has been self-consistently calculated by means of an empirical tight-binding (TB) Hamiltonian within the surface Green's function matching (SGFM) approach.[5] The method is exact and allows us to determine the electronic properties of any desired layer of the entire semi-infinite crystals. The SGFM yields the interface Green's function (GF) in terms of the Hamiltonians and GF's of the bulk constituents and the interaction across the interface. It deals equally with interface states and bulk resonances. The interface GF is evaluated as a function of energy E, two-dimensional wave vector $\mathbf{k}_\parallel$ parallel to the interfaces and layer indexes n and n'. To calculate the total Layer Density of States (LDOS), a weighted sum of the Cunningham special points[6] in the two-dimensional Brillouin zone have been used. The bcc and fcc (001) semicrystals are coupled by rotating the fcc lattice 45° around the z axis.[7] The small lattice mismatch is neglected, since the Fe lattice constant is almost a factor of $\sqrt{2}$ smaller than the Ag, Au, Pt, and Al lattice parameters. Then, the two-dimensional lattice is square and $a_\parallel$ is the same for both constituent semicrystals and equal to that of Fe, while $a_\perp$ is different on each side of the geometrical interface. The distance between the Fe and the fcc metal layers is obtained averaging the interlayer distances of both sublattices.

An empirical TB Hamiltonian, with a spd orbital basis has been used to describe the bulk materials. Because the bcc third-neighbor and fcc second-neighbor distances coincide, we have taken up to third-nearest-neighbor interactions for Fe, and second-nearest-neighbor interactions for fcc metals. The orthogonal two-center TB parameters given by Papaconstantopoulos[8] have been used. To calculate the cross-coupling matrix elements, we consider the actual Fe–X (X =Ag,Au,Pt,Al) bond angles, while for the TB parameters we take the arithmetic averages of the corresponding bulk ones. This is a good approximation, since the bulk parameters have either the same sign or one is much larger than the other.

To obtain charge neutrality we add a diagonal potential to the Hamiltonian of the first two layers on each side of the geometrical interface. Its main effect is to shift in energy the interface LDOS, and consequently to vary the orbital occupancies. In all the interfaces, charge neutrality, to within 0.05 electrons, has been achieved.

III. RESULTS AND DISCUSSION

A. Fe/transition metal interfaces

In the Fe/transition metal interfaces, the overlap between the fcc metal and the Fe bands increases along the Ag, Au, and Pt series, since the bulk valence band becomes wider and at higher energy. Figures 1–3 show the LDOS for the first two atomic planes and for a bulk plane on each side of the Fe/Ag, Fe/Au, and Fe/Pt interfaces. Solid and dashed lines correspond to majority and minority spin states, respectively. The energy zero is at the Fermi level. The LDOS of the three metals, Ag, Au, and Pt, exhibits spin-polarization. For Ag the

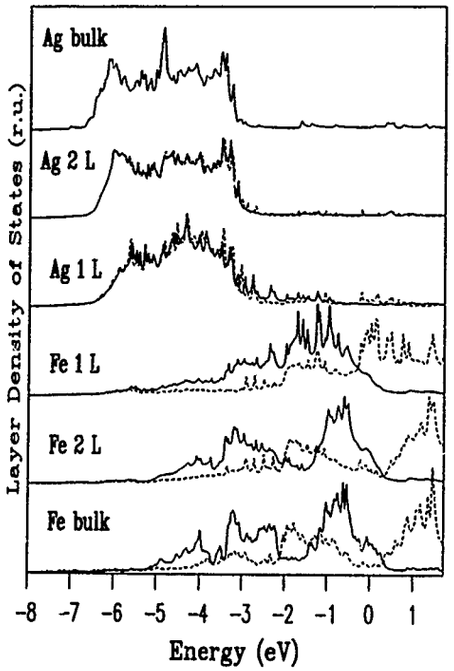

FIG. 1. Total LDOS for the first two atomic planes and a bulk plane on each side of the Fe/Ag (001) interface. Solid lines represent majority-spin states and dashed lines represent minority-spin states.

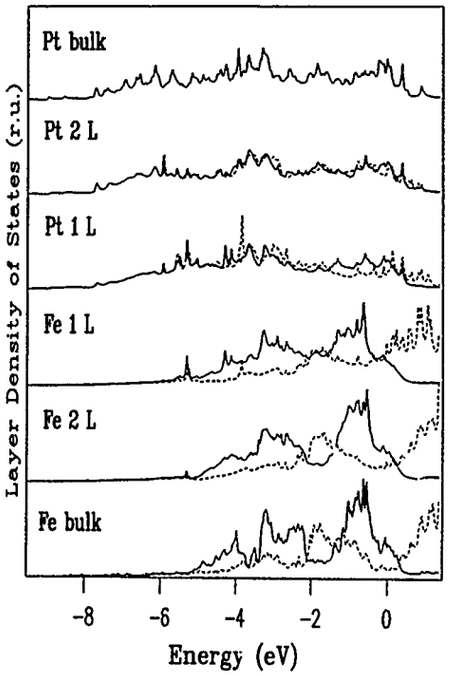

FIG. 3. As in Fig. 1, for the Fe/Pt(001) interface.

splitting is very small and almost restricted to the first layer. It is positive in the entire range of the Ag d band, except around -6 eV. Bulk resonances, particularly at about -4 eV, are induced by the Fe layer. The splitting of the Au band is larger and is also observable in the second Au layer. The strongest modification of the first Au LDOS is around the top of the d band (-1.5 eV), where besides a decrease of the Au-like states, the appearance of Fe induced resonant states is observed. However, comparing the three interface systems, the greatest spin polarization is induced in the Pt interface layer, where hybridization of the d bands is noticeable along all the band extend. The MM of the nonmagnetic interface layers takes the values $0.01\mu_B$ for Ag, $0.08\mu_B$ for Au, and $0.18\mu_B$ for Pt, which agree reasonably with those calculated for overlayers and superlattices.[9] Namely, zero and $0.05\mu_B$ for one and two MLs of Fe grown on Ag; $0.015\mu_B$ for a Fe ML on Au, and $0.3\mu_B$ for Pt/Fe superlattices. The present results indicate that the increase of the MM correlates with a stronger band hybridization at the interfaces.

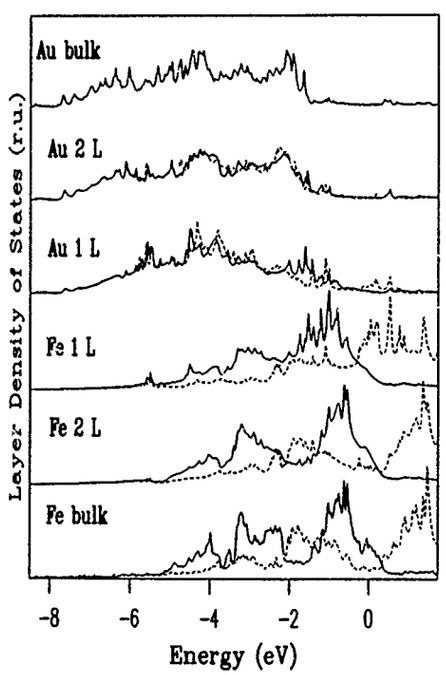

FIG. 2. As in Fig. 1, for the Fe/Au(001) interface.

The overall structure of the first Fe LDOS is similar for the three interfaces. There is a depletion of states at the bottom and an enhancement near the top of the d band for both majority and minority spin polarization. These effects are more appreciable in Ag, while for the Fe/Pt interface the LDOS is closer to that of a bulk Fe plane. The dominant structure is located at about -1.5 eV on the majority and at Fermi level on the minority-spin band, being larger for the Fe/Ag interface. Since the Ag d band is below -2 eV, this structure must be due to not only $d-d$ but also $sp-d$ hybridization. Furthermore, the modifications of the majority-spin LDOS are mainly in the occupied states region, while those of the minority-spin LDOS are in the empty-state area. Therefore, there is an imbalance of spin-up and spin-down states, which gives rise to the enhancement of the Fe magnetization at the interface layers.

The MM of the first and second Fe layers increases by 16% and 1% for Ag, 10% and 5% for Au, and 5% and 6% for Pt interfaces, respectively. In the Fe/Pt system, the slow decay of the Fe MM to the bulk value, besides the appre-

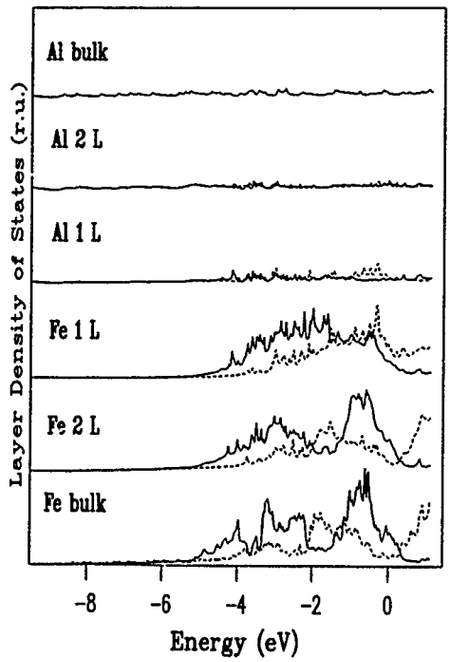

FIG. 4. As in Fig. 1, for the Fe/Al(001) interface.

ciable Pt induced MM, may explain the great magneto-optical Kerr effect observed in Fe/Pt modulated structures.[10]

B. Fe/Al interface

The LDOS for the Fe/Al interface is represented in Fig. 4. The planes displayed are those of Figs. 1–3. In spite of the different electron occupancy -the Al band has three sp electrons per spin—the large modification of the Al and Fe interface LDOS suggests a strong $sp-d$ interaction. In fact, the interface resonances, and consequently the $sp-d$ hybridization, extend to all the band for both majority and minority spin polarization. The Al induced MM in the first layer is $0.15\mu_B$, comparable to the Pt MM. Nevertheless, while the Pt–Fe MMs are ferromagnetically oriented, the Al–Fe MMs are antiferromagnetically coupled. This is due to the strong $sp-d$ hybridization of the minority spin band just below the Fermi level. On the other hand, the MM of the Fe interface layer diminishes by as much as 24%. The strong $sp-d$ interaction seems to be responsible for this significant reduction.

In summary, the interaction between the Fe and the fcc metals induces spin-polarization on the interface nonmagnetic bands for all the systems studied. However, a noticiable MM is only exhibited by the Pt and Al interface layers. Enhancement of the Fe interface MM is obtained for the transition metal interfaces, while a large decrease is predicted for the Fe/Al system. In this system the coupling at the interface is antiferromagnetic.

The temperature dependence of the bilinear and biquadratic exchange coupling in Fe/Cu, Ag/Fe(001) structures (abstract)

Z. Celinski, B. Heinrich, and J. F. Cochran
Physics Department, Simon Fraser University, Burnaby, British Columbia V5A 1S6, Canada

The exchange coupling through nonmagnetic metallic interlayers is described by bilinear and biquadratic exchange coupling terms. In simple metals such as Cu(001) and Ag(001), the bilinear exchange coupling exhibits strong short wavelength oscillations (~2 ML). The exchange coupling through non ferromagnetic interlayers is strongly affected by the interface roughness. Realistic interfaces consist of finite atomic terraces that result in variations of the interlayer thickness. Slonczewski showed that in this case the biquadratic exchange term can be produced by frustration of local magnetic moments. Recent band structure calculations showed that the biquadratic exchange coupling can be intrinsic. In this case its strength is usually found to be significantly weaker than that of bilinear coupling. The temperature dependence of biquadratic exchange coupling is expected to be different for the Slonczewski and intrinsic mechanisms. The intrinsic biquadratic exchange coupling is expected to vary with temperature faster than that predicted by the Slonczewski mechanism. In the present studies using the FMR and MOKE techniques we have investigated extensively the temperature dependence of the bilinear and biquadratic exchange coupling in Fe/Cu/Fe and Fe/Ag/Fe(001) structures. The quantitative studies of the exchange coupling were carried out in the temperature range 77–400 K. By growing the first Fe layer at various substrate temperatures one can prepare samples possessing interfaces with a variable atomic terrace width at the Fe/Cu, Ag interface. That way one can control the strength of the biquadratic exchange coupling. Two limits were investigated: (a) The strength of the biquadratic term in the exchange coupling was much smaller (10%) compared to the bilinear term; (b) the strength of the biquadratic term was comparable to the bilinear exchange coupling. The results are discussed within the framework of existing theories.

Exchange coupling through ferromagnetic bridges in magnetic multilayers (abstract)

J. C. Slonczewski
IBM Research Division, Thomas J. Watson Research Center, P.O. Box 218, Yorktown Heights, New York 10598

It has been known for 27 years[1] that ferromagnetic bridges joining two ferromagnetic films can result in a $\cos\theta$ dependence of the exchange-coupling energy W_b only under very restricted circumstances. In more natural circumstances, considered here, one expects $W_b = C\theta^2 \geq 0$ to hold in the full angular range $0 \leq \theta \leq \pi$. The principal condition for this relation to hold is that local spontaneous spin polarization actually exists at the given temperature for all sites composing complete chains of exchange-coupled local spins extending between the ferromagnetic films. One easily finds estimation formulas in special limits; e.g., for a set of thin uniform filamentary bridges, $C = A\phi/w$, where A is the exchange stiffness, ϕ is the fractional cross section of filaments, and w is the spacer thickness. Because of this peculiar angular dependence of W_b, ferromagnetic bridges are conducive to noncolinear arrangements of the sublayer moments. In particular, nearly 90°-domain arrangements are favored in epitaxial (100) multilayers which have sufficiently strong positive cubic anisotropy W_k. Observed 90° arrangements were previously attributed to biquadratic coupling.[2] One condition for 90° arrangements due to bridges is that the additional coupling $W_a = -J\cos\theta$ through the normal-metal spacer medium is antiferromagnetic and its strength is in the appropriate range. Let the total energy be $W = W_k + W_a + W_b$. Then, if $W(0)$ is thus made nearly equal to $W(\pi)$, the θ^2 dependence of the bridge term insures that W is minimized near $\theta = \pi/2$.

Exchange coupling between ferromagnetic layers: Effect of quantum well states (abstract)

James R. Cullen and Kristi B. Hathaway
Naval Surface Warfare Center, Dahlgren Division, White Oak Detachment, 10901 New Hampshire Avenue, Silver Spring, Maryland 20903-5640

It is a well-established experimental result that the exchange coupling between ferromagnetic metals Fe, Co, or Ni is an oscillatory function of the thickness of the paramagnetic spacer. Theories of this coupling are almost in complete unanimity in attributing the observed periodicity to the properties of the Fermi surface of the paramagnetic spacer. Little has been done, and no consensus reached, as to the origin of the strength of the coupling. A realistic assessment of this quantity requires the use of an itinerant picture of the ferromagnetic constituent. From a recent study based on this picture,[1] it became clear that the ratio of the spin-split band gap to the Fermi energy is important in establishing not only the strength of the coupling, but the phase of the oscillations in the nonasymptotic spacer thickness regime. Here we extend the work, which was limited to cases in which the minority-spin band of the ferromagnet was energy matched to the paramagnetic band, to cases in which the match is to that of the majority-spin band. In the latter arrangement, electrons of one spin are trapped in a well whose width equals the thickness of the spacer. We calculated the spin-flip current, and hence, the torque, exerted by one ferromagnet on the other as the magnetization direction of the former is rotated with respect to that of the latter. As in the earlier case, the torque leads to higher-order (in the cosine of the angle between the magnetizations of the ferromagnets) coupling as well as the usual linear coupling. The bound states produced by the quantum well structure are most important when the band splitting in the ferromagnet is large. The new features produced by these states will be discussed; in particular, their effects on the coupling strength and the phase shift will be discussed.

Ferromagnetic resonance studies of Py bilayers for the system (Permalloy/Al_2O_3) (abstract)

H. Hurdequint, N. Bouterfas, and A. Vaurés
Laboratoire de Physique des Solides, Université Paris-Sud, 91405 Orsay Cédex, France

We report a detailed ferromagnetic resonance study, performed at X band and room temperature, of magnetic permalloy (Py) bilayers (Py1/Al_2O_3/Py2) deposited by rf sputtering on mica substrates. We will present and discuss results relative to two series of Py bilayers characterized by an ultrathin Py layer thickness and corresponding to the two following sets of spacer thickness t_s: (40;30;19 Å) and (15;12;9 Å). These films have been deposited at room temperature and subsequently annealed (at T=220 and 190 °C, respectively, for these two sets). The resonance spectrum is studied as a function of the orientation [$\Theta_H=(N,H)$ with respect to the film normal N] of the applied dc field H in a plane perpendicular to the film. (i) For the three samples of the first series the resonance spectrum is composed of two resolved lines which can be attributed to the resonances of the individual layers (Py1 and Py2) dynamically uncoupled. As for a single[1] Py layer, the angular variation $H_{res}(\Theta_H)$ of each line observed is well accounted for in terms of a unique parameter $(4\Pi M-H_A)$, where H_A is a uniaxial perpendicular anisotropy field arising from the interface-induced anisotropy. The anisotropy fields H_{A1} (for Py1) and H_{A2} (for Py2) are found slightly different ($H_{A2}-H_{A1}$=500 G), reflecting some differences in the structural characteristics of the (Py/Al_2O_3) interfaces in the two Py layers. (ii) In the second series of lower t_s values, by contrast, the observed resonance spectrum is more complex revealing for a given orientation Θ_H two main modes (with a more intense one) and for specific geometries (around Θ_H=0) the presence of other resonance modes of much weaker intensities. For these samples the angular variation $H_{res}(\Theta_H)$ of the different modes observed, by comparison to the behavior found in the Py single-layer control sample, provides clear evidence for the presence of a dynamical coupling between the magnetizations of the two Py layers. The main mechanisms, likely responsible for this intermagnetic layer coupling, will be discussed: dipolar coupling and exchange coupling (either direct through pinholes or indirect).

Exchange coupling in [Dy|Er] metallic superlattices

W. T. Lee, H. Kaiser, and J. J. Rhyne

Magnetic exchange coupling in metallic superlattices of [Dy|Er], grown by molecular-beam epitaxy, has been examined by neutron diffraction. In a superlattice of 65-Å layers of Dy and 55-Å layers of Er, distinct ordering temperatures were observed for the Dy and Er layers. Basal plane helical ordering of the Dy layers was initiated at temperatures close to T_N for bulk Dy (178 K) with a long-range interaction, preserving both phase and chirality, mediated through the Er layers. At a temperature near 70 K, the helical coupling of the Dy spins is replaced by an antiferromagnetic coupling of adjacent ferromagnetically ordered Dy layers coexisting with a remanent helical order. At a temperature well below T_N of bulk Er, c-axis ordering of the Er spins occurs in the superlattice, and in measurements at 10 K there is evidence of basal plane moment ordering in the Er.

INTRODUCTION

Rare-earth superlattices, consisting of layers of a magnetic rare earth alternated with layers of a nonmagnetic rare earth,[1] have provided unique insight into the propagation of long-range magnetic order via spin density wave coupling mechanisms and on the effect of lattice strains on the occurrence of different periodic moment and ferromagnetic spin states.

In a new departure, superlattices have recently been grown at the University of Nancy that consist of alternate layers of the dissimilar magnetic elements Dy and Er. These superlattices have been grown by molecular-beam epitaxy (MBE) techniques and have been examined by x-ray and neutron diffraction and magnetization measurements. Only the neutron scattering results are presented in this article.

In bulk elemental form, Dy orders at 178 K (T_N) in a helical spin structure consisting of ferromagnetic sheets perpendicular to the c crystal axis that are rotated from plane to plane through a temperature-dependent turn angle. Below 85 K, magneto-elastic effects destroy the helical order and induce a ferromagnetic spin state. In superlattices of [Dy|Y], epitaxial clamping of the Dy to the larger basal plane lattice of Y has been shown[1] to completely suppress the ferromagnetic transition due to constraints on the magnetostatic modes that drive the transition. Conversely, [Dy|Lu] superlattices[2] exhibit an enhanced ferromagnetic transition temperature due to the epitaxy of the Dy to the smaller Lu lattice.

In contrast to the basal plane spin ordering of Dy, bulk Er orders initially at 85 K (T_N) into a sinusoidally modulated moment structure with spins along the c axis. At temperatures below about 56 K, a more complex structure ensues involving ordering of both c-axis and transverse (basal plane) moment components. This structure collapses into a c-axis conical ferromagnetic state below 20 K. Superlattices of [Er|Y] again show a suppression of the ferromagnetic state[1] due to strain effects.

EXPERIMENTAL DIFFRACTION RESULTS

Neutron scattering data on [Dy|Er] superlattices were taken at the University of Missouri Research Reactor on a triple-axis spectrometer with the analyzer set for zero energy transfer and used to minimize background. The incident neutron wavelength was 2.357 Å from a Si monochromator. Soller slit collimations of 27′-10′-23′-19′ were used before and after the monochromator and analyzer, respectively, yielding an elastic resolution width of 0.0136 $Å^{-1}$. In a superlattice consisting of 65-Å layers of Dy alternated with 55-Å layers of Er, distinct ordering temperatures were observed for the Dy basal plane and Er c-axis moments. Basal plane helical ordering of the Dy layers was initiated at temperatures close to T_N for bulk Dy. The occurrence of fully resolved superlattice harmonics of the magnetic satellites symmetric about the (0002) Bragg reflection (Fig. 1) confirmed that the ordering was long range, extending across multiple bilayers and preserving both phase and chirality of the Dy spin structure. This coupling was mediated through the Er layers, which are ostensibly paramagnetic.

At approximately 70 K, the Dy layers exhibit a collapse into a planar ferromagnetic state with the adjacent layers coupled in an antiferromagnetic arrangement. This is manifested by the appearance of an additional magnetic diffraction peak (and harmonics) between the principal nuclear structural peak and its first harmonic (Fig. 2). The reflections associated with the helical spin ordering of the Dy coexist with the antiferromagnetic reflection, but diminish in intensity at lower temperatures.

 0021-8979/94/75(10)/6477/3/$6.00 © 1994 American Institute of Physics

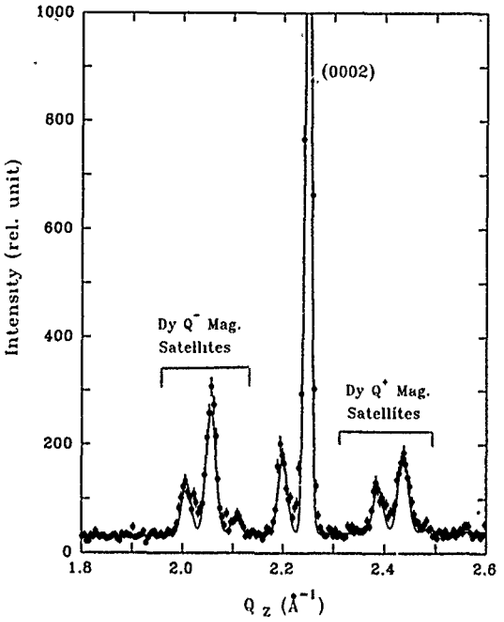

FIG. 1. Diffraction scan along (0002) of a [Dy|Er] superlattice at 110 K showing the development of long-range helical incommensurate order in the Dy planes mediated through the alternate paramagnetic Er layers.

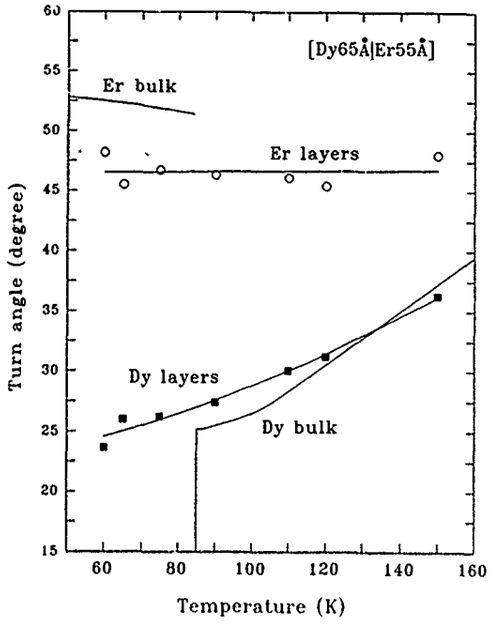

FIG. 3. Turn angles of spins in the Dy and Er layers as a function of temperature. The results for bulk Dy and Er are shown for comparison.

At temperature below the T_N of bulk Er, c-axis ordering appears for the Er spins, as evidenced by the appearance of magnetic satellites about the $(10\bar{1}0)$ reflection. The scattering intensity from this ordering is delineated from the basal plane components by geometrical factors in the scattering cross section. Because of inadequate statistics, no attempt was made to calculate magnetic moment values from these results. In the 10-K (0002) scan shown in Fig. 2, there is evidence of a shift in **q** of the incommensurate magnetic reflections and an increase of intensity over that observed at 30 K that suggests an ordering of the basal plane components of the Er structure in addition to the vestigial Dy helical ordering.

The low temperature data (e.g., 10 K in Fig. 2) also show evidence of a broad magnetic peak underlying the pattern and centered on the (0002) nuclear peak. This peak has a width that would correspond to short-range ferromagnetic correlations of approximately 17 Å range. Similar short-range correlations have also been observed in other rare-earth superlattices[1] at low temperature and have been ascribed to spins near the interfaces.

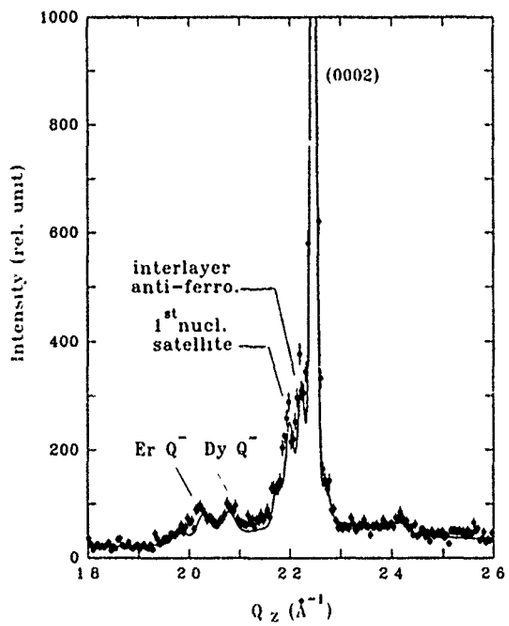

FIG. 2. Scan at 10 K along (0002) exhibiting an additional magnetic peak between the principal nuclear structure peak and its first harmonic illustrating the development of antiferromagnetic coupling of alternate Dy layers, each internally ferromagnetically ordered. The incommensurate order peaks suggest a remanent ordering of the Er and Dy spins.

TURN ANGLES AND MAGNETIC MOMENTS

The neutron diffraction data have been analyzed by least-squares fitting to a structure factor containing both nuclear and magnetic scattering components to obtain the magnetic periodicity in both the Dy and Er layers. These results are shown in Fig. 3. The Dy turn angle is strongly temperature dependent and, over the range 85 K$<T<$150 K, exhibits similar values to that in bulk Dy. Even though the Er is ostensibly paramagnetic, it is still possible to assign an "effective turn angle" to an Er spin density wave induced by the Dy helically ordered layer moments. The existence of a spin-density-wave-like coupling is manifested by the phase coherence of the helical order extending over several bilayers. This Er turn angle is nearly temperature independent

over the range analyzed, 60 K$<T<$150 K, with a value near 47°/plane. This is roughly comparable with that found in bulk Er.

The helical ordering peaks in the c^*-axis scans have also been analyzed to obtain the Dy moment associated with the helical ordering. The moment values range from $6.4\mu_B$ at 60 K down to $4.8\mu_B$ at 150 K. The low-temperature moment values are lower than in bulk Dy at the same temperature ($\mu_{T=0}=10\mu_B$) and exhibit a weaker temperature dependence.

SUMMARY

These results demonstrate that long-range magnetic order occurs in superlattices of two dissimilar magnetic rare earths, Dy and Er, and that the Dy spin coupling can be propagated through Er while it is in a paramagnetic state. The Dy and Er layers exhibit distinct ordering temperatures not far from their bulk counterpart elements, and show approximately the same magnetic periodicity. Further work is in progress with superlattices of varying Er and Dy thickness to examine thickness effects on the magnetic coherence and the role of epitaxial strain in the ordering transitions.

Spin-valve structures exchange biased with a-$Tb_{0.23}Co_{0.77}$ layers

P. P. Freitas[a] J. L. Leal,[b] T. S. Plaskett, and L. V. Melo[a]
INESC, R. Alves Redol 9-1, 1000 Lisbon, Portugal

J. C. Soares
CFNUL, Av. Prof. Gama Pinto, 1010 Lisbon, Portugal

Spin-valve structures, glass/NiFeI/Cu/NiFeII/a-TbCo/Cu, were prepared where the pinned Permalloy layer is exchanged biased by a 200 to 400 Å thick a-$Tb_{0.23}Co_{0.77}$ layer. Exchange fields between 50 and 250 Oe were achieved with TbCo thicknesses below 400 Å, for a pinned Permalloy layer 150 Å thick. The exchange fields are strongly dependent on substrate bias. The magnetoresistance of these structures reaches 4.5% when thin Co layers are added at the NiFe/Cu interfaces.

INTRODUCTION

Spin-valve structures consist of two ferromagnetic layers separated by a low resistivity nonmagnetic metal spacer.[1,2] One of the ferromagnetic layers is pinned through exchange coupling to an antiferromagnetic film, while the other ferromagnetic layer is free. This structure provides an antiparallel alignment of the ferromagnetic layers for an applied field between the coercive field of the free layer, and the exchange field at the pinned layer. Due to spin-dependent scattering in the bulk of the ferromagnetic layers, or at the noble-metal/ferromagnet interfaces, the resistivity is higher when the ferromagnetic layers are antiparallel, and lower when they are parallel. In order to be considered for magnetoresistive head applications, these structures must surpass Permalloy, with a magnetoresistance (MR) signal of 2%–3% at room temperature (RT) and coercivities below 1 Oe for films 200–400 Å thick. A typical spin valve has the following structure, substrate/NiFeI/Cu/NiFeII/FeMn/cap. NiFeI is the free Permalloy layer ($Ni_{81}Fe_{19}$), with a thickness between 100 and 200 Å in order to maximize the spin-valve MR effect. The Cu layer thickness is between 30 and 50 Å, thick enough to provide continuity, no pinholes and to avoid strong coupling between NiFeI and NiFeII. NiFeII is pinned through exchange coupling to FeMn, and the NiFeII thickness determines the exchange field ($H_{ex} \propto 1/t_{NiFeII}$).[3] Exchange fields up to 100 Oe can be obtained with NiFeII thickness ranging from 100 to 150 Å, and FeMn thickness of 150 Å. In order to achieve exchange coupling, FeMn must be in its fcc antiferromagnetic phase, which requires a fcc seed layer (NiFeII) and correct film stoichiometry (Fe48Mn52). The exchange field value can only be controlled by varying NiFeII thickness. The direction of the induced exchange field can be chosen by deposition under a small magnetic field, or by *a posteriori* field annealing.

Amorphous ferrimagnetic Tb_xCo_{1-x} films have been proposed as an alternative candidate for biasing MR heads, since it was found that in a restricted composition range they would exchange couple to Permalloy.[4–7] This material has the advantage of allowing exchange field tuning by slight composition variations, substrate RF bias, or Tb_xCo_{1-x} thickness variation.

For conventional MR Permalloy head applications, a 1500 Å thick $Tb_{0.28}Co_{0.72}$ film was exchanged coupled to a 500 Å Permalloy layer, leading to an exchange field of 100–150 Oe.[3] For 250 Å thick Permalloy films, these authors quoted exchange fields ranging from 300 to 500 Oe. A drastic decrease in the exchange field was reported for a TbCo thickness of 500 Å. Considering spin-valve applications, a 60–100 Å Permalloy layer is needed to maximize the MR signal. Also, thinner TbCo layers are required for particular head designs. We were able to maintain the exchange field within the required limits (100–200 Oe), by decreasing the Tb_xCo_{1-x} film thickness, and by using a different Tb_xCo_{1-x} composition with a small in-plane magnetization component.

In this work we show that TbCo amorphous films with thicknesses between 200 and 400 Å can be successively used to exchange bias spin valves, leading to exchange fields up to 250 Oe, which can be tuned by RF substrate bias, or by varying the TbCo thickness. The spin valves produced so far have a MR signal close to 4.5%.

EXPERIMENTAL METHOD

The spin valves were prepared in an automated NORDIKO 2000 sputtering system with a base pressure of 2×10^{-8} Torr. A mosaic target for the Tb_xCo_{1-x} alloy was prepared using Co squares 0.7 mm thick on a three inch Tb target. We aimed at a Tb content leading to a compensation temperature, close to room temperature, that is $0.23<x<0.28$. For these compositions the rare-earth and transition metal sublattices compensate, and exchange coupling occurs. Four mosaic targets were studied, giving rise to the following compositions $x=0.18$, 0.23, 0.24, and 0.27, checked by the Rutherford Backscattering Analysis. The Tb_xCo_{1-x} films were RF sputtered at 100 W and 10 mTorr(Ar). The target to substrate distance was 10 cm. No field was applied during deposition apart from the residual field of the magnetron of the order of 10–20 Oe, in the plane of the substrate. RF substrate bias during deposition was used to fine tune the

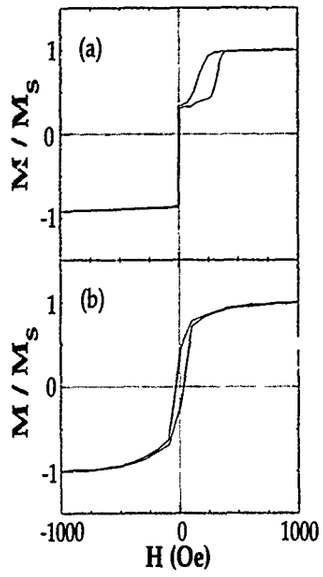

FIG. 1. Hysteresis loop for a glass/$NiFe_{250\ Å}$/$Cu_{30\ Å}$/$NiFe_{150\ Å}$/$TbCo_{380\ Å}$/$Cu_{30\ Å}$ spin valve with an exchange field of 230 Oe, (a) with the applied field along the induced in-plane easy axis, and (b) with the applied perpendicular to the easy axis.

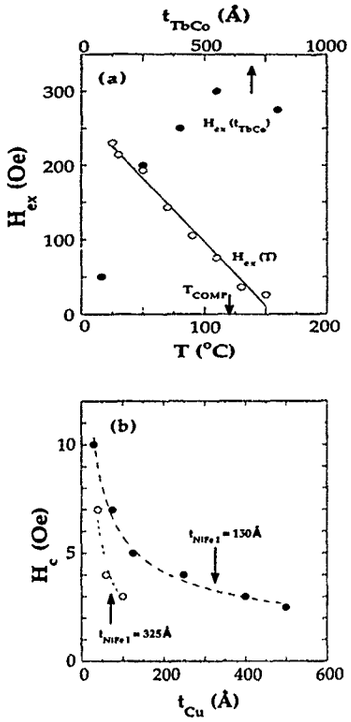

FIG. 2. (a) Exchange field dependence on the thickness of the TbCo layer for fixed NiFeII layer thickness, and exchange field dependence on temperature. (b) Dependence of the coercive field on the free Permalloy layer (NiFeI) on the Cu spacer thickness, for a TbCo exchange layer 380 Å thick. This result clearly indicates coupling across the Cu layer.

in-plane and out-of-plane magnetization components. Permalloy and Cu were dc sputtered at 3 mTorr. Room temperature resistivities for 500 Å thick Permalloy, Cu, and TbCo films are, respectively, $(27\pm2)\mu\Omega$ cm, $(5\pm2)\mu\Omega$ cm, and $(236\pm10)\mu\Omega$ cm, respectively. Transport measurements were done with a linear four-point dc method, on samples 10 mm long by 3 mm wide.

EXPERIMENTAL RESULTS AND DISCUSSION

From the four Tb_xCo_{1-x} compositions prepared only $x=0.23$ and $x=0.24$ gave exchange coupling. For $x=0.18$, we found in-plane magnetization, but with this composition the compensation temperature is already below room temperature, so that exchange no longer occurs at 300 K. For $x=0.27$, we found perpendicular anisotropy and no exchange coupling to the adjacent Permalloy layer. For $x=0.23$ and 0.24, we find dominant perpendicular anisotropy in the TbCo layer, but there is a small in-plane magnetization component that is strongly bias dependent. The compensation temperature is around 120 °C. Unidirectional in-plane anisotropy is induced in the NiFeII layer, leading to well-defined easy-direction hysteresis loops.

Figure 1 shows the hysteresis loop for a glass/$NiFe_{250\ Å}$/$Cu_{30\ Å}$/$NiFe_{150\ Å}$/$TbCo_{380\ Å}$/$Cu_{30\ Å}$ structure, with the field applied along the induced in-plane easy axis (a), or perpendicular to the easy-axis (b). The exchange field is 230 Oe, and the coercivity of the free NiFeI layer is 8 Oe.

Figure 2(a) shows the spin-valve exchange field dependence on $Tb_{0.23}Co_{0.77}$ thickness for a fixed NiFeII thickness of 150 Å, as well as the temperature dependence of the exchange field. Above TbCo thicknesses of 500 Å, H_{ex} is practically constant. A drastic decrease occurs below 200 Å, with the unidirectional anisotropy becoming too weak below 100 Å. This decrease could be associated to a reduction of the in-plane component of the magnetization, related to the initial stages of growth of the TbCo film on the Permalloy layer.[4] The exchange field decreases linearly with temperature increase, vanishing slightly above the compensation temperature ($T=120$ °C).

Figure 2(b) shows the coercive field of the free Permalloy layer (NiFeI) of the spin valve, as a function of Cu spacer thickness. The coercive field of both Permalloy layers in a glass/NiFeI/$Cu_{30\ Å}$/NiFeII structure is 1.5 Oe. When a 380 Å TbCo layer is deposited on top of the NiFeII, the coercivity of the NiFeI layer increases to 10 Oe, decreasing gradually as the Cu thickness increases, to a value of 2.5 Oe for a Cu thickness of 500 Å. This is a clear indication of coupling across the Cu layer. The coupling decreases and becomes negligible for Cu thicknesses larger than 400–500 Å.

Figure 3 shows the spin-valve hysteresis loops for different substrate bias voltages. The results were compared with hysteresis loops for a single 380 Å thick $Tb_{0.23}Co_{0.77}$ layer grown on Si, and capped by 30 Å of Cu, at the same substrate bias voltages (see the inserts). Three regimes are found. Moderate substrate bias (from 0 up to −35 V) decreases the exchange field from 250 to 100 Oe. In this bias range, strong perpendicular anisotropy is found in the TbCo layer. For bias voltages between −40 and −60 V a symmetric hysteresis cycle is observed for the spin valve. The TbCo layer has similar in-plane and perpendicular magnetization components. The symmetric hysteresis cycle occurs because

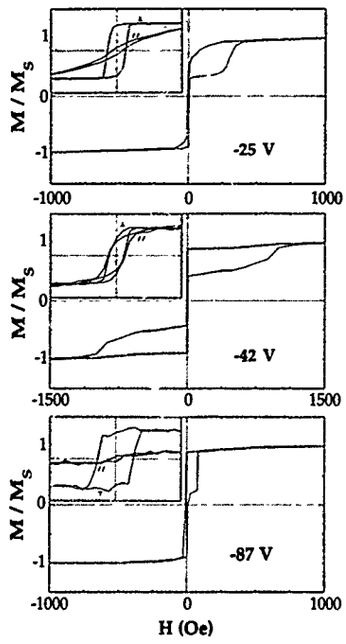

FIG. 3. Hysteresis loops for the spin valve as a function of substrate voltage bias. In the inserts we show data for a single layer TbCo film 380 Å thick on Si(data from −10 000 to 10 000 Oe). Assymetric hysteresis cycles are observed when the TbCo layer has strong perpendicular anisotropy. For a bias voltage of −42 V, a symmetric hysteresis loop is observed, corresponding to a larger in-plane magnetization component in the TbCo layer.

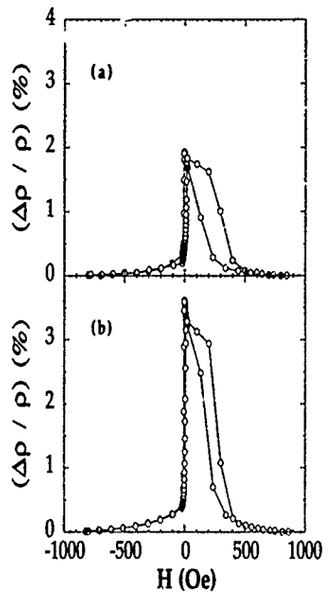

FIG. 4. Magnetoresistance signal for two spin valves: one with the conventional structure described so far (a), and another with 10 Å Co introduced at the NiFe/Cu interfaces (b).

the applied field is strong enough to reverse the TbCo in-plane magnetization component.[7] For bias greater than −60 V a small unidirectional anisotropy reappears, corresponding to a return to strong perpendicular anisotropy in the TbCo layer. A RBS analysis of samples prepared under substrate bias indicate that for a bias voltage of −180 V, the Co content has decreased by almost 5 at. %, and Ar has begun to get incorporated in the sample (up to 7 at. %).

Figure 4 shows the MR signal for two spin-valves, at room temperature, one with the structure previously described, and with a MR of 2% (a), and another where a 10 Å Co layer was introduced at the NiFe/Cu interfaces,[8] leading to a MR of 4.5% (b). This is evidence for the strong role of interface spin-dependent scattering at the Co/Cu interfaces, apart from bulk spin-dependent scattering in the NiFeI and NiFeII layers. The MR was measured with the current along the length of the sample, perpendicular to the easy axis and the applied field.

CONCLUSIONS

Spin valves have been successively prepared, where the exchange coupling layer is an amorphous ferrimagnetic $Tb_{0.23}Co_{0.77}$ alloy, 200–400 Å thick. The exchange field can be varied by almost two orders of magnitude, either by changing TbCo substrate bias, or TbCo thickness. The coercivity of the unpinned Permalloy layer is slightly degraded due to coupling across the Cu layer. The substrate bias strongly affects the exchange field and the TbCo anisotropy. MR signals up to 4.5% were observed in spin valves, where a 10 Å Co layer was introduced in between the Permalloy and the Cu layers.

Mössbauer spectroscopy with ^{151}Eu nuclei was applied to study magnetic properties of Fe/Eu multilayers as a function of the Eu layer thickness. The Mössbauer spectra at 4.2 K for [Fe(40 Å)/Eu(x Å)] with x=70, 100, and 200 consist of two magnetic components: a major component with hyperfine parameters close to those of bulk Eu metal and an additional component with a smaller hyperfine field. The latter component is attributed to Eu at the interface region. The spectrum at 4.2 K for [Fe(40 Å)/Eu(30 Å)] has only a component with a reduced hyperfine field, indicating that the Eu layers lose the bulk magnetic properties.

I. INTRODUCTION

Fe/rare-earth (RE) multilayers show a variety of magnetic properties dependent on the sort of RE metals. For example, Fe/Gd multilayers, which are composed of two ferromagnetic metals with relatively small magnetocrystalline anisotropy, exhibit characteristic spin structures on account of the antiferromagnetic coupling at the interfaces.[1–4] Perpendicular magnetic anisotropy is observed in Fe/Tb,[5–9] Fe/Dy,[6,10,11] and Fe/Nd [11–13] multilayers when the Fe and RE layer thicknesses are properly controlled. From a systematic study on the Fe spin directions for all the Fe/RE systems, perpendicular magnetic anisotropy is found also in Fe/Pr multilayers.[14] The RE layers are usually polycrystalline with no preferred orientation, and the magnetic structures often turn out to be complicated. It has been rare that information on the local magnetism in the RE layers is obtained; only a ^{161}Dy Mössbauer study on Fe/Dy multilayers is reported so far.[15] In order to study the intrinsic RE magnetism in Fe/RE multilayers, local magnetic properties should be investigated for crystallographically oriented RE layers.

In this article, magnetic properties of Fe/Eu multilayers are studied with ^{151}Eu Mössbauer measurements. Eu is divalent in the bulk metal. The bulk Eu metal is antiferromagnetic below 90 K with a helical spin structure and the magnetic anisotropy is relatively small. The crystal structure is bcc, in contrast with the other trivalent RE metals with hexagonal structures. Thus, rather simple crystallographic and magnetic structures are expected to be realized in thin Eu layers. Besides, since there is no solid solution or intermetallic compound for the Fe-Eu binary system in equilibrium states, chemically sharp interfaces are expected for Fe/Eu multilayers. Information on local Eu magnetism is obtained by Mössbauer spectroscopy with ^{151}Eu, which is one of the most convenient Mössbauer isotopes among RE elements.

II. EXPERIMENTAL

Fe/Eu multilayers were prepared by alternate deposition in ultrahigh vacuum. The films were deposited on polyimide films that were kept at −50 °C. The Fe layer thickness was fixed to be 40 Å, and the Eu layer thickness was changed from 30 to 200 Å. Two reference samples were also prepared: a Eu(3000 Å) film sandwiched with Fe(100 Å) layers to examine the magnetic properties of a sufficiently thick Eu layer, and a film with the nominal thickness of [Fe(1 Å)/Eu(4 Å)] to check the possibility of forming a nonequilibrium alloy. Since Eu is one of the most reactive RE metals, the deposition was started with an Fe layer and ended with an Fe layer and a Cu protection layer was put on top of it.

^{151}Eu Mössbauer spectra were measured with a $^{151}SmF_3$ source by a conventional absorption method. The spectra were taken at 300 K and 4.2 K with the source and absorber at the same temperature. Isomer shifts are expressed relative to the $^{151}SmF_3$ source.

III. SAMPLE CHARACTERIZATION

The structures of the prepared samples were checked with x-ray diffraction measurements. The multilayer samples show well-established artificial periodic structures. The Fe layers (40 Å) have a bcc polycrystalline structure and the Eu layers (from 30 to 3000 Å) have a bcc structure with (110) texture. Since the crystal parameters of Fe and Eu do not fit well, epitaxial growth is not expected in this system. There is no oxide peak or hydride peak in the x-ray patterns taken just after the preparation. However, peaks from EuO appear in several days. The Eu layers are oxidized gradually as the time passes. The ^{151}Eu Mössbauer spectra also change in several weeks, so that only the spectra for nonoxidized samples are treated in this article.

The x-ray diffraction patterns for the reference sample [Fe(1 Å)/Eu(4 Å)] have strong peaks from Eu(110) and Eu(220) and a diffuse peak from Fe(110). The sample appears to be composed of segregated bcc Eu grains and amorphouslike Fe grains rather than of a nonequilibrium alloy.

According to an ^{57}Fe Mössbauer study on [Fe(40 Å)/RE(30 Å)], the Fe layers have an interface ferromagnetic component with reduced hyperfine fields beside a major component from inner ferromagnetic α-Fe.[14] For the Fe/Eu system, the corresponding Fe thickness of the interface component is less than 3 Å, the smallest among all the Fe/RE systems. Chemically sharp interfaces are realized in this system on account of immiscibility between Fe and Eu.

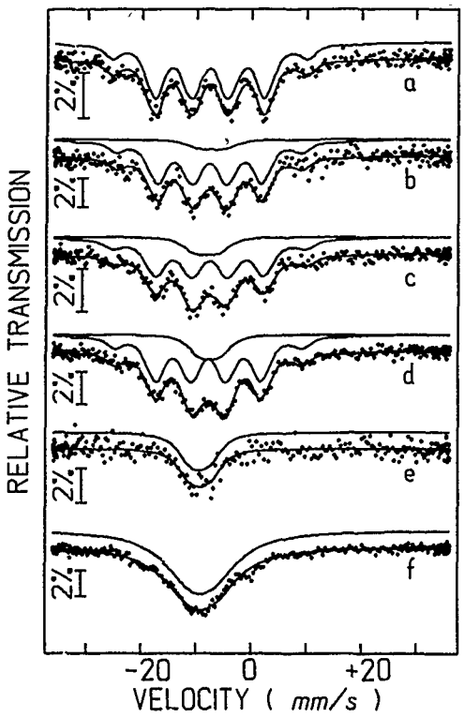

FIG. 1. ^{151}Eu Mössbauer spectra at 4.2 K for (a) Eu(3000 Å), (b) [Fe(40 Å)/Eu(200 Å)], (c) [Fe(40 Å)/Eu(100 Å)], (d) [Fe(40 Å)/Eu(70 Å)], (e) [Fe(40 Å)/Eu(30 Å)], and (f) [Fe(1 Å)/Eu(4 Å)].

IV. MÖSSBAUER RESULTS

The ^{151}Eu Mössbauer spectra of the Fe/Eu multilayers at 300 K are almost nonmagnetic. According to ^{57}Fe Mössbauer and magnetization measurements, the Fe layers are ferromagnetic at 300 K, and the Eu magnetic moments at the interface region are magnetically ordered through an exchange interaction between the interface Fe. The interface magnetic component is, however, not clearly observed in the Eu Mössbauer spectra. The time dependence of the spectra shows that the Eu layers are gradually oxidized to be EuO as the time passes.

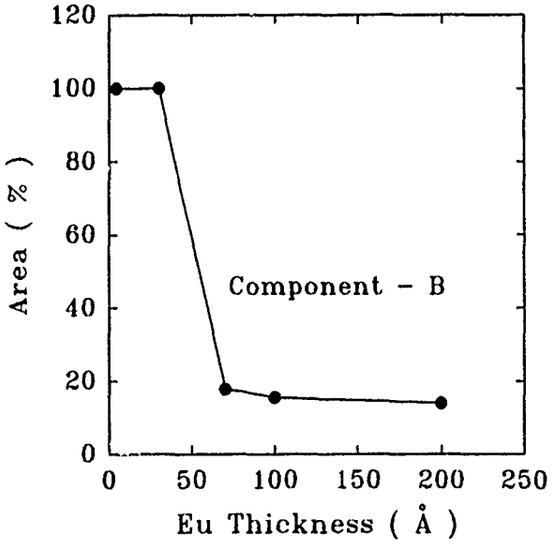

FIG. 2. Relative area of the component with a reduced hyperfine field as a function of the Eu layer thickness.

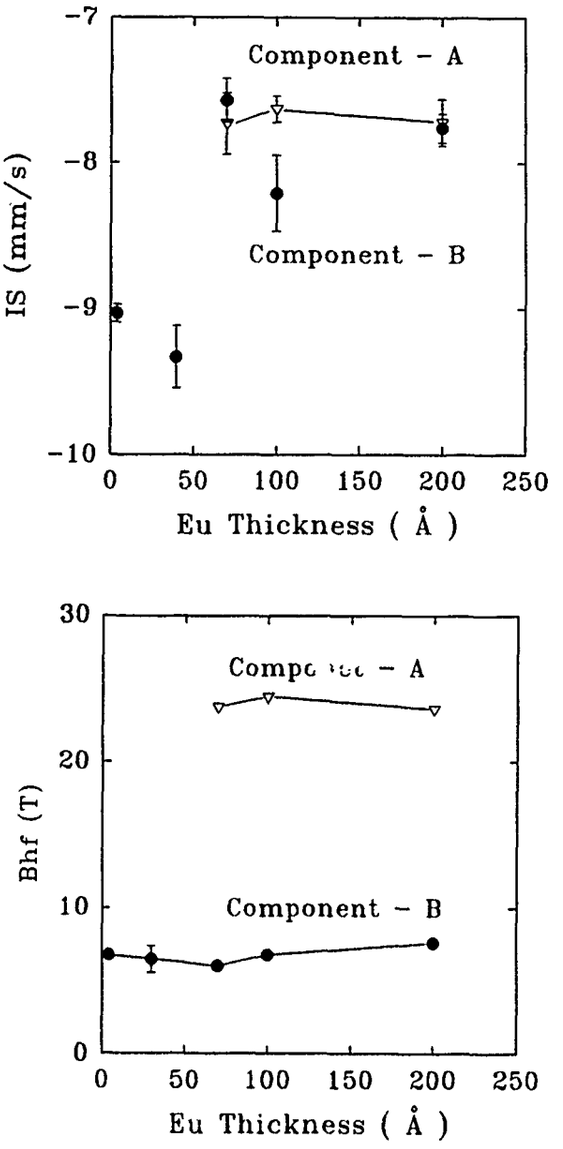

FIG. 3. (a) Isomer shifts and (b) hyperfine fields of each component of the ^{151}Eu Mössbauer spectra at 4.2 K as a function of the Eu layer thickness.

The Mössbauer spectra for all the prepared samples at 4.2 K are shown in Fig. 1. The spectrum for the Eu(3000 Å) film is fitted with a single magnetic component with the isomer shift of −7.74 mm/s and the hyperfine field of 24.8 T. The hyperfine parameters are close to the bulk values, showing that the film is composed of metallic Eu. The spectra for [Fe(40 Å)/Eu(x Å)] with x=70, 100, and 200 cannot be fitted with a single component with the bulk hyperfine parameters, but an extra component with a smaller hyperfine field coexists. The spectrum for [Fe(40 Å)/Eu(30 Å)] has only a component with a reduced hyperfine field, suggesting that the Eu layers lose the bulk properties. The spectrum for [Fe(1 Å)/Eu(4 Å)] is similar to that for [Fe(40 Å)/Eu(30 Å)]. Thus, all

the spectra are fitted with two components: component A with hyperfine parameters similar to that of bulk Eu metal, and component B with a reduced hyperfine field. The relative area of the component B as a function of the Eu layer thickness is shown in Fig. 2. The isomer shifts and hyperfine fields for each component are also shown in Figs. 3(a) and 3(b).

The magnetization curve (M-H curve) for the multilayers at each temperature is explained with superposition of a ferromagnetic curve with saturation magnetization M_s and a para(antiferro)magnetic curve with magnetic susceptibility χ: $M(H)=M_s+\chi H$. The M_s and χ are both temperature dependent. The ferromagnetic part is due to the Fe layer magnetization and antiferromagnetically coupled interface Eu magnetization. The para(antiferro)magnetic component is a contribution from the Eu magnetic moments at the inner part of the Eu layers. From the temperature dependence of χ, the Néel temperature is estimated to be about 90 K for Eu(3000 Å) and about 80 K for [Fe(40 Å)/Eu(100 Å)]. For [Fe(40 Å)/Eu(30 Å)], the magnetic transition is not observed clearly in the χ-T curve. The detail of the results on the magnetization measurements will be published elsewhere.

With the results of the magnetization measurements taken into consideration, the ^{151}Eu Mössbauer spectra of the Fe/Eu multilayers are explained as follows: the component A is attributed to the inner Eu with the magnetic properties close to the bulk properties, and the component B to the interface Eu. The corresponding Eu thickness of the interface component is estimated to be 6–14 Å per interface. As mentioned previously, the interfaces of Fe/Eu multilayers are rather chemically sharp, so that the reduction of the hyperfine field is probably due to intrinsic interface effects rather than due to a nonequilibrium alloy. The spectrum for [Fe(40 Å)/Eu(30 Å)] has only the component with a reduced hyperfine field and shows no indication of the existence of the bulk Eu component. The reduction of hyperfine fields appears not only due to the interface effect but also due to a size effect or strain effect. The hyperfine field of [Fe(1 Å)/Eu(4 Å)] may also be reduced with the same mechanism.

V. SUMMARY

Magnetic properties of Fe/Eu multilayers are studied as a function of the Eu layer thickness using ^{151}Eu Mössbauer spectroscopy for the first time. The spectra at 4.2 K for [Fe(40 Å)/Eu(x Å)] with x=70, 100, and 200 consist of two magnetic components: a component from the inner Eu with the hyperfine parameters close to bulk Eu, and a component from the interface Eu with a reduced hyperfine field. For [Fe(40 Å)/Eu(30 Å)], only a component with a reduced hyperfine field exists. The Eu layers appear to lose the bulk magnetic properties. A thin-film effect such as a size effect and strain effect is thought to affect the magnetic properties of the Eu layers.

Phase transitions in coupled double-layer systems

Xiao Hu and Yoshiyuki Kawazoe
Institute for Materials Research, Tohoku University, 2-1-1 Katahira, Aoba-ku, Sendai 980, Japan

Magnetic systems consisting of a capping layer with uniaxial anisotropy and a recording layer with vertical anisotropy are studied by means of a variational method for a continuum model covering the exchange, anisotropy, and Zeeman energies. The phase transitions between different alignments of magnetization are observed when the thickness of the capping layer and/or the temperature is varied. For the capping layer with in-plane anisotropy, the phase transitions are in second order and the critical behaviors are characterized by a critical exponent $\frac{1}{2}$. For the capping layer with vertical anisotropy, the phase transitions are in first order. The analytic expressions of the critical points are presented, in terms of the relevant magnetic constants.

I. INTRODUCTION

Magnetic multilayer systems have attracted much attention recently from both fundamental and practical points of view. The magnetic double-layer systems studied in this work consist of a capping layer of uniaxial anisotropy, layer 1, and a recording layer of vertical anisotropy, layer 2, with a geometric structure shown in Fig. 1.[1,2] The capping layer is of in-plane anisotropy in system I and of vertical anisotropy in system II. We set the z axis vertically to the layers and the origin at the interface. The direction of magnetization φ is measured from the negative direction of the z axis while an external field H_{ext} applied along the z axis is chosen to be positive. The thickness of the capping layer is denoted by a and the thickness of the recording layer is taken to be infinity as a sufficient approximation.[1]

The total magnetic energy per unit area for system I is expressed as

$$\gamma=\int_0^a\left[A_1\left(\frac{d\varphi}{dz}\right)^2+K_1\cos^2\varphi+M_{s1}H_{ext}\cos\varphi\right]dz$$

$$+\int_{-\infty}^0\left[A_2\left(\frac{d\varphi}{dz}\right)^2+K_2\sin^2\varphi+M_{s2}H_{ext}\cos\varphi\right]dz. \quad (1)$$

Typical magnetic constants at room temperature are $A_1=1.0\times10^{-7}$ erg/cm, $K_1=0.25\times10^6$ erg/cm^3, and $M_{s1}=200$ emu/cm^3 for the capping layer, while $A_2=2.0\times10^{-7}$ erg/cm, $K_2=2.0\times10^6$ erg/cm^3, and $M_{s2}=90$ emu/cm^3 for the recording layer. The exchange coupling between the two layers is supposed to be ferromagnetic and is taken into account imposing that the direction of magnetization should be continuous at the interface.[1,3]

II. SYSTEM I: CAPPING LAYER OF IN-PLANE ANISOTROPY

For the sake of simplicity, let us consider the case of null external field. The equation for the direction of magnetization at the top surface, φ_a, is derived by a variational method on energy (1) as

$$\frac{\mathrm{sn}[a\sqrt{K_1/A_1},\sin\varphi_a]}{\mathrm{cn}[a\sqrt{K_1/A_1},\sin\varphi_a]}\cos\varphi_a=\sqrt{\frac{A_2K_2}{A_1K_1}} \quad (2)$$

with Jacobian elliptic functions.[1] The total configuration of magnetization is expressed in terms of φ_a.

The left-hand side of the above equation is finite and decreases continuously with φ_a while increases uniformly with a. Therefore, for a value of $\sqrt{A_2K_2/A_1K_1}$, there exists a critical thickness below which $\varphi_a=0$ and thus $\varphi(z)=0$ in the whole system, in spite of the fact that the magnetization is directed against the easy axis in the capping layer. A phase transition from the above trivial configuration to one with nonzero $\varphi(z)$, which is determined by Eq. (2), occurs at this critical thickness. Since the left-hand side of Eq. (2) assumes its maximum at $\varphi_a=0$, the phase transition is in second order and the critical thickness is derived from Eq. (2) (Ref. 1):

$$a_{\min}=\sqrt{\frac{A_1}{K_1}}\tan^{-1}\sqrt{\frac{A_2K_2}{A_1K_1}}. \quad (3)$$

It is easy to see that this critical point coincides with the minimal thickness of the capping layer that exhibits the *capping effect* in magnetic double-layer systems.[1,4] The critical behavior for φ_a is derived analytically as[1,5]

$$\varphi_a\simeq\tilde{\varphi}_a\times\sqrt{a/a_{\min}-1},\quad a\geq a_{\min}, \quad (4)$$

and is shown in Fig. 2(a).[6]

A phase transition between different alignments of magnetization is also observed in a system with fixed thickness when the temperature is varied.[2] This phenomenon can be understood from the above arguments, noting that a value of thickness larger than the critical value in Eq. (3) in a low-temperature region becomes less than that in a high-temperature region. The critical behavior is[2,5]

$$\varphi_a\simeq\hat{\varphi}_a\times\sqrt{T_c/T-1},\quad T\leq T_c, \quad (5)$$

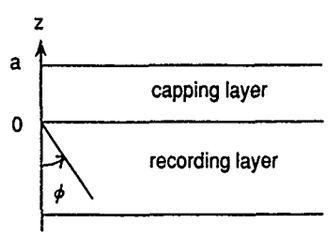

FIG. 1. Geometric structure of the double-layer system studied in the present work.

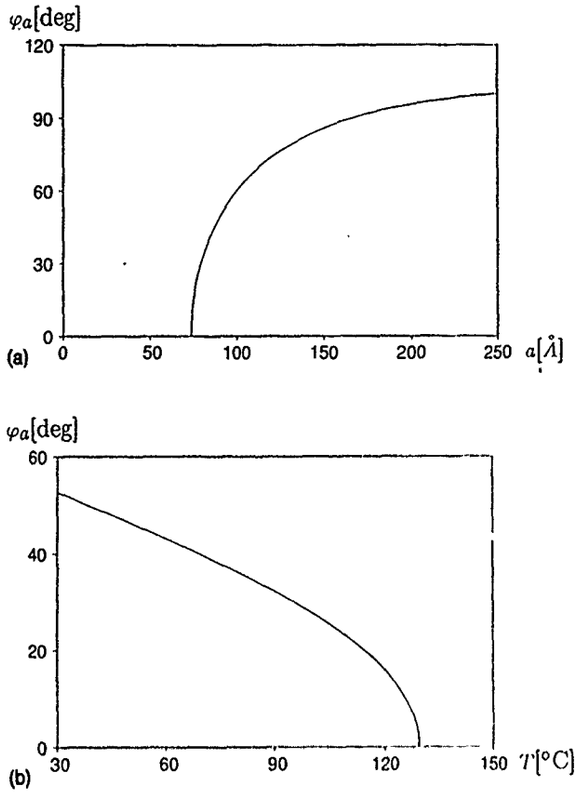

FIG. 2. (a) Thickness a dependence of the direction of magnetization at the top surface for system I. (b) Same as (a) except for temperature dependence.

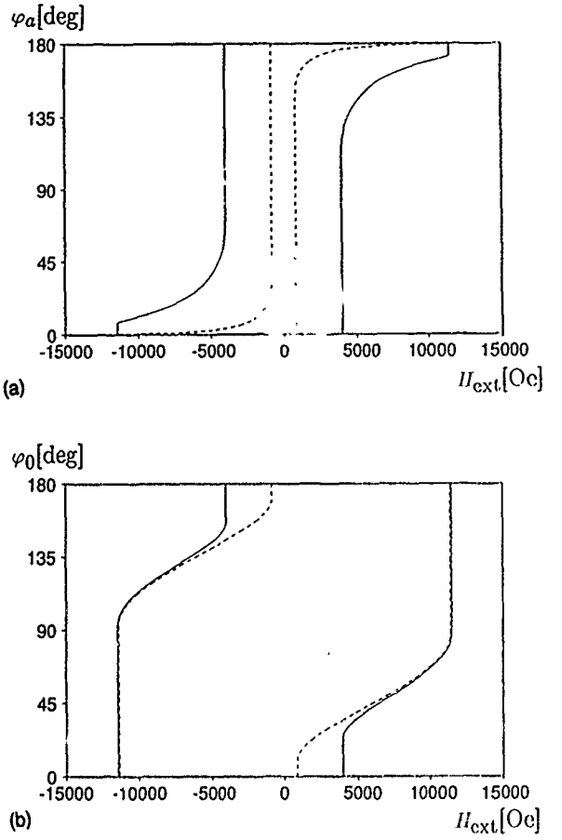

FIG. 3. (a) Hysteresis loop (solid line: $a=100$ Å; dashed line: $a=200$ Å) of the direction of magnetization at the top surface for system II. (b) Same as (a) except for at the interface.

and is shown in Fig. 2(b) with $T_c \simeq 130$ °C.[7] The critical temperature is also determined by Eq. (3) provided that a_{min} is replaced by the capping film thickness of the system under study and that the temperature dependences of the relevant magnetic constants are involved.

It is worthy to point out that the phase transition according to variance of the temperature could be used as a new device for magneto-optical recording where a laser pulse adjusts the temperature.[2]

The mechanism of phase transitions under a finite external field is the same with that for null field and the critical thickness is given by[1]

$$a_{min}=\sqrt{\frac{A_1}{K_1+M_{s1}H_{ext}/2}}\tan^{-1}\sqrt{\frac{A_2(K_2-M_{s2}H_{ext}/2)}{A_1(K_1+M_{s1}H_{ext}/2)}}. \quad (6)$$

III. SYSTEM II: CAPPING LAYER OF VERTICAL ANISOTROPY

For system II, $\cos\varphi$ in Eq. (1) is replaced by $\sin\varphi$ and a finite external field is necessary in order to observe phase transitions. For comparison, the same magnetic constants are used for numerical calculations in what follows except for that $M_{s1}=150$ emu/cm^3 is adopted since a larger magnetization will cause the easy axis to be in-plane from the geometrical effect.

For system II, Eq. (2) is replaced by

$$\frac{\mathrm{sn}[\hat{a},k]\,\mathrm{dn}[\hat{a},k]}{\mathrm{cn}[\hat{a},k]}\times\sqrt{\frac{-2\cos\varphi_a+M_{s1}H_{ext}/K_1}{2-(1+\tan^2(\varphi_a/2)\mathrm{cn}^2[\hat{a},k])M_{s2}H_{ext}/K_2}}=\sqrt{\frac{A_2K_2}{A_1K_1}} \quad (7)$$

with

$$\hat{a}=a\sqrt{K_1/A_1}\sqrt{-\cos\varphi_a+M_{s1}H_{ext}/2K_1}$$

and

$$k^2=\frac{\sin^2(\varphi_a/2)(1-\cos\varphi_a+M_{s1}H_{ext}/K_1)}{(-2\cos\varphi_a+M_{s1}H_{ext}/K_1)}.$$

Hysteresis loops for system II are shown in Figs. 3(a) and 3(b). There are two vertical parts in each branch of the hysteresis loops. The ones for the weak fields correspond to magnetization reversals in the capping layer, while those for the strong fields are associated with the complete magnetization reversals in the whole system. The phase transitions discussed in the present section are related to the formers.

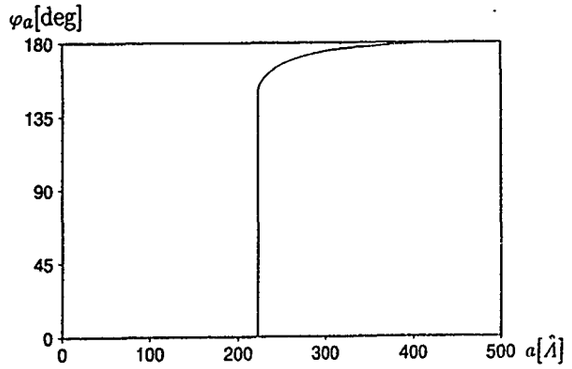

FIG. 4. Thickness a dependence of the direction of magnetization at the top surface for system II.

The phase transition between the trivial configuration $\varphi(z)=0$ and a configuration characterized by a nonzero φ_a, according to variance of the thickness a, is in first order as shown in Fig. 4. The dependence of the critical thickness on the external field is displayed in Fig. 5. We have found that the present numerical results fit satisfactorily to the following logarithmic function:

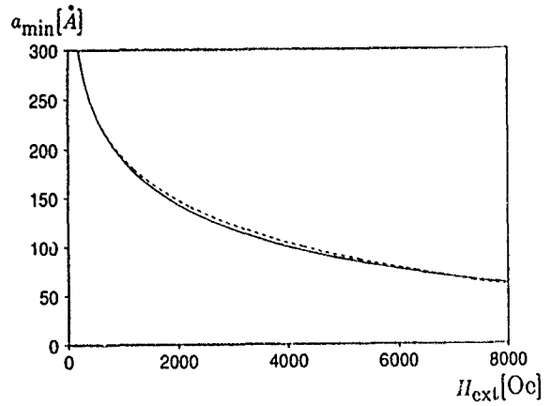

FIG. 5. Dependence of the critical thickness on the external field for system II [solid line: numerical results according to Eq. (7); dashed line: curve of Eq. (8)].

$$a_{min} \simeq \sqrt{\frac{A_1}{K_1}} \times \ln \frac{H_0}{H_{ext}} \tag{8}$$

with $H_0 \simeq 20$ kOe. The divergence of a_{min} at null external field and the slow drop with the external field show sharp contrasts with the behavior of Eq. (6).

A similar first-order phase transition can be observed in system II when the temperature is varied, provided that temperature dependences of the saturation magnetizations are given.

IV. SUMMARY

To summarize, we have studied double-layer systems with different anisotropies. Phase transitions between different magnetization configurations have been observed and the responsible mechanism is revealed. The critical point a_{min} corresponds to the minimal thickness of the capping layer, which achieves better field sensitivity compared with that of single-magnetic-layer recording. The present study will shed light on the design of multilayer recording media.

Critical phenomena of a φ^4 model for paraferromagnetic phase transition in a system consisting of a thin layer and a semi-infinite bulk has also been studied by mean-field theory, and the renormalization group theory is used to investigate the effect of thermal fluctuations.[5]

[5] X. Hu and Y. Kawazoe (unpublished).

[6] H. Wakabayashi, H. Notarys, and T. Suzuki, J. Magn. Soc. Jpn. **15**, Suppl. S1, 87 (1991). The authors studied a similar system by a numerical approach for a discrete model. A good agreement with an experiment was achieved for the critical thickness. Unfortunately, the dependence of the critical thickness on the relevant magnetic constants as that in Eq. (3) has not been revealed. No detailed discussion about the critical exponent was given, and their value of the critical exponent seems to be unit, different from the present one in Eq. (4).

[7] Although sin decays and linear ones of stiffness constants A's and anisotropy constants K's, respectively, as the temperature is increased from room temperature towards the critical points ($T_{c1}=180$ °C and $T_{c2}=270$ °C), have been assumed in order to derive numerical results shown in Fig. 2(b), we notice that these assumptions do not affect the critical behaviors.

Comparison of the electron-spin-resonance linewidth in multilayered CuMn spin glasses with insulating versus conducting interlayers

D. L. Leslie-Pelecky, F. VanWijland, C. N. Hoff, and J. A. Cowen
Department of Physics and Astronomy and Center for Fundamental Materials Research, Michigan State University, East Lansing, Michigan 48824-1116

A. Gavrin[a] and C.-L. Chien
Department of Physics and Astronomy, The Johns Hopkins University, Baltimore, Maryland 21218

The temperature-dependent electron-spin-resonance linewidth $\Delta H(T)$ may be used to investigate the effect of the geometry and interlayer material on the magnetic properties of multilayered systems. We compare $\Delta H(T)$ in CuMn/Al_2O_3 multilayers with previous measurements of CuMn/Cu samples. CuMn/Al_2O_3 samples with CuMn thicknesses, W_{SG}, from 40 Å to 20 000 Å obey the same form as the CuMn/Cu system, but show quantitative differences in the fitting parameters. The linewidths of the CuMn/Al_2O_3 samples, even in the bulk, are systematically larger than the linewidths for the CuMn/Cu samples, suggesting that the ESR linewidth is sensitive to differences in sample growth and structure. The value of the minimum linewidth decreases with decreasing W_{SG} in the CuMn/Al_2O_3 series, but remains constant in the CuMn/Cu series. Although susceptibility measurements of the freezing temperature T_f do not differentiate between samples with $W_{SG} \geq 5000$ Å, the ESR linewidth is sensitive to changes at larger length scales. This experiment emphasizes the importance of considering both the total sample thickness, as defined by the range of the conduction electrons, and the spin-glass layer thickness in analyzing the ESR linewidth in multilayers.

INTRODUCTION

Finite-size and dimensionality effects in multilayered spin glasses have been shown to depend on the interlayer material, especially when the spin-glass layer thickness W_{SG} becomes small.[1-3] We have previously demonstrated that the temperature-dependent electron-spin-resonance linewidth in multilayered CuMn/Cu systems[4,5] provides detailed information about spin relaxation rates. In this article, we compare the temperature dependence of the electron-spin-resonance linewidth $\Delta H(T)$ in $Cu_{0.92}Mn_{0.08}/Al_2O_3$ multilayers with previous measurements of the $Cu_{0.93}Mn_{0.07}$/Cu system.

DATA AND ANALYSIS

$Cu_{0.92}Mn_{0.08}/Al_2O_3$ samples, with 40 Å$\leq W_{SG} \leq$20 000 Å, were fabricated at the Johns Hopkins University using dc and rf sputtering. $Cu_{0.93}Mn_{0.07}$/Cu samples were fabricated by dc sputtering at Michigan State University. In both cases, the interlayer thicknesses are held constant at values large enough (75 Å for Al_2O_3 and 300 Å for Cu) to prevent coupling between the CuMn layers.

The depression of the spin-glass freezing temperature, T_f, with decreasing W_{SG} is described in terms of ϵ, with

$$\epsilon = \left(\frac{T_f(\infty) - T_f(W_{SG})}{T_f(\infty)} \right). \quad (1)$$

$T_f(\infty)$ is the freezing temperature of the bulk. Finite-size scaling predicts[6] $\epsilon \propto W_{SG}^{-1/\nu}$. A crossover from three-dimensional (3D) to two-dimensional (2D) behavior has been demonstrated by frequency dependent[7] and nonlinear susceptibility measurements.[3,8] Figure 1 compares the depression of $T_f(W_{SG})/T_f(\infty) = 1-\epsilon$ for insulating and conducting interlayers. Solid lines show fits to Eq. (1) with $\nu = 1.3$ for CuMn/Cu samples[4] and $\nu = 1.6$ for CuMn/Al_2O_3 samples.[3] The depression of T_f in CuMn/Al_2O_3 multilayers is similar to that observed in CuMn/Si.[9]

Above T_f, $\Delta H(T)$ in spin glasses is described by a superposition of two behaviors—a linear temperature dependence and a critical divergence as T_f is approached.

$$\Delta H(T) = A + BT + C\left(\frac{T - T_f}{T_f} \right)^{-\kappa}. \quad (2)$$

In Eq. (2), A is the residual linewidth, B the thermal broadening coefficient, C the divergence strength, and κ a critical exponent. The $A+BT$ behavior reflects the relative magnitudes of relaxation rates between the localized moments, conduction electrons, and lattice.[10,11] In particular, the thermal broadening coefficient B can be modeled to include ef-

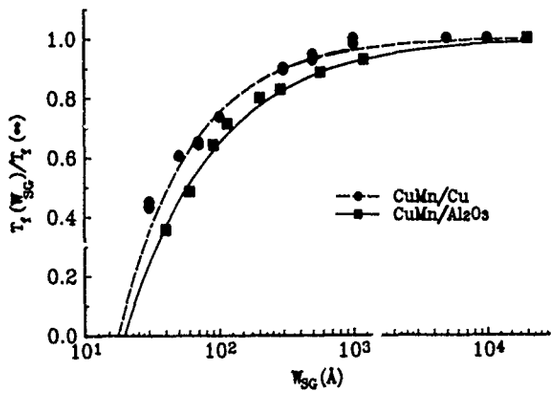

FIG. 1. The depression of the freezing temperature, $T_f(W_{SG})$, normalized to the bulk value, $T_f(\infty)$ as a function of $\log_{10}(W_{SG})$ for CuMn/Al_2O_3 (triangles) and CuMn/Cu (circles). Solid lines are fits to finite-size scaling.

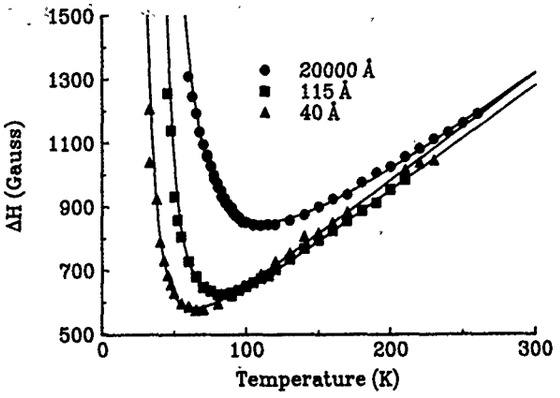

FIG. 2. Dependence of the ESR linewidth in $CuMn/Al_2O_3$ on temperature for CuMn layer thicknesses of 20 000 Å (circles), 115 Å (squares), and 40 Å (triangles). Solid lines represent fits to Eq. (2).

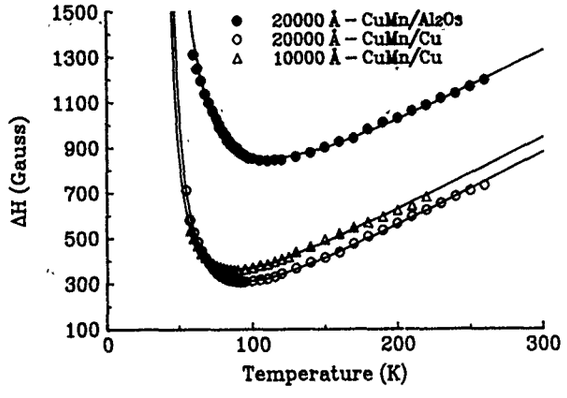

FIG. 3. Comparison of the ESR linewidth as a function of temperature for the 20 000-Å film from the $CuMn/Al_2O_3$ series (solid circles), and 20 000-Å (open circles) and 10 000-Å (open triangles) films from the CuMn/Cu series. Solid lines are fits to Eq. (2).

fects due to interfaces and surfaces.[4] The linewidth diverges as T_f is approached, with $\kappa \approx 1.5$ in the bulk.[5]

Previous measurements[4,5] of $\Delta H(T)$ in the CuMn/Cu system shows that the behavior described by Eq. (2) is obeyed for 10 Å$\leq W_{SG} \leq$10 000 Å, with systematic changes in the parameters as a function of W_{SG}. Samples with W_{SG}<about 50 Å fit preferentially to a two-dimensional form ($T_f \rightarrow 0$) of Eq. (2). The data may be parametrized[4] in terms of ϵ, with both A and B increasing linearly with ϵ. The crossover of the critical behavior from the 3D to 2D limit can be described by a continuous function of ϵ. The detailed information obtained from this study indicates that ESR is useful for studying the dependence of $\Delta H(T)$ on interlayer material.

Figure 2 shows $\Delta H(T)$ for a 20 000-Å CuMn film, and multilayered $CuMn/Al_2O_3$ samples with W_{SG}=115 Å and 40 Å. The solid lines represent fits to Eq. (2), with the fitting parameters shown in Table I. The sample with W_{SG}=40 Å fits preferentially to the T_f=0 form, with the exponent from this fit shown in parenthesis in Table I.[12]

With the exception of the residual linewidth A, which remains approximately constant, all parameters obey the same general trends with decreasing W_{SG} as those from the CuMn/Cu series. The magnitudes of the thermal broadening coefficients B are comparable to those observed in the CuMn/Cu samples. The values of κ, while comparable in the bulk, are larger in the $CuMn/Al_2O_3$ multilayers, as are the divergence strengths. Extension of these measurements to a greater range of W_{SG} is necessary to determine if the parameters follow the same dependence on ϵ as CuMn/Cu.[13]

Distinct differences between the two sets of samples are observed. Figure 3 compares the temperature dependence of $\Delta H(T)$ for 20 000-Å films from the CuMn/Cu (Ref. 14) and the $CuMn/Al_2O_3$ series. The values of the parameters from fitting the CuMn/Cu sample to Eq. (1) are also shown in Table I. The linewidths for the $CuMn/Al_2O_3$ series are approximately 500-G larger than those of the corresponding CuMn/Cu data. The magnitude of the difference in the linewidths cannot be explained by the concentration difference, which is less than 1 at. %. Table I shows that the thermal broadening coefficients and values of κ are the same for both 20 000-Å samples, but that the residual linewidths and divergence strengths are different. Comparison of sample-growth parameters indicates no obvious differences that might explain these results.

The second significant difference between Al_2O_3 and Cu interlayers is that the $CuMn/Al_2O_3$ series shows a decrease in the magnitude of the minimum linewidth with decreasing W_{SG}. The minimum linewidth of the CuMn/Cu series was approximately constant for all W_{SG}.[4,5] In the CuMn/Cu system, scattering from CuMn/Cu boundaries is negligible compared to CuMn/air boundaries and we expect surface effects due to the total sample thickness to dominate. In samples with insulating interlayers, the electrons are restricted to the CuMn layers and W_{SG} should be the dominant length. The constant values of the minimum linewidth in the CuMn/Cu series may be the result of all samples having approximately the same total thickness. This illustrates the need to consider both the total sample thickness and the spin-glass layer thickness, as the type of interlayer material will determine which length scale is dominant. Detailed conclusions are prohibited by the complicated dependence of the value of the minimum linewidth on the parameters of Eq. (2).

The dependence of $\Delta H(T)$ on the total sample thickness was studied by Nagashima and Abe[15] in $Cu_{1-x}Mn_x$ (x=0.01

TABLE I. Parameters obtained by fitting to Eq. (1).

W_{SG} (Å)	T_f (K)	A (G)	B (G/K)	C (G)	κ
		$Cu_{0.92}Mn_{0.08}/Al_2O_3$			
20 000	35	296	3.31	561	1.4
115	25	285	3.32	594	2.6
40	12.5	306	3.38	3601	2.9 (3.8)[a]
		$Cu_{0.93}Mn_{0.07}/Cu$			
20 000	37	−133	3.31	241	1.40
10 000	37	−43	3.23	184	1.35

[a]The value in parenthesis for the 40-Å sample represents the exponent obtained by fitting to the 2D (T_f=0) form of Eq. (1). In this fit, the values of A and B remain the same and the prefactor of the divergence does not correspond directly to C. See Ref. 4 for details and the CuMn/Cu data.

and 0.055 at. %) films of thicknesses from 1000 Å to 50 000 Å. They found an increase in both the minimum value of the linewidth and in A, the residual linewidth, with decreasing W_{SG}. This is attributed to the increased importance of surface scattering relative to bulk scattering as the film thickness decreases. Nagashima and Abe did not investigate the divergence of the linewidth, so extracting reliable values for A and B for comparison to the present data is difficult.

The open triangles in Fig. 3 represent $\Delta H(T)$ for a 10 000-Å CuMn film from the CuMn/Cu series and are consistent with the behavior observed by Nagashima and Abe. Parameters from fitting to Eq. (2) are included in Table I. The values of κ are comparable for the two films, but the divergence strengths C are different. A detailed study of the dependence of these parameters on film thickness is required to determine the origin of these variances, whether the behavior is due to finite size or surface effects, and if the approach to the freezing transition is affected even on this larger length scale.

CONCLUSION

We have reported measurements of the ESR linewidth as a function of temperature in multilayered $Cu_{0.92}Mn_{0.08}/Al_2O_3$ samples with 20 000 Å$\geq W_{SG} \geq$40 Å. We find that these data are qualitatively consistent with measurements from CuMn/Cu multilayers, but quantitatively differ. Differences between the magnitudes of the linewidths in samples fabricated at different locations suggest that this technique is sensitive to details of sample fabrication, which may include homogeneity, structure, and purity. The comparison of insulating versus conducting interlayers emphasizes the presence of two significant length scales—the total sample thickness as determined by the range of the conduction electrons and the spin-glass layer thickness. Our preliminary examination of CuMn films confirms that the electron-spin-resonance linewidth is sensitive to changes in the total thickness in samples showing no depression in T_f. We believe that study of these parameters as a function of interlayer material can provide a convenient framework within which to understand the importance of the different length scales.

Although interpretation of the temperature-dependent ESR linewidth is complicated, this technique has the potential to provide detailed information on relaxation processes not available from other types of measurements. Further effort must be given to extending the theory of electron-spin resonance in multilayered structures to fully utilize this technique.

[12] For the $T=0$ fit, the values of A and B are unchanged and the prefactor for the divergence is not directly comparable with C.
[13] A. Gavrin (unpublished). The values of κ in the $CuMn/Al_2O_3$ increase faster with W_{SG} than the corresponding CuMn/Cu samples. One explanation may be that the Al_2O_3 interlayered samples approach 2D behavior at larger values of W_{SG} than CuMn/Cu samples.
[14] A minor difference between the samples is that the film from the CuMn/Cu series shown in Fig. 3 is capped with 100 Å of Cu on the top and bottom of the film to protect the sample from oxidation and diffusion of silicon from the substrate. Measurements of films without the protective layer show linewidths that are slightly *lower* than in the sample with the protective layers.

The magnetic anisotropy of Co/Cu(111) thin films has been investigated using the ferromagnetic resonance (FMR) technique. The films were prepared by molecular-beam epitaxy in ultrahigh vacuum on sapphire substrates with niobium as a buffer layer. *In situ* RHEED investigations, *ex situ* x-ray low-angle reflectivity measurements, and high-angle Bragg scans confirm the structural quality of the films. Angular dependent FMR measurements are performed in the plane of the films and out-of-plane. The angular dependence of the line positions in-plane shows a competition between the sixfold anisotropy, which is expected for bulk Co, and a twofold anisotropy contribution. It is demonstrated that by FMR one can detect even small values of the higher-order anisotropy terms. In the analysis, we put emphasis on the relationship between magnetic and structural properties.

INTRODUCTION

Two of the main fields of interest in magnetic thin films are their exchange and anisotropy properties. Both are related to the growth process and the structure and, additionally, often connected with each other in the experimental study.[1,2] In Co/Cu(111), the investigation of the oscillatory exchange of the Co layers via the Cu interlayer has posed problems and has not been unambiguously clarified for some time. Quite recently, the second regime of the antiferromagnetic coupling in molecular-beam-epitaxy-grown samples at $t_{Cu}^{AF}(2)\approx 19$ Å [the first regime being at $t_{Cu}^{AF}(1)\approx 9$ Å (Ref. 3)] has been found,[4,5] in agreement with theoretical predictions.[6]

It has been argued[6] that the exchange coupling in Co/Cu(111) is much more sensitive to strain and roughness effects than in Co/Cu(001), because in the (111) system the electrons that are responsible for the coupling are not propagating parallel to the interface normal. Local thinning of the Cu layers or pinholes were suggested to have a significant influence in samples grown by molecular-beam epitaxy (MBE).

A recent scanning tunneling microscopy (STM) study has shown that in fact the growth of Co on Cu(111) to some degree exhibits an island structure,[7] an observation that explains part of the Co/Cu(111) controversy in the last few years.

In view of these peculiarities of the Co/Cu(111) system, we have studied the in-plane and out-of-plane anisotropy by FMR in connection with investigations of the structural parameters.

SAMPLE PREPARATION AND EXPERIMENT

A detailed description of the sample preparation can be found in recent publications.[8,9] Onto the $Al_2O_3(11\bar{2}0)$ substrates we have grown by MBE a Nb(110) buffer layer (≈100 Å), followed by Cu(111) of about 30 Å. Co was then grown with thicknesses t_{Co} ranging from 14 to 180 Å. All samples were covered by a Cu layer (≈30 Å).

The growth was observed by RHEED. *Ex situ*, the samples were investigated by x-ray low-angle reflectivity measurements and high-angle Bragg scans, confirming the high structural quality. The values for the mosaicity are smaller than 0.1°. The interface roughness is of the order of 10 Å as determined from x-ray low-angle scans. Remarks on the interpretation of roughness data and correlation lengths from x-ray measurements can be found in (Ref. 9).

Figure 1 shows an x-ray low-angle reflectivity and high-angle Bragg scan for the film with $t_{Co}=85$ Å. The oscillations in the second half of the low-angle scan and those around 38.6° in the Bragg scan are due to the Nb buffer. In the fit of the low-angle reflectivity measurement, a partly oxidized Cu layer on top has been taken into account.

The FMR experiments were carried out at room temperature at X-band frequencies. The angular dependence of the spectra was measured in two configurations: (i) external field rotated in the plane of the sample and (ii) external field rotated to the film normal, starting in-plane from an easy direction.

To describe the angular dependence, we use a model that

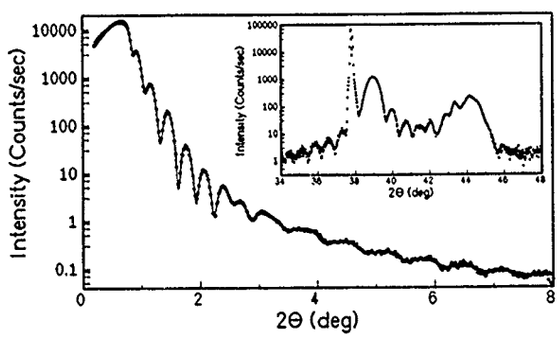

FIG. 1. X-ray low-angle reflectivity and high-angle Bragg scan (inset) of the film with $t_{Co}=85$ Å. In the Bragg scan, the peak at 37.75° is due to the sapphire substrate. About four oscillations from Nb can be seen at each side of its main peak at 38.6°. The feature around 44° including its substructure is due to Co and Cu.

 0021-8979/94/75(10)/6492/3/$6.00 © 1994 American Institute of Physics

takes into account in the expression for the total free energy density F_{tot}, the Zeeman energy $(-\mathbf{H}\cdot\mathbf{M})$, the demagnetizing energy $(-2\pi M^2 \sin^2\Theta)$, and anisotropy terms of the form

$$F_{ani}=K_1 \sin^2\Theta+K_2 \sin^4\Theta + [K_3+K_4 \cos(6\Phi)]\sin^6\Theta - K_u \sin^2\Theta \cos^2(\Phi-\Phi_u), \quad (1)$$

which is appropriate for fcc(111)- and hcp(0001)-oriented films. The term K_u allows for an additional uniaxial anisotropy. Θ is measured with respect to the film normal, and Φ is the in-plane angle of the magnetization. Using standard FMR theory for the resonance condition[10] yields for the case of the external field in the film plane

$$\left(\frac{\omega}{\gamma}\right)^2=[H\cos(\Phi-\phi)+A-6H_{A4}\cos(6\Phi) +2H_{Au}\cos^2(\Phi-\Phi_u)]\times\{H\cos(\Phi-\phi) -36H_{A4}\cos(6\Phi)+2H_{Au}\cos[2(\Phi-\Phi_u)]\}. \quad (2)$$

$\gamma=g\mu_B/\hbar$ is the gyromagnetic ratio, H the external magnetic field, ϕ the in-plane external field angle, $A=4\pi M-2H_{A1}-4H_{A2}-6H_{A3}$, and $H_{Ai}=K_i/M$. As the angular derivatives of F_{tot} determine the resonance condition,[10] the higher-order anisotropy term H_{A4} enters with a higher factor and therefore FMR can detect even a small sixfold in-plane anisotropy contribution.

RESULTS AND DISCUSSION

The in-plane FMR measurements show a competition between a sixfold and a uniaxial anisotropy contribution. The thicker samples are dominated by the sixfold rather than the uniaxial anisotropy and vice versa (see Fig. 2).

The origin of the *uniaxial* anisotropy H_{Au} that dominates in the thin samples may be explained by the evaporation process and the growth. As mentioned above, the bcc Nb buffer layer grows with its (110) plane on $Al_2O_3(11\bar{2}0)$. The (110) plane of Nb, i.e., a crystallographic plane with twofold symmetry, may be responsible for the induced twofold anisotropy of the Co layer. During the growth of the Cu layer, in the RHEED pattern the streaks characteristic for the (110) plane of Nb have been observed—in coexistence with the Cu(111) streaks. Furthermore, even after finishing the growth of the Cu layer, we could still detect considerable Auger signals from Nb. Therefore, we believe that it is possible that a small amount of Nb (probably only about one monolayer) is located upon the Cu layer, which may also contribute to H_{Au}. The rapid decrease of H_{Au} with increasing t_{Co} supports the assertion that the uniaxial anisotropy is an interface effect.

As it reflects the crystallographic symmetry, i.e., the atomic environment in the closest packed planes [fcc (111)], the *sixfold* anisotropy H_{A4} might be expected to have the same magnitude in all films, but the experiments show that H_{A4} is smaller in the thin films. As the dependence on t_{Co} is less pronounced than in the case of the uniaxial anisotropy, it is reasonable to assume that the intrinsic properties of Co on Cu(111) rather than real interface effects play an important role. As pointed out by de la Figuera *et al.*,[7] the Co layer on Cu(111) is formed by islands that do not exhibit a perfect coalescence up to seven monolayers. One can expect the sixfold anisotropy to be very sensitive to possible small in-plane crystallographic misorientations of these islands.

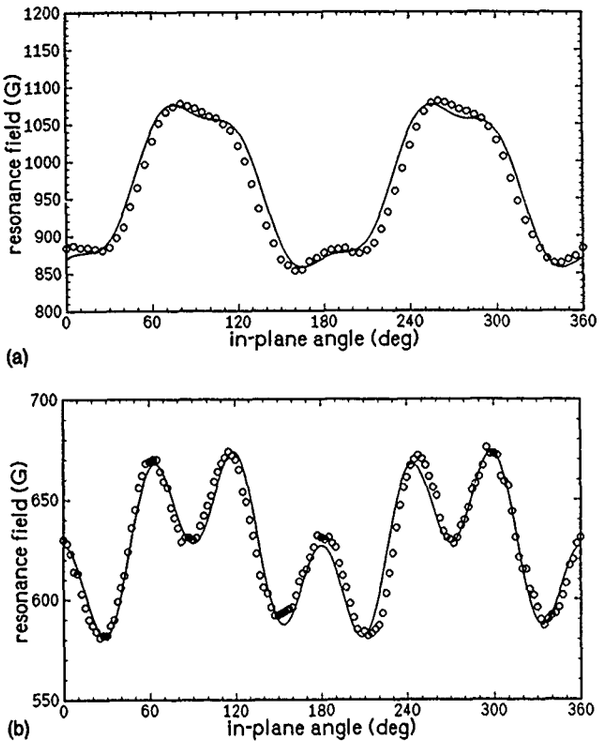

FIG. 2. In-plane angular dependence of the FMR line position for two samples. The starting angle is arbitrary. Part (a) corresponds to t_{Co}=14 Å. This film is dominated by the twofold anisotropy, but the sixfold contribution is already visible, as it causes changes at the extrema of the twofold anisotropy. The film with t_{Co}=85 Å (b) exhibits a stronger sixfold contribution. H_{A4} can be estimated from the difference between the maximum and the minimum of the line positions divided by 72 (see in-plane resonance condition).

From the angle-dependent FMR measurements with the external field rotated with respect to the film normal we can get information on the out-of-plane anisotropy. As the K_1 term has the same angular dependence as the demagnetization energy, we can only determine the quantity $4\pi M_{eff}=4\pi M-2K_1/M$. In this definition, K_1 also contains the surface anisotropy contribution $2K_S/t_{Co}$. The resonance field at $\Theta=0°$ depends on $4\pi M_{eff}$ (and K_u), but not on the higher-order terms (see e.g., Ref. 11), so we can determine $4\pi M_{eff}$ directly, assuming the value of the g factor to be the bulk value of 2.18. For the thinnest film, the line positions can be fitted within the whole range of $\Theta(0°\leq\Theta\leq90°)$ by using only $4\pi M_{eff}$, i.e., the higher-order contributions are very small. The analysis of the thicker films renders some difficulties as a substructure is found in the spectra around the perpendicular orientation. In an interval of about ±5° around $\Theta=0°$ often two lines appear, which partly overlap and which exhibit varying relative intensities. Therefore, we give only an estimate of $4\pi M_{eff}$ for these films. As the value of the higher-order anisotropy constants is strongly influenced by the angular dependence of the resonances close to

TABLE I. Anisotropy parameters for the four samples under investigation. $H_{A4}=K_4/M$ and $H_{Au}=K_u/M$ are obtained from a fit of the in-plane FMR measurements. $4\pi M_{eff}=4\pi M-2K_1/M$ is determined from the position of the resonance line at $\Theta=0$.

t_{Co} (Å)	H_{A4} (G)	H_{Au} (G)	$4\pi M_{eff}$ (kG)
14	0.6	60	9.7
85	0.8	15	13.5
93	0.8	13	13.3
178	1.7	9	14.0

$\Theta=0°$, their determination is complicated by the above mentioned behavior.

In x-ray investigations of the stacking sequence of thin Co layers on Cu(111) grown by the same recipe (with the Nb buffer layer) only fcc stacking was found.[9] Recent NMR experiments on our thicker films yielded a significant hcp contribution.[12] This difference in the stacking may contribute to the substructure of the out-of-plane FMR spectra. Note that an hcp stacking is expected to lead to a decrease of $4\pi M_{eff}$ compared to pure fcc, because of the higher value of K_1 in the hcp structure.

As the spectrum of the film with $t_{Co}=14$ Å shows no such irregularities, we can analyze its linewidth behavior. If the film is perfectly homogeneous, one can expect $\Delta H(\Theta=0°)\approx\Delta H(\Theta=90°)$. However, we observe a certain deviation from this. We introduce the inhomogeneity $\delta H_i=\delta(4\pi M-2K_1/M)$ of the first-order internal field contributions and write

$$\Delta H=\Delta H_0+\left|\frac{\partial H_{res}}{\partial H_i}\right|\delta H_i. \tag{3}$$

Comparing the in-plane and the out-of-plane linewidth yields $\delta H_i\approx1100$ G. We have assumed a Lorentzian shape of the absorption curve, so that the peak-to-peak linewidth measured with the field modulation technique corresponds to $(1/\sqrt{3})\Delta H$. In the case of this thin film, the inhomogeneity δH_i should be mainly caused by roughness effects. We note that measurements on polycrystalline Co on Au(111) also yielded considerable values for the inhomogeneity of the internal field in thin films.[11]

In conclusion, we have investigated the in-plane and out-of-plane anisotropy of MBE-grown Co/Cu(111) films. In plane, the expected sixfold anisotropy is clearly visible, but for the thin films it is less pronounced, which can be taken as an indication for the nonperfect coalescence of Co on Cu(111) within the first Co layers. An additional uniaxial contribution is found that is thought to be closely related to the buffer layer.

The out-of-plane anisotropy of the film with $t_{Co}=14$ Å can be fully described by using only the lowest-order term, i.e., $4\pi M_{eff}=4\pi M-2K_1/M$. The higher-order contribution is very small. For this film, an estimate of the inhomogeneity of the internal field has been given on the basis of the FMR linewidth. The out-of-plane spectra of the thicker films exhibit some substructure and not only a single resonance line. In these samples significant hcp stacking contributions have been found.

The results confirm that the Co/Cu(111) system has its peculiarities mainly connected with the growth process and the structure.

We have investigated the magnetic and magneto-optic properties of Co/Ni multilayers deposited on Ag and Au buffer layers. The samples with Au buffer layers show perpendicular magnetic anisotropy, but those with Ag buffer layers do not. The structure and degree of crystalline alignment of the buffer layer are evidently crucial to development of perpendicular magnetic anisotropy. We also present the results of polar Kerr rotation measurements as a function of wavelength and layer thickness of the multilayers.

INTRODUCTION

Magnetic multilayers have attracted much attention[1] due to the resulting novel properties that are suitable for a variety of applications. One interesting phenomenon is the so-called perpendicular magnetic anisotropy that has been found in Co/*X* (*X* being a nonmagnetic metal such as Pt, Pd, Au, or Ir) multilayers.[2–4] The large perpendicular magnetic anisotropy shown in these multilayers makes them potential candidates for MO recording media. Recently, Co/Ni multilayers were also predicted to have perpendicular magnetic anisotropy, and this was confirmed in *e*-beam evaporated multilayer samples.[5] Magneto-optic and thermomagnetic writing tests on this *e-beam evaporated* multilayer have yielded encouraging results.[6]

In this article, the magnetic and magneto-optic properties of *sputtered* Co/Ni multilayers are reported. The effects of Au and Ag buffer layers on the perpendicular magnetic anisotropy of the sputtered Co/Ni multilayers are discussed, then the dependencies of the magneto-optic properties on the wavelength and the multilayer structure parameters are presented.

EXPERIMENT

Samples were prepared using both dc and rf magnetron sputtering. The system was first evacuated to below 5×10^{-7} Torr before sputtering, and Ar gas (5×10^{-3} Torr) was used in the sputtering process. In most cases, 50-nm-thick Au or Ag buffer layers were first deposited onto glass substrates. The Co thickness was varied from 0.1 to 0.4 nm and the Ni thickness from 0.2 to 1.2 nm. Multilayered structures were realized by rotating the substrates above the separate guns. The total Co/Ni thickness was varied between 5 to 30 nm.

The magnetic properties were measured using an alternating gradient force magnetometer (AGFM). Crystalline texture studies were performed using x-ray diffractometry with a Cu $K\alpha$ target in the θ–2θ mode, and a scanning angle of 10°–90°. The Kerr rotation (θ_k) and the Kerr ellipticity (ϵ_k) were measured at normal incidence over the wavelength range from 300 to 800 nm using apparatus previously described.[7] All experiments are performed at room temperature.

RESULTS AND DISCUSSIONS

Figure 1(a) shows hysteresis loops obtained with the AGFM for Co(0.2 nm)/Ni(0.8 nm) on Ag for magnetic fields applied both in the plane and perpendicular to the film plane. Clearly, this sample has in-plane magnetic anisotropy, as did all other samples deposited on Ag buffer layers. In contrast, Fig. 1(b) shows perpendicular and parallel hysteresis loops for a similar multilayer deposited on a Au buffer layer. This sample clearly has perpendicular anisotropy, and the value of the uniaxial anisotropy constant (as determined by the loop-area method) is about 100 kJ/m^3. All of our Co/Ni multilayers deposited on Au showed perpendicular anisotropy, in agreement with the results of Daalderop *et al.*[5]

While the origins of perpendicular magnetic anisotropy (PMA) are often difficult to determine, PMA can be due to tensile internal stresses.[8] Thus the structural details of the buffer layer may be of considerable importance in determining the magnitude of the anisotropy. Figure 2 shows x-ray diffraction scans of the fcc Au and Ag buffer layers, each 50 nm thick. The dominant feature of both scans is the [111]

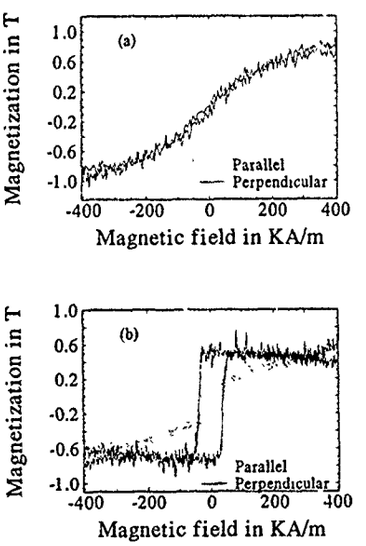

FIG. 1. Room temperature hysteresis loops for (a) Co(0.2)/Ni(0.8)×12 multilayers on Ag buffer layers and (b) Co(0.2)/Ni(0.8)×8 on Au buffer layers.

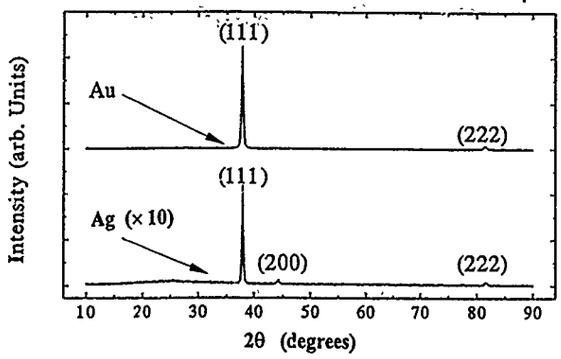

FIG. 2. 2θ x-ray diffraction patterns of Au and Ag buffer layers.

peak, indicating that the films are highly textured. The intensity of the Au peak is 10 times that of the Ag peak, whereas the ratio of the electron densities squared is only 2.8. This result suggests that the Au buffer layers exhibit either a higher degree of crystallinity or a higher degree of texture, either of which could lead to the differences in anisotropy. The presence of a weak [200] diffraction peak for the Ag buffer layer, but not for the Au buffer layer (see Fig. 2), is direct evidence that the Au buffer layer is more completely textured than the Ag buffer layer.

To further test these ideas, we carried out annealing experiments, where the buffer layer was annealed prior to deposition of the Co/Ni multilayer. Annealing the Ag buffer layer in vacuum at 400 °C for 1.5 h prior to depositing the Co/Ni multilayer resulting in significant changes in the shape of the perpendicular hysteresis loop. The remanence ratio M_r/M_s of the Co/Ni multilayers increased considerably, and the coercivity increased by a factor of nearly 5. However, the easy magnetization direction remained in the film plane. Similar annealing experiments on Au buffer layer resulted in only minor changes in the hysteresis loops. One can speculate that if the [111] texture of the Ag buffer layer could be improved, Co/Ni multilayers deposited on Ag might also show PMA.

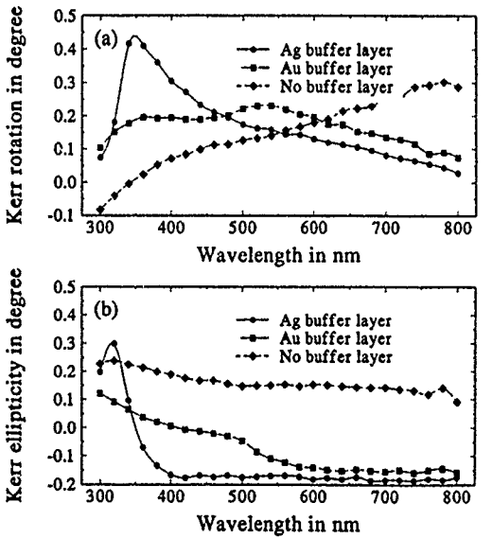

FIG. 3. Wavelength dependencies of Co(0.2)/Ni(0.8)×16 multilayers (a) polar Kerr rotation, (b) polar Kerr ellipticity.

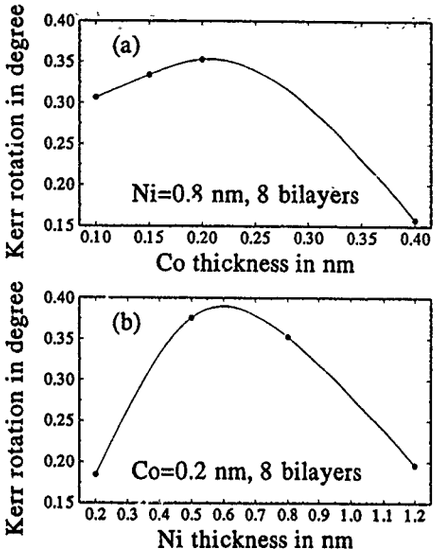

FIG. 4. Polar Kerr rotation at 350 nm as a function of (a) Co thickness and (b) Ni thickness for multilayers on Ag buffer layers.

The wavelength dependencies of θ_k and ϵ_k for Co/Ni multilayers on both Au and Ag buffer layers are shown in

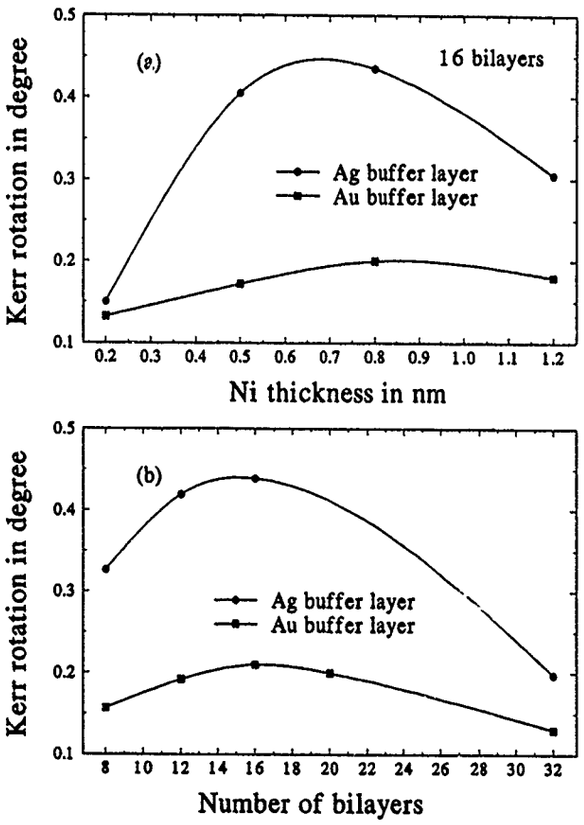

FIG. 5. Polar Kerr rotation at 350 nm as a function of (a) Ni thickness at Co=0.2 nm, (b) bilayer numbers for Co(0.2)/Ni(0.8) multilayers on Ag and Au buffer layers.

Fig. 3. For Co/Ni multilayer thickness near 10 nm, the optical effects of the buffer layer or the glass substrate is considerable,[9] since the magnitudes of θ_k and ϵ_k are due to a combination of the magneto-optical properties of the Co/Ni multilayer and the optical properties of the buffer layer. From Fig. 3, we note that the peak of θ_k for Co/Ni on Ag falls at 350 nm, or at about the same wavelength where ϵ_k drops rapidly. These two effects occur where the optical properties of Ag are changing rapidly due to d-band transitions.[10] Similar, but less dramatic, effects are noted for Co/Ni on Au. It should also be noted that the short-wavelength polar Kerr rotations of Co/Ni multilayers with Au buffer layers are considerably larger than those of rare-earth–transition-metal alloys.[11]

We varied the individual Co and Ni layer thicknesses, and also the number of bilayers, to optimize the polar Kerr rotation, and the results are shown in Figs. 4 and 5. The maximum polar Kerr rotation is obtained for Co≈0.2 nm, Ni≈0.6 nm, at about 16 bilayers. The Kerr rotation for Co/Ni on Ag is considerably larger than that of Co/Ni on Au (see Fig. 5), primarily because the measurements were performed at λ=350 nm, where the optical properties of Ag cause a considerable enhancement of the Kerr rotation.

SUMMARY AND CONCLUSIONS

Sputtered Co/Ni multilayers show perpendicular magnetic anisotropy when deposited on a Au buffer layer, but in-plane anisotropy when deposited on a Ag buffer layer. This difference most likely arises because the Au buffer layers are more completely oriented with the [111] direction perpendicular to the film plane. The optical properties of the buffer layer also strongly affect the magnitude of the Kerr rotation. The largest Kerr rotation measured was 0.44° for Co(0.2 nm)/Ni(0.6 nm)×16 bilayers on a Ag buffer layer.

We have measured the specular reflectivity of spin-polarized neutrons from two (111) superlattices, [Pd 80 Å|Co 60 Å]×20/Pd 300 Å/Co 10 Å/GaAs and [Pd 53 Å|Co 32 Å]×10/Pd 30 Å/Cu 354 Å/Si, grown by molecular-beam epitaxy. In a saturating field of 2300 Oe, we extract for the first superlattice a Co moment value of corresponding to 78% of the bulk Co moment. At temperatures ranging from 38 to 295 K, no excess magnetic moment from polarization of the Pd atoms is evident in the nominal Pd layer. Comparable reflectivity data from the second sample support these conclusions.

The application of controlled deposition techniques to the growth of magnetic films and multilayers has prompted novel studies of the nature of spin interactions in transition metals.[1] For example, the discovery of perpendicular magnetic anisotropy in Co/Pd superlattices[2,3] has attracted technological interest, while a related topic of fundamental importance has been the polarization of the nonmagnetic Pd atoms[2–4] arising from the proximity of Co at the superlattice interfaces. Even though its d band is not completely filled pure Pd is paramagnetic rather than ferromagnetic like Ni, its structural analog. A "giant moment" as large as $0.4\mu_B$ per Pd atom occurs in dilute Pd alloys with magnetic transition metals principally due to the $3d$-$4d$ hybridization of the impurities with the Pd atoms.[5] For a Co monolayer on a Pd substrate, a theoretical study[6] predicts that the Co magnetization is enhanced by as much as $0.4\mu_B$ per atom and that a moment of $0.33\mu_B$ per atom is induced nearest the Pd layer. A similar calculation for Fe/Pd superlattices[7] confirms that only the Pd atomic layer nearest the interface develops a significant moment ($>0.3\mu_B$).

Experimental measurements such as conventional magnetization[2–4] provide widely varying estimates of the Pd moment in Co/Pd superlattices. In contrast with this technique, polarized-neutron reflectivity is sensitive to the depth-dependent moment distribution through the superlattice and is insensitive to sample volume. Pasyuk *et al.*[8] have used this procedure to examine a Pd/Co/Pd trilayer structure and obtain an induced Pd moment of $0.4\mu_B$ at the Co/Pd interfaces. In this study, we have measured and modeled the specular reflectivity of x-rays and spin-polarized neutrons from two Co/Pd superlattices, [Pd 80 Å|Co 60 Å]×20/Pd 300 Å/Co 10 Å/GaAs (sample A) and [Pd 53 Å|Co 32 Å]×10/Pd 30 Å/Cu 354 Å/Si (sample B), in order to extract the average moment in each of the individual Co and Pd interlayers. These crystalline, (111)-oriented samples were prepared at the University of Arizona using molecular-beam epitaxy procedures detailed elsewhere.[4] Because neutron reflectivity is sensitive only to those moments that lie in the sample plane, we require superlattices with thicker Co and Pd interlayers than those that typically generate perpendicular magnetic anisotropy.[2–4] In neither sample do we find evidence of an excess moment in the nominal Pd interlayers at temperatures ranging from 38 K to 300 K. In addition, the Co moment in sample A saturates to only 78% of its bulk value in an applied field of 2300 Oe. While the apparent moment depletion observed in the superlattices seems to contradict the trilayer reflectivity study by Pasyuk *et al.*,[8] we discuss here the precision of this measurement technique for both sample geometries and place limits on the resultant Co and Pd moment values.

We performed the neutron reflectivity studies on the BT-7 reflectometer[9] at the NIST research reactor with the samples magnetized in-plane in fields ranging from 95 Oe to 2300 Oe. Since neutrons interact with both the nuclei and electron spins of the scattering material, the refractive indices describing the reflectivity have a structural and magnetic component. For a simple ferromagnet, the refractive index can be written

$$n_{\pm} = \sqrt{1 - \frac{N\lambda^2}{\pi}\,(b \pm p)}, \tag{1}$$

where N is the number density of the scatterers, b is the nuclear scattering length, and $p = \sigma_m \mu$ is the magnetic scattering amplitude where $\sigma_m = 0.2695 \times 10^{-4}$ Å/μ_B and μ is the magnetic moment per atom in the sample plane. The plus and minus subscripts designate the indices for neutrons polarized parallel and antiparallel to the sample moment. Measuring both spin states, one can, in principle, obtain a spatial profile of the distribution of structural and magnetic scatterers through the sample using a model based upon the one-dimensional wave equation for a stratified medium.[10]

To reduce the number of variables in the neutron data analysis, we first determine the structural characteristics of the superlattice using x-ray reflectivity. Figure 1(a) shows room-temperature data for sample A plotted as a function of the wave vector Q. The fitted curve was generated from the density profile shown in Fig. 1(b) and parametrized in Table I. Despite the presence of four superlattice reflections above background, the fit reveals that the superlattice interfaces are somewhat rounded. The scattering densities in the centers of the interlayers fall short of the bulk Co and Pd values [dashed lines in Fig. 1(b)], suggesting that Co atoms are present throughout the nominal Pd layer and vice versa. The structural characteristics of sample B (Table I) are comparable to those of sample A despite differences in the substrate materials and growth procedures.[4] In both samples the ob-

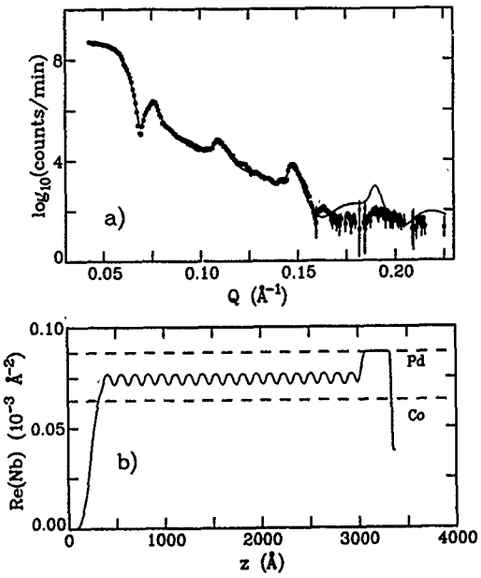

FIG. 1. (a) X-ray specular reflectivity of sample A at room temperature. The squares are the data and the solid line is the fit. (b) Scattering density profile for the x-ray reflectivity fit as a function of depth into the sample. The dashed lines mark the bulk densities of Co and Pd.

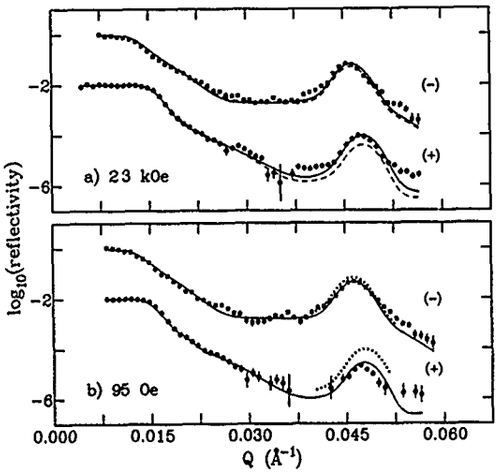

FIG. 2. (a) Polarized-neutron reflectivity of sample A at 38 K in a saturating field of 2300 Oe. The + and − cross sections are designated by circles and squares, respectively, and the former is vertically offset for clarity. The solid lines represent the fit to the data, and the dashed lines describe the reflectivities calculated assuming that the Co atoms present in both the nominal Co and Pd interlayers are magnetized with 78% of the bulk Co moment. (b) Polarized-neutron reflectivity of the same sample at 38 K in a remanent field of 95 Oe. The dotted lines here reproduce the fit to the 2300-Oe reflectivities in (a) above to enable a direct comparison of the data sets.

served interfacial "mixing" could originate from a combination of diffusion, atomic-scale roughness, or correlated roughness arising from substrate miscut.

Polarized-neutron scans for sample A reveal only a single superlattice reflection above the diffuse background, as demonstrated in Fig. 2(a) for measurements at 38 K in an applied field of 2300 Oe. The + and − cross sections were fit simultaneously, holding the structural parameters constant, in order to extract the moment distribution as a function of depth. The results from this analysis are summarized in Table I. The fit is guided principally by the critical angles, which are related to the square of the total bilayer moment, and by the relative intensities of the + and − superlattice peaks, which are determined by the difference between the magnetization in the nominal Co and Pd layers. Following Fourier-transform arguments, the absence of higher-order superlattice reflections limits the sensitivity of the fit to the *average* moments through the separate Co-rich and Pd-rich interlayers. Specifically, the magnetic densities of the Pd atomic planes nearest the Co/Pd interfaces cannot be distinguished.

The magnetization profile that generates the fit (solid line) in Fig. 2(a) is shown in Fig. 3(a). The average magnetic moment in the nominal Co interlayer equals $(1.37\pm0.08)\mu_B$ per Co atom, corresponding to 78% of the Co bulk moment $(1.74\mu_B)$. The remaining 22% of the spins elude experimental detection and are, therefore, either disordered or aligned perpendicular to the sample plane. (Complementary magnetometry measurements, normalized by the number of Co atoms in the sample, give a saturation moment of $(1.62\pm0.08)\mu_B$ per Co atom.) Figure 3(a) also demonstrates that the magnetic density Re(Np) of the Pd-rich layer is smaller than would be expected if those Co atoms dispersed through the layer exhibited the same moment as those in the Co-rich layer. In addition, the moment in the nominal Pd interlayer decreases from $1.08\mu_B$ to $0.95\mu_B$ per Co atom upon warming the sample from 38 K to room temperature, possibly reflecting a gradient of Co Curie temperatures through the interfaces. At both temperatures we clearly observe a depletion of the magnetic moment in the nominal Pd

TABLE I. Parameters describing the fits to the x-ray and neutron reflectivity data for samples A and B. The interlayer thicknesses d and nuclear scattering densities Nb were extracted from room temperature x-ray data, while the magnetic densities Np were extracted from neutron data in a 2300-Oe applied field at 38 K for sample A and at room temperature for sample B.

	X-ray reflectivity				Neutron reflectivity	
Sample	d_{Co} (Å)	d_{Pd} (Å)	Re(Nb)$_{Co}$ (10^{-6} Å^{-2})	Re(Nb)$_{Pd}$ (10^{-6} Å^{-2})	Re(Np)$_{Co}$ (10^{-6} Å^{-2})	Re(Np)$_{Pd}$ (10^{-6} Å^{-2})
A	59.2	80.5	71.6	76.8	2.41	1.05
B	31.7	53.4	69.8	77.0	3.16	1.87
Co			73.7		4.28	
Pd				87.5		0

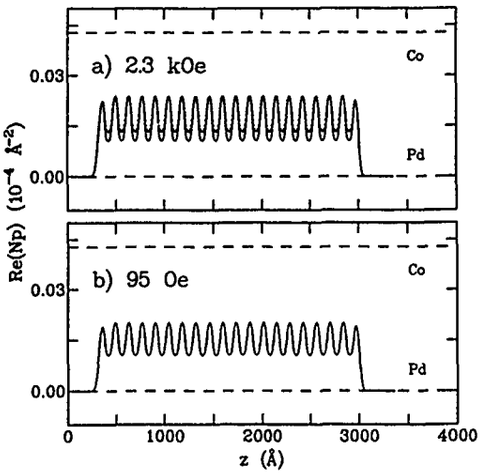

FIG. 3. (a) Magnetic scattering density profile for sample A at 38 K in a saturating field of 2300 Oe determined from the reflectivity fit in Fig. 2(a). The dashed lines mark the bulk densities of Co and Pd. The dotted line describes the density profile calculated assuming that the Co atoms present in both the nominal Co and Pd interlayers are magnetized with 78% of the bulk Co moment. (b) Magnetic scattering density profile for the same sample at 38 K in a remanent field of 95 Oe determined from the reflectivity fit in Fig. 2(b).

interlayer, rather than the predicted enhancement.

In order to place limits on our moment estimates, we have calculated reflectivity curves for sample A assuming that the Co atoms through the entire bilayer order with 78% of the bulk Co moment [dotted line in Fig. 3(a)]. As can be seen from Fig. 2(a), the differences between these curves (dashed lines) and the fitted curves (solid lines) are striking. Any enhancement of the magnetization in the nominal Pd layer would further diminish the amplitude of the + and − superlattice reflections, an effect not evident in our data.

The 38-K reflectivity for sample A does, in fact, change substantially upon lowering the applied field to 95 Oe, as shown in Fig. 2(b). The intensity of the + superlattice reflection is almost an order of magnitude smaller than that in Fig. 2(a) and the critical angles are slightly reduced. The plot of the resultant density profile in Fig. 3(b) reveals that these features originate from a decrease in the magnetic scattering contrast between the bilayer components (Table I). The moment per Co atom in the Co-rich interlayer equals $1.16\mu_B$, a reduction of $0.21\mu_B$ relative to that measured in a 2300-Oe saturating field, while the magnetization of the Pd-rich interlayer ($1.08\mu_B$ per Co atom) is identical to its high-field value. At room temperature, however, the magnetic profile extracted from 95-Oe reflectivity data approximates that shown in Fig. 3(a). The in-plane saturation field of the Co moments in the nominal Co interlayer apparently increases as the temperature decreases, an effect observed in comparable samples using conventional magnetometry techniques.[11] Though this behavior is generally attributed to a corresponding increase of the perpendicular magnetic anisotropy, we cannot, in this case, rule out the possible formation of ferromagnetic domains in the sample plane.

We have also measured the polarized-neutron reflectivity for sample B under comparable temperature and magnetic field conditions, but the results are less conclusive. Unfortunately, the scattering near the critical angle is dominated by the Cu baselayer. We can thus extract for this superlattice the relative magnetization of the Co and Pd interlayers, but cannot uniquely determine the absolute magnitude of the total bilayer moment. For simplicity, we assume that the Co atoms in the Co-rich layer saturate with the full Co moment. Table I lists the magnetic densities of the Co and Pd layers obtained from a fit to the reflectivities measured at room temperature in a saturating field of 2300 Oe. The deviation of these values from their bulk counterparts directly follows from the interfacial "mixing" quantified via x-ray analysis. The splitting between the + and − first-order superlattice reflections is well defined, and we observe that the Co atoms present in both the Co-rich and Pd-rich interlayers order with identical moments. Once again, no magnetic enhancement is evident through the nominal Pd interlayer.

We have extracted the spatial profile of the magnetization through two Co/Pd superlattices using polarized-neutron reflectivity techniques. As demonstrated, this analysis is particularly sensitive to differences between the magnetic densities of the Co and Pd interlayers. For the first sample, the Co moments in the nominal Co layer saturate to 78% of the bulk Co moment. This depletion may be associated with the structural disorder revealed by x-ray characterization. In both superlattices we do not detect any excess moment in the nominal Pd layer. Either the Pd in these samples is not polarized or the effect is *very* small. Subtle moment enhancements in a narrow interfacial region (<5 Å) as predicted by theory[6,7] and reported by Pasyuk *et al.*[8] are difficult to detect using either neutron reflectivity, which requires a level of interfacial perfection difficult to achieve, or conventional techniques such as magnetometry, which depend on sample volume. Upon refinement of the structural quality, specular reflectivity provides the sensitivity to detect these small enhancements and remains a topic for future investigation.

Electron-energy-loss spectroscopy of Fe thin films on GaAs(001)

J. Yuan, E. Gu, M. Gester, J. A. C. Bland, and L. M. Brown
Cavendish Laboratory, Cambridge CB3 OHE, United Kingdom

An electron-microscopy-based technique of electron-energy-loss spectroscopy (EELS) has been used to characterize electronic and magnetic properties of ultrathin Fe films grown on GaAs(100) surface, as a function of the film thickness. Large-area electron transparent membranes for microscopic analysis are prepared by ion-beam thinning or chemical etching from the substrate side, and the top surface of the ultrathin Fe film is protected by a thin Cr layer. Analysis of the Fe $2p$, Cr $2p$, and O $1s$ absorption spectra confirms that only the Cr layer is oxidized. The local magnetic moments of the ultrathin Fe films are deduced from the "white line" branching ratio in the Fe $2p$ absorption spectra. For Fe films as thin as 150 Å, the magnetic moment is not different from that found in bulk α-Fe. For a 70-Å Fe film, the local magnetic moment is enhanced although the average magnetization is reduced. As doping is suspected to be the cause for the departure from bulk α-Fe properties. In the case where the 50-Å film is polycrystalline and discontinuous, spatially resolved EELS has been used to distinguish small island clusters from large crystalline particles. The large particles are α-Fe crystallites and the islands are probably also heavily affected by As doping.

I. INTRODUCTION

Epitaxially grown Fe thin films on GaAs(100) hold great promise for the integration of magnetic film technology into semiconductor and opto-electronic technologies.[1-3] However, many physical properties of the thin films have a strong thickness dependence and the origins of these are currently poorly understood. For example, the average magnetization per Fe atom starts to decrease from the bulk value for films as thick as 230 Å.[4] To understand the microscopic origin of this behavior, we have to separate the intrinsic physical effects from the effect of defects, impurities, etc., associated with the growth problem. This can be achieved by studying the Fe film with a *localized magnetic probe*. In this article, we carried out such a characterization of thin and ultrathin Fe films by studying element-selective inner-shell ionization using electron-energy-loss spectroscopy (EELS).[5] The EELS measurement is carried out using a scanning transmission electron microscope (STEM), which not only allows us to study uniformly deposited films, but also permits analysis of inhomogeneous films with high spatial resolution. All the Fe films are preserved from oxidation and degradation by encapsulation between the substrate and a top protective layer. This distinguishes us from early studies of transition metal films that are thermally evaporated with poor control for impurity and crystallinity and inevitably contains surface oxide layers. We will be able to show from the Fe $2p$ absorption, which accesses to the final states involving the Fe $3d$ conduction band, that the electronic structure of Fe films grown on the GaAs(100) surface is bulklike at 150 Å but different from the bulk for 70-Å and 50-Å ultrathin films; and that the difference is consistent with As doping.

II. EXPERIMENT

The ultrathin Fe films are deposited on a GaAs(001) substrate inside a UHV chamber with a base pressure better than 5×10^{-9} mbar during the growth. A detailed characterization of the growth process by both reflection high-energy electron diffraction (RHEED) and low-energy electron diffraction (LEED) techniques can be found in Ref. 6. At the end of Fe deposition, the top surface is covered with a thin layer of Cr to prevent the oxidation of Fe films. To produce electron-beam-transparent samples for transmission electron microscopy and transmission electron-energy-loss analysis, the sandwich film is thinned from the substrate side only. This is achieved by either ion-beam sputtering or by chemical etching. The latter is particularly favored since a large uniform thin membrane can be produced using a thin layer (about 0.2 μm thick) of the relatively chemically inert $Ga_{0.7}Al_{0.3}As$ as an "etching stop" layer[6] on top of the GaAs(100) substrate.

EELS is conducted inside a dedicated vacuum generate (VG)-HB501 STEM operating at 100 keV. The transmitted electrons are analyzed by a VG magnetic sector prism, and the spectrum is further magnified by a quadrapole lens system before being collected on a CCD (charge-coupled device)-based parallel detection system.[7] All the spectra have been corrected for the dark current and flat-field response of the CCD camera. The convergence semiangle of the incident electron is about 7 mrad, and the collection semiangle of the spectrometer is about 8 mrad. Under such experimental conditions, inner-shell transitions of interest (O $1s$ at 530 eV, Cr $2p$ at 576 eV, and Fe $2p$ at 706 eV) all obey the dipole-selection rule. The spatial resolution of the focused electron probe is better than 5 Å and the optimal energy resolution of the EELS system is 0.3 eV.

III. RESULTS

A. Cr(25 Å)/Fe(150 Å)/GaAs(001) structure

The magnetization measurement of this 150-Å Fe film shows a pronounced fourfold anisotropy.[8] Thin membrane of the sandwich structure is produced by chemical etching. The electron diffraction pattern is consistent with an epitaxial α-Fe film lattice-matched on a GaAs(001) substrate. The composition analysis using the theoretical cross sections[5] for the continuum part of the Cr and Fe $2p$ absorption shows that the Fe and Cr concentrations are in the ratio 6.33, close to the expected ratio of 6.10, which is calculated from the

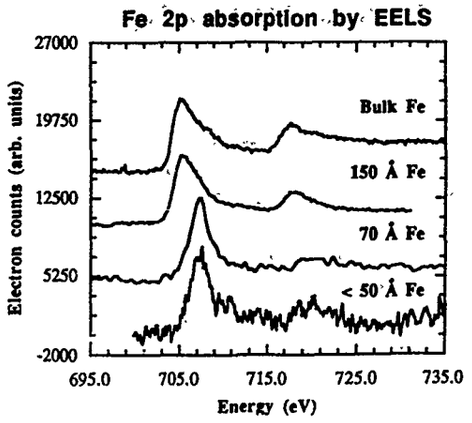

FIG. 1. The Fe $2p$ absorption spectra from ultrathin films of different thickness. The bulk reference spectra is taken from 2000-Å thick particles (see the text for detail).

thickness difference of the two films as measured by quartz microbalance, *in situ*. The thickness of the membrane is estimated from the low-loss spectrum to be about 300–400 Å and is very uniform. An analysis of the Cr $2p$ absorption spectra indicates that at least a part of Cr has been converted into oxides.[9] The Fe $2p$ absorption for the thin film is shown in Fig. 1. It is similar to that for the bulk Fe absorption spectrum shown on the same figure, with the energy of the first peak at 706 eV. There is no sign of Fe oxidation since its white line would appear at much higher energies.[9]

B. Cr(25 Å)/Fe(70 Å)/GaAs(001) structure

The magnetization of this 70-Å Fe film shows a mixture of fourfold and twofold anisotropy.[8] As there is no built-in etching stop on the GaAs substrate, ion-beam thinning was used to produce electron-beam transparent membrane. From electron diffraction analysis, the Fe film growth is again found to be epitaxial. To avoid areas where the GaAs substrate has been completely removed, we deliberately move to areas where the sandwich structure is over 700 Å thick and where signal from the GaAs substrate is unmistakable. With at least about 600 Å of the GaAs substrate still intact, the possibility of ion-beam-induced effects on the thin Fe film is very small. The Fe $2p$ absorption spectrum taken from this thick sample is deconvoluted to remove multiple scattering, and the result is also shown in Fig. 1. It is clear that the 70-Å Fe film is already different from the bulk and 150-Å Fe film. The first peak in the Fe $2p$ absorption spectrum from the 70-Å Fe film has a shoulder at 706 eV where the $2p$ absorption of the bulk Fe has its maximum.

C. Cr(25 Å)/Fe(50 Å)/GaAs(001) structure

This film is slightly different in its fabrication from the above two films. The GaAs wafer containing the etching stop layer has been thinned to produce a membrane window prior to Fe deposition. The magnetization of the film is found to be isotropic[8] and is associated with the polycrystalline nature of the film, as shown by electron diffraction. In addition, electron microscopy shows that the Fe film is discontinuous and that the grains have two characteristic sizes. The Fe is mostly sparsely distributed in clusters of small islands of the order of 50 Å across. From the analysis of the ionization cross sections, using that of the Cr layer as a standard, the thickness of the Fe islands is deduced to be about 20–30 Å. The Fe $2p$ absorption spectrum from one of these nanometer-sized islands is shown in Fig. 1. It is similar to that of the 70-Å film, except for an additional shoulder at 710 eV. Much less numerous are the large Fe particles with diameters over several thousand angstroms. The energy-loss spectrum from the large particles has been taken as representative of the bulk Fe films and is also presented in Fig. 1 for comparison purpose.

IV. DISCUSSION

In a one-electron picture, the inner-shell transition should give information about a symmetry-projected, empty density of states localized on the excited atoms, and the result can be compared with the bandstructure calculation. In the case of Fe $2p$ absorption, it probes the empty density of states of the conduction band with the $3d$, and to a less extent $4s$ character. However, strong coupling between the partially filled d band and the remaining inner-shell p electrons produce a significant distortion to the empty density of state. The spectra are dominated by two "white-line" structures separated by 12.5 eV, approximately the energy difference between the Fe $2p_{1/2}$ and $2p_{3/2}$ core levels. Information about the electronic structure of the Fe film can still be assessed in these cases. For example, the density of the conduction electrons controls the lifetime of the core hole states, hence the width of the core level transition. In bulk metal Fe (see Fig. 1), the width of the white line is quite large (3.5 eV), reflecting a large conduction electron density around Fe. It is reduced to less than 2.1 eV for the 70-Å and 50-Å films, indicating a large reduction in the density of the conduction electron. Because of this reduction in the width, the multiplet structures in the white lines becomes visible for the spectra from these two films. These are due to resonant transition from the $2p^6 3d^n$ initial states into $2p^5 3d^{n+1}$ final states, and are sensitive to the d-level occupancy of the Fe atom. Comparison of line shape of l_3 peak with an atomic multiplet calculation[10] suggests that the average d-level occupancy (n) in the 70-Å film is 6, assuming the crystal-field effect is unimportant.

Because of the spin-orbit coupling, the branching ratio of the white lines arising from transitions from the two sublevels of the Fe $2p$ state (defined as $I_3(2p_{3/2})/[I_2(2p_{1/2})+I_3(2p_{3/2})]$) deviates from the statistical values $\frac{2}{3}$ (Ref. 11) and depends on the specific configuration of the partially filled $3d$ levels.[9] Although a first-principle calculation of these effects is still not feasible for the time being, an empirical relationship has been found between the local magnetic moment per Fe atom (which depends on the $3d$ configuration of the Fe) and the branching ratio of the Fe $2p$ absorption.[12] The branching ratio of Fe $2p$ absorption from the bulk and 150-Å Fe is found to be 0.74 ($I_3/I_2=2.9$), in agreement with that reported from the literature.[12,13] The corresponding branching ratio for the 70-Å Fe film is 0.83 ($I_3/I_2=5$). This indicates an enhanced magnetic moment per

atom according to the empirical relationship of Kurata and Tanaka.[12] To translate local magnetic moments into volume magnetization, we need to consider the nature of local magnetic ordering. The branching ratio of the thinner film ("50 Å") film is not available due to poor statistics of the spectrum.

The cause for the departure from the bulk Fe signal in the thin and ultrathin films is not clear. The effect of low dimensionality is unlikely in this particular case as the Fe $2p$ absorption spectra of a two monolayer and a four monolayer film on Cu(100) substrate, obtained using *in situ* x-ray absorption,[13] is similar to that found for bulk Fe and the 150-Å film. A more likely cause maybe due to the atomic diffusion across the boundary. The Cr/Fe bilayer has been studied extensively in terms of ultrathin film, and multilayer fabrication and interdiffusion is generally not a problem. Contamination of the Fe film by more diffusive As species has been found in earlier deposition experiments,[4,14,15] and the formation of antiferromagnetically coupled Fe_2As microcrystallites has been speculated as a possible reason for the drop of the average magnetization per atom in thin film.[4] There are some evidence for As contamination of Fe film from *in situ* Auger spectroscopy; however, there is no electron diffraction evidence for Fe_2As microcrystalline particles in the films we have examined. On the other hand, the As-doped α-Fe is also possible in the equilibrium phase diagram of the Fe-As binary system[16] and cannot be dismissed purely from our plan-view electron microscopy and EELS results. We may speculate on the electronic structure of the As-doped Fe film. Crudely speaking, the more electronegetive As atom will be an electron acceptor and reduces the d-level occupancy in the Fe atom. This is consistent with the reduced branch ratio and decrease in the line width of the white lines in the Fe $2p$ absorption spectra from the 70- and 50-Å films. According to the empirical relationship between branch ratio and the local magnetic moment per atom, the magnetic moment per atom for the As-induced α-Fe film may actually increase (from 2.5 to 6 μ_B). This finding may not necessary be in conflict with the decrease in the average magnetization per atom, as the relationship between the two are not necessary in tandem particularly for an itinerant ferromagnetic Fe sample, since the local ordering of the atomic moments is also important and may also be affected by As doping.

V. SUMMARY

Thin Fe films grown on GaAs(100) surface have been examined by electron-microscopy-based high-energy EELS. Special sandwich structure has been produced to prevent the oxidation of the ultrathin Fe film at ambient atmosphere. This allows, for the first time, observation of the electron-energy-loss spectrum of Fe metal films not tainted by the surface oxide. For the 150-Å film, the Fe $L_{2,3}$ absorption edge is similar in shape to that obtained from the bulk. But the spectrum from the 70-Å Fe film is very different. The local magnetic moment deduced from the branching ratio of the Fe $2p$ spectrum from the 70-Å Fe film is higher than that from the bulk. For the 50-Å film examined, the magnetization behavior is isotropic because the film is polycrystalline. The film is also discontinuous and has two distinct grain sizes. The electronic structure of the small Fe islands (about 50 Å across) is similar to that of the 70-Å Fe film. The larger grains have diameters of the order of thousand angstroms and bulklike properties. The exact nature of the electronic structure of the deposited Fe films are still under investigation. It is suspected that the changes are partially caused by the proximity of the interface and the related As diffusion across the boundary, which can induce both doping as well as alloying.

Effect of interface on the properties of Ti/NiFe thin films

Shuxiang Li, Minglang Yan, Chengtao Yu, and Wuyan Lai
Institute of Physics, Chinese Academy of Sciences, P.O. Box 603, Beijing 100080, China

The microstructure, anisotropic magnetoresistance, and magnetic properties of $Ti/Ni_{81}Fe_{19}$ thin films have been investigated with respect to annealing temperatures (T_A) up to 450 °C as well as to anneal times (t_A). It has been shown that 120 °C is the optimum annealing temperature and that t_A has no significant influence on the properties with annealing at 270 °C. Auger depth profiling was used to study interdiffusion kinetics. The diffusivity D and activation energy ϵ have been estimated at about 2.0×10^{-17} cm^2/s and 1.69 eV, respectively.

I. INTRODUCTION

The polycrystalline NiFe thin film is of technological importance because of its unique soft magnetic properties. In particular, it is a popular sensor material for magnetoresistive (MR) sensors because of its small magnetostriction and large anisotropic magnetoresistance. The reliability of MR sensors not only depends on anisotropic magnetoresistance (AMR) values (actually in the percent regime), but also on other properties, such as magnetic properties and the sensitivity to temperature or stress of the sensor material. In order to have better adhesion to gold contacts, NiFe films are often used with an overlayer of another metal such as Ti or Ta. In the photolithographic process of patterning, films are often exposed to temperatures above 200 °C. This probably changes characteristics of interface and stress, and then reduces AMR. On the other hand, a suitable annealing treatment can reduce bulk resistance, and it is beneficial to improve the AMR. Narayan *et al.*[1] have investigated the effect of annealing of Ti/NiFe composites qualitatively and pointed out that the limit of T_A for this composite is less than 300 °C. Hashim and Atwater[2] have studied the interdiffusion of a Ta/NiFe multilayer using x-ray diffraction and obtained D and ϵ quantitatively.

In this article, the microstructure, magnetic properties, and anisotropic magnetoresistance of $Ti/Ni_{81}Fe_{19}$ thin films have been studied with respect to annealing temperatures T_A up to 450 °C as well as to anneal times t_A with annealing at 270 °C. The diffusivity D and activation energy ϵ have been calculated. The AMR and magnetic properties are improved with T_A up to 120 °C. These properties, however, become slightly inferior with a further increase of T_A in the range from 120 to 450 °C. The values of D and ϵ show that the interdiffusion between Ti and NiFe is slower than that of Ta in NiFe reported in Ref. 2. Interdiffusion, contamination of stress, etc., may account for the variation of properties.

II. EXPERIMENT

A Ti(20 nm)/NiFe(100 nm) film was deposited on a glass substrate using dc magnetron sputtering. The deposition rate was about 1.5 Å/s. In order to distinguish interface effects from bulk effects, a NiFe layer was deposited on a glass substrate at a temperature of 470 °C and held at the same temperature for 1 h to homogenize the structure; then a Ti layer was deposited on the NiFe layer when the substrate was cooled to 40 °C. There were two procedures in annealing treatment: (1) t_A was fixed at 3 h, and T_A was taken as 120, 220, 290, 360, and 420 °C; (2) T_A was fixed at 270 °C, and t_A was taken as 1, 2, 4, 6, and 8 h. All annealing treatments were carried out in a vacuum annealing furnace after achieving a base pressure of 5×10^{-6} Torr. The crystal structure was determined by x-ray diffraction. The resistance was measured at room temperature with a four-point probe on unpatterned stripes cut from the glasses. The compositional profiles were obtained by Auger depth profiling. The diffusivity D and activation energy ϵ were calculated from the compositional profiles.

III. RESULTS AND DISCUSSION

The x-ray diffraction pattern of the as-deposited Ti/NiFe film is shown in Fig. 1. It indicates that the Ti/NiFe film has already developed texture in the (002) orientation of hcp Ti and the dominant (111) orientation of fcc NiFe. The lattices between NiFe and Ti match well, which results in a minimum interface stress. Narayan *et al.*[1] found that the annealed NiFe film has texture in the (111) orientation too. Figure 2 shows the dependence of the AMR and saturation field H_s on annealing temperature T_A. It demonstrates that the AMR increases with an increase of T_A and then decreases slowly with a further increase of T_A. There is a maximum AMR of 3.1% with a minimum saturation field of 7.5 Oe at 120 °C. There are no sharp changes of the AMR and magnetic properties from 120 to 450 °C. In fact, the AMR is inversely proportional to the resistivity of the polycrystalline permalloy film, ρ, which is affected by surface scattering and grain-boundary scattering.[3] ρ can be significantly reduced by an annealing treatment because of grain growth and the elimi-

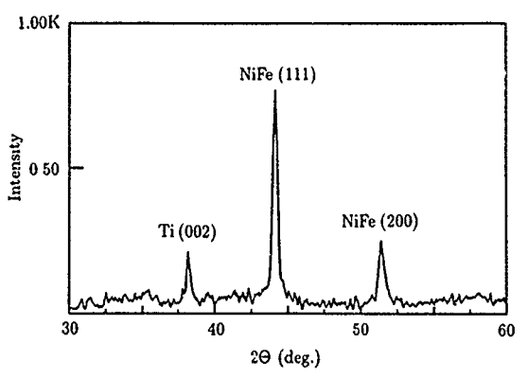

FIG. 1. X-ray diffraction pattern of an as-deposited Ti/NiFe film.

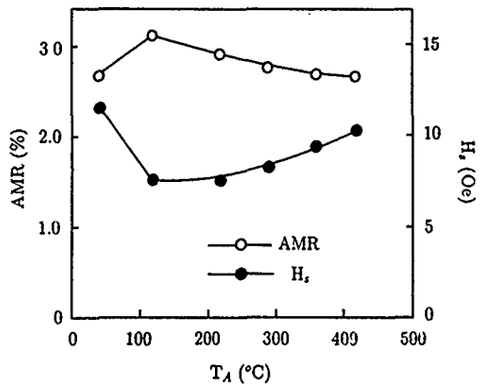

FIG. 2. The dependences of the AMR and saturation field H_s on annealing temperature T_A.

nation of crystal defects, whereas $\Delta\rho$ is almost unchanged by annealing treatment. With T_A up to 120 °C, the interface stress and crystal defects within the interface between Ti and NiFe layers are eliminated partially, so that the AMR is increased and soft magnetic properties are improved. It may be expected that the AMR should increase more with a further increase of T_A because ρ will decrease due to the consequent elimination of interface stress. The AMR, however, unexpectedly decreases with a further increase of T_A. This probably can be attributed to interdiffusion between NiFe and Ti. On the other hand, the AMR is almost unchanged with an increase of annealing time t_A with annealing at 270 °C. This result is due to the fact that the interdiffusion tends to be stable and the diffusion depth increases very slowly in this temperature range. In order to clarify the role of interdiffusion, Auger depth profiling was studied.

The Auger depth profiles (see Fig. 3) of Ti/NiFe films before and after annealing at 120 and 360 °C for 3 h show that the interface thicknesses (t_{in}) of Ti/NiFe increase about 36% and 40%, respectively, due to the annealing treatment. It is indicated that the increment of t_{in} is small when the annealing temperature T_A is above 120 °C, which is consistent with the temperature dependence of the AMR and H_s shown in Fig. 2. All these findings demonstrate that interdiffusion plays an important role in the variation of properties.

According to the Auger depth profiles of Ti/NiFe films annealed at 270 °C for 1, 2, 4, 6, and 8 h, the diffusivity D was calculated using the resolution of diffusion equation as follows:

$$C(x,t)=\frac{2}{\sqrt{4\pi Dt}}\int_0^\infty f(\xi)\exp\left(-\frac{(x-\xi)^2}{4\pi Dt}\right)d\xi, \quad 0\leq\xi\leq\infty \tag{1}$$

and

$$\overline{x^2}=2Dt, \tag{2}$$

where $C(x,t)$ is the concentration, $f(\xi)$ is the distribution of the concentration before diffusion, D is diffusivity, t is time, and x is depth profile. D was calculated to be about 2.0×10^{-17} cm^2/s. From the results of $D(T)$, the activation energy ϵ was estimated at 1.69 eV. Information on Ni and Fe

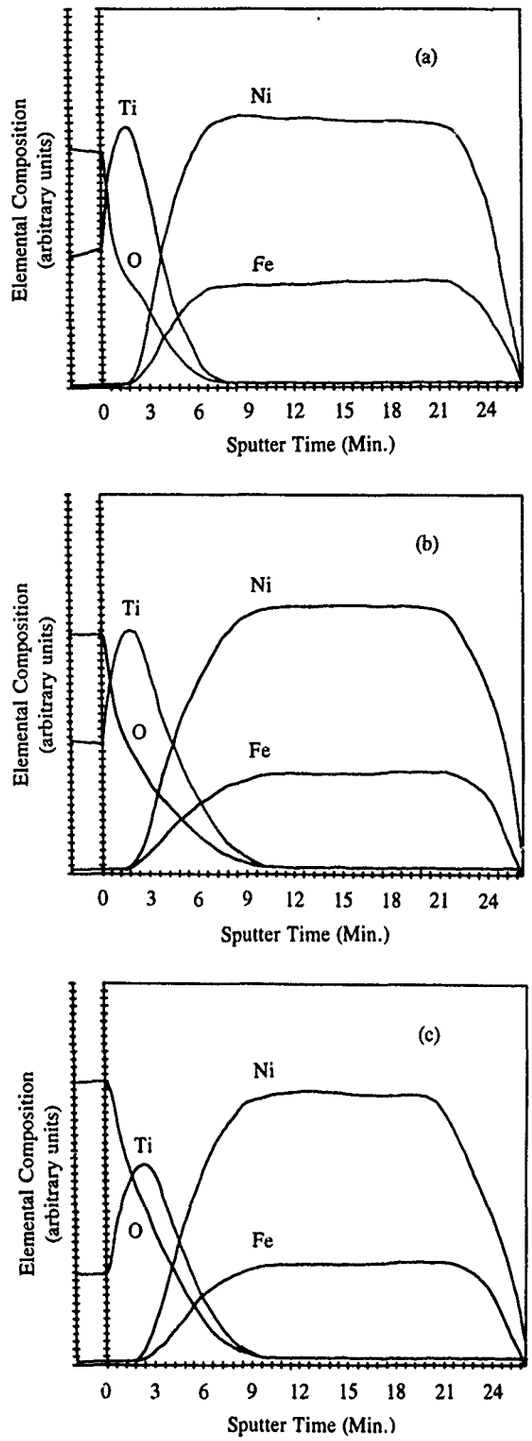

FIG. 3. Auger depth profiles of the film (a) as-deposited, and (b) and (c) annealed at 120 and 360 °C for 3 h, respectively.

lattice diffusion in Ti or vice versa is unavailable, but the activation energy for lattice self-diffusion in Ni (Ref. 4) has been reported to be 2.27 eV. Typically, the activation energy for grain-boundary diffusion is significantly less than that for lattice diffusion: $\epsilon_{gb}\approx(0.4-0.7)\epsilon_{lat}$.[5] This suggests that grain-boundary diffusion between Ti and NiFe is dominant when T_A is below 450 °C. On the other hand, because the crystal structure is perfect enough before annealing, the

grain-boundary diffusion is restrained, so that the interdiffusion is very slow and D is small in our temperature range. It is confirmed that the AMR and H_s are not affected obviously by the anneal time t_A. Another result obtained is that the diffusion of Ti in NiFe is slower than that of Ta in NiFe reported by Hashim and Atwater.[2] Ti is a good material when used with sensor material NiFe magnetic layers.

In summary, our as-deposited $Ti/Ni_{81}Fe_{19}$ film possesses good texture, which results in high AMR and low saturation field. With annealing at 120 °C for 3 h, both maximum AMR, 3.1%, and minimum saturation field, 7.5 Oe, are obtained. The variation of AMR and H_s is small when T_A is in the 120–450 °C range. The diffusivity D and activation energy ϵ are estimated at about 2.0×10^{-17} cm^2/s and 1.69 eV, respectively. It is concluded that the interdiffusion between Ti and NiFe is very slow.

Magnetization reversal in compositionally modulated Tb/Fe multilayers (abstract)

Roger D. Kirby, J. X. Shen, and D. J. Sellmyer
Behlen Laboratory of Physics and Center for Materials Research and Analysis, University of Nebraska, Lincoln, Nebraska 68588-0111

We have prepared compositionally modulated Tb(X Å)/Fe(5 Å) thin film multilayers with X ranging from 3.5 to 7 Å by magnetron sputtering on glass substrates. Magnetization measurements using SQUID and alternating gradient force magnetometers show that these samples have uniaxial anisotropies (K_u) up to 10^7 erg/cm^3 and saturation magnetizations (M_s) between 50 and 350 emu/cm^3. Constant field magnetization reversal measurements at room temperature show that these samples reverse by slow nucleation followed by relatively rapid domain wall motion. The samples with larger uniaxial anisotropies and smaller saturation magnetizations reverse completely for applied fields less than the coercivity, while those samples on the other end of the spectrum do not. The magnetization reversal curves are correlated with the shapes of the hysteresis loops, and the experimental results are interpreted using a recently developed uniaxial anisotropy model of magnetization reversal.[1]

Remanence and coercivity in exchange coupled amorphous R-TM/Fe bilayers and multilayers (abstract)

Hong Wan, A. Tsoukatos, and G. C. Hadjipanayis[a)]
Department of Physics and Astronomy, University of Delaware, Newark, Delaware 19716

We have investigated the hysteresis behavior of rare-earth (R)-transition metal (TM) bilayers and multilayers consisting of a fine mixture of hard and soft phases. The films with bilayer thickness in the range of 5–100 Å were fabricated using a dc sputtering system. X-ray diffraction was used to check the crystal structure and multilayer structure. The magnetic properties were measured with a SQUID magnetometer in the temperature range of 10–300 K with fields up to 55 kOe. A strong exchange coupling between the hard magnetic phase (R-TM) and the soft phase (Fe) leads to a smooth hysteresis loop in samples with a certain thickness range. The remanent magnetization is enhanced significantly at the expense of a reduced coercivity. For example, in NdFe/Fe multilayer films, the reduced remanence increases from 0.63 to 0.92 at 10 K while the coercivity decreases from 9.3 to 1 kOe as the Fe layer thickness is varied from 0 to 10 nm. The effect of interface roughness on the exchange coupling has been investigated via different sputtering pressures and rates. The dependence of magnetic hysteresis on the layer thickness and temperature has been examined and the results will be reported.

Paramagnetic/ferromagnetic transition of Co/Cu(001) films during growth (abstract)

F. O. Schumann, M. E. Buckley, and J. A. C. Bland
Cavendish Laboratory, Madingley Road, Cambridge CB3 OHE, United Kingdom

We have investigated paramagnetism in epitaxial Co/Cu(001) films grown at room temperature in ultrahigh vacuum (UHV) using the transverse magneto-optical Kerr effect. These measurements are made possible by the very strong magnetic response[1] of a two-dimensional (2D) paramagnet, and in this way we have extended our previous study of the thickness dependent coercivity close to the magnetic phase transition.[2] The optical reflectivity was used to determine the thickness in reduced units d/d_c to better than 10% accuracy where the critical thickness d_c is determined by the onset of long-range order. In the paramagnetic region we observe a linear M-H curve with a sensitively thickness dependent saturation field H_s, which decreases to zero as the critical thickness d_c is approached. At the critical point, the onset of long range order is manifested by a strongly thickness-dependent coercive field H_c, which is found to increase from zero with thickness as a power law.[2]

Photothermally modulated ferromagnetic resonance investigations of epitaxially grown thin films (abstract)

R. Meckenstock, F. Schreiber, O. von Geisau, and J. Pelzl
Institut für Experimentalphysik III, Ruhr-Universität, 44780 Bochum, Germany

Photothermally modulated (PM) ferromagnetic resonance (FMR) is applied, for the first time, to locally investigate the magnetic anisotropy of thin epitaxially grown Fe and Co films. The PM-FMR measurements were performed at 9.2 GHz in an optical cavity. The microwave resonance absorption was thermally modulated by an intensity modulated laser beam and the change of the microwave power reflected at the cavity was synchronously detected by a lock-in amplifier. By focusing the laser beam a lateral resolution of 20 μm could be achieved. The PM-FMR signal was studied as a function of the position of the laser spot on the film, of the modulation frequency (10 Hz–10 MHz) and of the temperature. The PM-FMR measurements were complemented by temperature (5–700 K) and angle dependent conventional FMR studies. The temperature variation of the PM-FMR and its comparison with the behavior of the conventional signal yields evidence for a signal generation process of the PM-FMR that is governed by anisotropy effects. Therefore the local variation of the PM-FMR signal was used to deduce the lateral inhomogeneity of the magnetic anisotropy in the plane of the films.

Structural and magnetic characteristics of $Co_{81}Cr_{19}$/Al multilayers deposited by plasma-free sputtering with Kr gas (abstract)

Takakazu Takahashi
Department of Electronic and Computer Engineering, Faculty of Engineering, Toyama University, 3190, Gofuku, Toyama-shi, Toyama 930, Japan

Masahiko Naoe
Department of Physical Electronics, Faculty of Engineering, Tokyo Institute of Technology, 2-12-1, O-okayama, Meguro-ku, Tokyo 152, Japan

In multilayers deposited by sputtering, interfaces between each layer are necessary to be extremely sharp and flat. Therefore, the kinetic energy and number of sputtering gas atoms and ions recoiled from the target plane must be satisfactorily decreased. So, in this study, Kr, which is heavier than both Co and Cr in atomic weight, was used as a sputtering gas, while Ar used in conventional sputtering is lighter than them. The $Co_{81}Cr_{19}$/Al multilayers have been prepared on plasma-free glass slide substrate at room temperature by alternately depositing $Co_{81}Cr_{19}$ and Al layers, using the facing targets sputtering (FTS) apparatus. The thickness of $Co_{81}Cr_{19}$ layer $l_{Co\text{-}Cr}$ was varied in the range of 45–140 Å, while the thicknesses of Al layer l_{Al} were approximately 7 and 14 Å. The total layer thickness was in the range of 1450–1530 Å. It has been found from the small angle x-ray diffraction diagrams and the scanning electron microscope (SEM) images that the clear periodic structure could be formed in all specimen multilayers. In the multilayers with l_{al} of 7 Å, the $Co_{81}Cr_{19}$ layers were intrinsically composed of hcp phase crystallites with c-axis orientation $\Delta\theta_{50}$ normal to the layer plane ranging from 5.4 to 8.4. In the multilayers with l_{Al} of 14 Å, the $Co_{81}Cr_{19}$ layers seemed to be composed of hcp phase crystallites with very large $\Delta\theta_{50}$ of which value could not be estimated. However, for all specimen multilayers, the interplanar spacing between (002) planes $d_{(002)}$ were in the range of 2.033–2.038 Å. These values were nearly equal to those of $Co_{81}Cr_{19}$ single layer films (2.035 Å). M_s and H_c were significantly varied in the range of 500–1150 emu/cc and 35–260 Oe, respectively. In the multilayers with l_{Al} of 7 Å, $(Mr/Ms)_1$ was in the range of 0.28–0.36 and the perpendicular magnetic anisotropy was rather remarkable. On the other hand, in the multilayers with l_{Al} of 14 Å, $(Mr/Ms)_1$ was in the range of 0.61–0.7 and the in-plane magnetic anisotropy was significantly dominant. Co-Cr grains for l_{Al} of 14 Å were finer than those for l_{Al} of 7 Å. These results may indicate that the kinetic energy and number of atoms and ions recoiled from the target plane were significantly decreased by using Kr instead of Ar. So, the multilayers deposited by sputtering with Kr gas had excellently sharp and flat interfaces suitable for use of the apparent magnetoresistance effect.

Effects of exchange bond disorder on transport measurements

P. A. Stampe, H. Ma,[a] H. P. Kunkel, and G. Williams
Department of Physics, University of Manitoba, Winnipeg MB R3T 2N2, Canada

Measurements of the low field resistive anisotropy (LFRA) in amorphous $Fe_{91}Zr_9$ with and without hydrogen loading are presented. The temperature dependence of these data is compared with model calculations of the quadrupolar term $[\langle\langle S_Z^2\rangle_T\rangle_J - S(S+1)/3]$, from which it is concluded that the model calculations reproduce both the temperature and the exchange bond dependence of this transport coefficient.

I. INTRODUCTION

The influence of exchange bond disorder on the magnetic properties of interacting spin systems has been studied extensively from both an experimental and a theoretical standpoint for a number of year.[1,2] Briefly, in the frequently quoted approach[3] in which the exchange bond distribution is approximated by a Gaussian with first and second moments $\bar{J}_0$ and $\bar{J}$ respectively, models predict that the ground state of the system is a ferromagnet when the ratio $\eta=\bar{J}_0/\bar{J}\gg 1$, a spin-glass when $\eta<1$, while for $1<\eta<2$ sequential paramagnetic to ferromagnetic to (transverse) spin-glass transitions occur on cooling. Many of these predictions are in agreement with experiment; in systems with $\eta\gg 1$ a well defined paramagnetic to ferromagnetic phase transition is observed at temperature $T_c(\propto\bar{J}_0)$, often exhibiting asymptotic critical exponents close to the values predicted by the isotropic, 3d Heisenberg model[4] (in agreement with the Harris criterion[5]). Away from the critical point the influence of the exchange distribution can be seen in a marked temperature dependence of the effective exponent.[2,6] Experiments on systems with $\eta<1$ now appear to agree that a true phase transition occurs at temperature $T_{sg}(\propto\bar{J})$ marked by a divergence in the nonlinear response (reflecting a more complex order parameter/function). Experiments on sequential transitions, however, remain controversial.

By contrast much less effort has been directed towards understanding the transport properties of these systems; those few model approaches that have been investigated have focused primarily on the effects of disorder on scattering from low-lying collective excitations,[7,8] i.e., at temperatures well below the transition temperature.

Here we report the results of the effects of exchange bond disorder on a novel transport coefficient—the low field anisotropy in the magnetoresistance—and compare the results of model calculations with measurements on amorphous Fe_xZr_{1-x} ($x\simeq 0.1$) with and without hydrogen loading. Fe–Zr is a well-known system in which simple hydrogenation can convert a non-collinear ferromagnet to a uniform ferromagnet reflecting a narrowing of the exchange bond distribution (i.e., an increase in η).

II. DESCRIPTION OF MODEL

The low field resistive anisotropy (LFRA) is given by the ratio

$$\frac{\Delta\rho(H_a)}{\rho_0}=\left\{\frac{3[\rho_\parallel(H_a)-\rho_\perp(H_a)]}{\rho_\parallel(H_a)+2\rho_\perp(H_a)}\right\} \tag{1}$$

for a single small *applied* field $\mu_0 H_a$. This ratio differs from the more well established spontaneous resistive anisotropy (SRA), defined as

$$\frac{\Delta\rho(B)}{\rho_0}=\left\{\frac{3[\rho_\parallel(B)-\rho_\perp(B)]}{\rho_\parallel(B)+2\rho_\perp(B)}\right\}_{B\to 0} \tag{2}$$

in which the extrapolation implicit in Eq. (2) is not only based on the induction[9] B, but also utilizes the variation of $\rho_\parallel$ and $\rho_\perp$ above technical saturation in making this extrapolation[10]. We advocate the use of the former in characterizing the behaviour of spin systems near a potential transition where the application of a large field/induction can significantly alter the intrinsic spin configuration/polarization.

The occurrence of a magnetoresistive anisotropy requires two basic ingredients, an internal/external field to polarize the spin system and spin-orbit coupling (and hence an orbital component) at scattering centers. Both localized and itinerant models have been used to analyze the SRA, but the origin of the anisotropy is more easily understood and calculated from localized approaches. Orbital components are associated with non spherical charge distributions, and a multipole moment analysis of such a distribution indicates that the lowest order contribution to the anisotropy/asymmetry arises from the electric quadrupole moment (the electric dipole term vanishes in a central potential). The corresponding Hamiltonian $\mathscr{H}$ for conduction electron scattering from state $\mathbf{k}$ to $\mathbf{k}'$ can then be written as[11]

[a]Present address: Department of Electrical Engineering, University of Toronto, Toronto ON M5S 1A4, Canada.

 0021-8979/94/75(10)/6510/3/$6.00 © 1994 American Institute of Physics

$$\mathscr{H}=\sum_{\mathbf{k},\mathbf{k}'}\left[V+J\mathbf{S}\cdot\boldsymbol{\sigma}-\frac{D}{k_F^2}\{(\mathbf{S}\cdot\mathbf{k})(\mathbf{S}\cdot\mathbf{k}')-S(S+1)\mathbf{k}\cdot\mathbf{k}'/3\}\right]a_{k'}^{+}a_k \tag{3}$$

in which V represents the screened Coulomb potential at the scattering site, $J\mathbf{S}.\boldsymbol{\sigma}$ the familiar exchange/magnetic dipole coupling between a localized spin (S) and a conduction electron (spin $\boldsymbol{\sigma}$), with the final term describing scattering from the electric quadrupole moment D. In the often realized limit $V\gg J,D$ the associated anisotropy becomes[11]

$$[\rho_{\parallel}(B)-\rho_{\perp}(B)]/\rho_0\simeq\left(\frac{D}{V}\right)[\langle S_Z^2\rangle-S(S+1)/3] \tag{4}$$

as the first two terms in $\mathscr{H}$ are isotropic in polycrystal/amorphous systems; this anisotropy exhibits the familiar $(3\cos^2\theta-1)$ angular variation expected from quadrupolar effects with axial symmetry about the field direction[12].

The localized model that we have investigated utilizes an effective field Ising approach[13] incorporating a uniform external field h_a, random local spin–spin exchange coupling J_{ij}, and arbitrary spin quantum number S. The J_{ij}'s are assumed to be Gaussian distributed, as discussed above, leading to a set of coupled equations[14] for the thermal and exchange averaged magnetization $m=\langle\langle S_Z\rangle_T\rangle_J$ and the parameter $q=\langle\langle S_Z\rangle_T^2\rangle_J$:

$$\begin{aligned} m(h,T)&=(2\pi)^{-1/2}\int_{-\infty}^{\infty}SB_s(x)\exp(-\alpha^2/2)d\alpha;\\ q(h,T)&=(2\pi)^{-1/2}\int_{-\infty}^{\infty}S^2B_s^2(x)\exp(-\alpha^2/2)d\alpha \end{aligned} \tag{5}$$

in which the argument x of the Brillouin function $B_s(x)$ is given by $x=S(\tilde{J}_0m+\tilde{J}\alpha\sqrt{q}+h_a)/k_BT$. In such a model the thermal average implicit in Eq. (4) is replaced by the double average $\langle\langle S_Z^2\rangle_T\rangle_J$. Furthermore, due to the limitations imposed by the Ising characteristics of the model,[15] the ratio $\tilde{J}_0/\tilde{J}$ has been kept larger than 1.25 so that a paramagnetic to ferromagnetic transition alone occurs on cooling.

III. EXPERIMENTAL DETAILS AND RESULTS

The measurements presented here were carried out on a ribbon sample of amorphous $Fe_{91}Zr_9$ with and without hydrogen loading; details of the melt spinning[16] and loading[17] techniques have given previously. The specimens, of approximate dimensions $(32\times1\times0.02)$ mm^3, were mounted so that the measuring current flowed along the largest dimension, and the low field longitudinal ($\parallel$) and transverse ($\perp$) magnetoresistance measured (using an ac technique[17]) by rotating an electromagnet (the field was applied along the two larger sample dimensions). The remanent field of the magnet ($\mu_0H_r\simeq5$ mT) introduces no significant modification to either the intrinsic spin alignment or the conduction electron trajectories; basically it is used simply to render the sample single domain over distances comparable to a mean-free path.

Figure 1 summarizes measurements of the LFRA

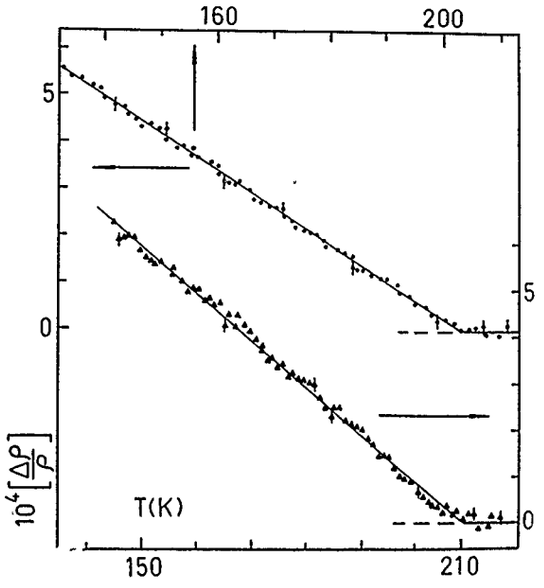

FIG. 1. The low field resistive anisotropy $\Delta\rho(H_r)/\rho_0$ plotted against temperature [T(K)] in the vicinity of the Curie temperature for amorphous $Fe_{91}Zr_9$ with (▲) and without (●) hydrogen loading. The lines drawn correspond to values of the coefficient $A(\eta)$ (see the text) of 21×10^{-4} and 16×10^{-4} respectively.

$[\rho_{\parallel}(H_r)-\rho_{\perp}(H_r)]/\rho_0$ in the temperature interval immediately below T_c. The latter temperature was estimated from the temperature at which the LFRA first vanished, and confirmed by detailed field and temperature-dependent ac susceptibility measurements.[18] This agreement, incidentally, confirms that the polarizing field in the present experiment is the exchange field, which collapses at T_c. Figure 1 clearly demonstrates that immediately below T_c the LFRA $\Delta\rho(H_r)/\rho_0$ can be expressed as

$$\Delta\rho(H_r)/\rho_0=A(\eta)(T_c-T)/T_c \tag{6}$$

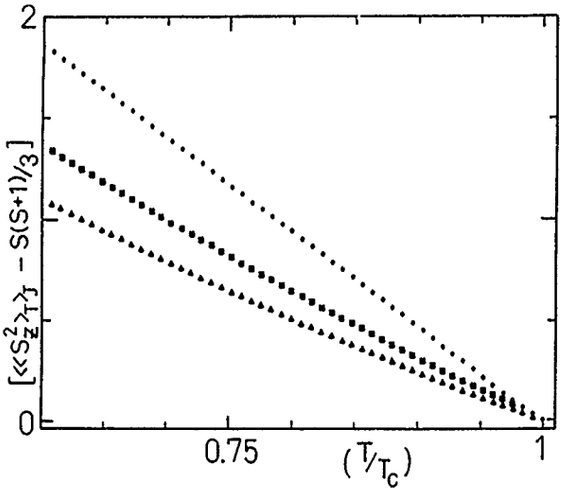

FIG. 2. The calculated variation of the quadrupolar term with reduced temperature for η values of 5 (●), 1.67 (■) and 1.25 (▲); these calculations use a local spin value of $S=5/2$ and an applied field of 5 mT (when $T_c=200$ K).

with the coeffient $A(\eta)$ increasing with hydrogen loading. The introduction of hydrogen is known to not only increase T_c (and hence $\bar{J}_0$—as can be seen from Fig. 1) but also to suppress the so-called reentrant transition,[19] thus reducing $\bar{J}$. Specifically then, the coefficient $A(\eta)$ increases as the ratio $\eta=\bar{J}_0/\bar{J}$ decreases. Additional measurements support this conclusion.[17,18]

Figure 2 reproduces calculations of the quadrupolar term $[\langle\langle S_Z^2\rangle_T\rangle_J - S(S+1)/3]$ plotted as a function of reduced temperature $t=T/T_c$, a natural parameter of the model described above. A comparison of Figs. 1 and 2 indicates that these model calculations not only reproduce the essentially linear increase of the LFRA with decreasing temperature immediately below T_c, but they also replicate the increase in the coefficient $A(\eta)$ (the slope of the plots shown in Fig. 1) with decreasing bond disorder, viz. increasing η.

It is important to bear in mind in making this comparison that it is the ratio $\Delta\rho(H_r)/\rho_0$ which is compared with the quadrupolar term. As indicated in Eq. (6), by taking this ratio the details of the band structure are removed as they contribute in the same way to both $\Delta\rho(H_r)$ and ρ_0; however as is also clear from this equation, the ratio of the two coupling constants (D/V) is involved in the relationship between the LFRA ratio and the quadrupolar term. In making the above comparison it is assumed that the term (D/V) is basically unchanged on hydrogenation, an assumption we suggest is reasonable based on the following observations. The amount of hydrogen introduced in the present experiment was deliberately kept small—we have no direct means of measuring the hydrogen uptake, but the increase in T_c following charging in the present experiment (~7 K) is far less than that accompanying complete loading[19] (~200 K). The room temperature resistivity was also monitered before and after charging, and it remained essentially unchanged between 120–125 $\mu\Omega$ cm within experimental error (typically $\leq$5%, due primarily to shape factor uncertainties). From this it is inferred that ρ_0—and hence V—remains unchanged, so that the above assumptions appear to be valid provided D is not significantly altered. We know of no direct means to estimate this parameter, but naive arguments suggest at least qualitatively that the introduction of impurities of low atomic number might be expected to weaken the overall influence of spin–orbit effects—and hence reduce the anisotropy—rather than enhance them as observed.

IV. CONCLUSIONS

Measurements of the LFRA in $Fe_{91}Zr_9$ with and without hydrogen loading are compared with model calculations of the quadrupolar term $[\langle\langle S_Z^2\rangle_T\rangle_J - S(S+1)/3]$. These calculations reproduce not only the linear increase in the LFRA with decreasing temperature immediately below T_c, but also the increase in magnitude of the LFRA with hydrogen loading. Such transport measurements can thus provide useful information on the extent of the exchange bond variance in disordered conductors. The full extent of this usefulness will be determined by future experiment and model calculation.

In ferromagnetic systems with random anisotropy (RA), long-range magnetic order is destroyed and the correlation function of the magnetization exhibits an exponential form e^{-r/R_f}, where the correlation length R_f corresponds to the size of Imry–Ma domains. Also, the law of approach to magnetic saturation follows a $1/\sqrt{H}$ law [ferromagnet with wandering axis (FWA) regime]. We have calculated the effect of magnetic correlations on the electrical resistivity and magnetoresistance of a RA ferromagnetic system at low temperatures. We find that in zero magnetic field RA introduces a positive contribution into the electrical resistivity, which increases with the anisotropy to exchange ratio, $D/\mathscr{J}$. In the FWA regime the magnetoresistance has a logarithmic dependence on the magnetic field with a slope $\Delta\rho/(\rho \ln H)$ inversely proportional to R_f. These features have been observed in an experimental study of the magnetoresistance at low temperatures ($T \approx 4$ K) of the amorphous series $(Dy_xGd_{1-x})Ni$ in which the $D/\mathscr{J}$ ratio can be varied from near zero up to one from GdNi to DyNi. A quantitative analysis of the results enables the direct determination of the correlation length R_f and of the volume of structural correlations Ω_c. We find that R_f varies from about 12 Å in DyNi up to 300 Å in $(Dy_{0.1}Gd_{0.9})Ni$ and Ω_c is the same throughout the series ($\Omega_c \approx 500$ Å^3) in excellent agreement with the values determined from magnetic measurements on the approach to saturation. These results provide an independent confirmation of the exponential decay with distance and field dependence of magnetic correlations in random anisotropy systems.

I. INTRODUCTION

Magnetic interactions make an important contribution to transport properties of metals, in particular in the vicinity of phase transitions, where magnetic correlations play a crucial role. These effects have been deeply investigated in the past,[1,2] both experimentally and theoretically. In the case of magnetic amorphous metals, in particular rare-earth-based random anisotropy systems, in which long-range ferromagnetic order is supressed by disorder, the situation is not so well understood. In fact, the theoretical studies of the magnetic contribution to the electrical resistivity done so far (Asomoza *et al.*,[3] Bhattacharjee and Coqblin,[4] Borchi *et al.*[5]) have always used severe approximations in the description of magnetic correlations, namely mean-field approximations beyond first neighbor distances.

Recent theoretical studies of the low-temperature ($T=0$) random anisotropy magnetism by Ignatchenko and Ishkakov[6] and Chudnovsky *et al.*[7] reached a thorough understanding of the interplay of magnetic and structural correlations in these systems, which are described by the HPZ Hamiltonian[8]

$$\mathscr{H} = -\frac{1}{2}\,\mathscr{J}\sum_{i\neq j}\sigma_i\cdot\sigma_j - D\sum_i(\mathbf{n}_i\cdot\sigma_i)^2 - \mathbf{H}\cdot\sum_i M_s\sigma_i. \tag{1}$$

$\mathscr{J}$ and D are the strengths of the exchange and random anisotropy interactions. The random anisotropy directions are given by the vector $\mathbf{n}_i$, and σ_i is the normalized magnetic moment at each site $\sigma_i = \mathbf{M}_i/M_s$.

Using a continuous version of this Hamiltonian it was shown that in zero magnetic field the reduced magnetic correlation function decays exponentially with distance:

$$\langle\sigma(\mathbf{r}_1)\cdot\sigma(\mathbf{r}_2)\rangle = \exp(|\mathbf{r}_1-\mathbf{r}_2|/R_f).$$

The magnetic correlation length R_f corresponds to the size of Imry–Ma domains[9] and is given by

$$\frac{R_f}{a} \approx \left(\frac{5\pi}{12}\right)\left(\frac{z\mathscr{J}}{D}\right)^2\left(\frac{a^3}{\Omega_c}\right), \tag{2}$$

where a is the distance between magnetic nearest neighbors (z) and Ω_c is the volume of correlation of random anisotropy directions (structural short-range order).

On the other hand, when a magnetic field is applied ($H<H_{ex}$, see below) and the system approaches saturation [ferromagnet with wandering axes (FWA) regime], the correlations between transverse components of the magnetization $[\sigma_\perp(\mathbf{r})]$ also decay exponentially, but with a new correlation length, R_H:

$\langle\sigma_\perp(\mathbf{r}_1)\cdot\sigma_\perp(\mathbf{r}_2)\rangle = \langle\sigma_\perp^2\rangle\exp(-|\mathbf{r}_1-\mathbf{r}_2|/R_H)$, where $\langle\sigma_\perp^2\rangle$ represents the reduced deviation of magnetic moments to saturation $\langle\sigma_\perp^2\rangle = 2(M_s-M)/M_s$ and varies like $1/\sqrt{H}$ in the FWA regime. The transverse correlation length is given by $R_H = R_f\langle\sigma_\perp^2\rangle = R_a\sqrt{H_{ex}/H}$, where $H_{ex} = z\mathscr{J}/6aM_sR_a^2$ and R_a is the structural correlation length ($\Omega_c \approx R_a^3$).

These predictions have already been confirmed experimentally, in particular with studies of the law of approach to saturation,[10,11] concerning the $1/\sqrt{H}$ dependence of the magnetization and neutron diffraction experiments,[7] as concerns the presence of exponential correlations and characteristic parameters, R_f and R_H.

II. THEORY

We have extended this treatment to the effects of magnetic correlations on the resistivity and magnetoresistance of

random anisotropy systems at low temperatures, considering the scattering of electrons by magnetic rare-earth ions of angular momentum J. For this calculation we used the approach of de Gennes and Friedel[12] for coherent magnetic scattering, which directly includes the Fourier transform of spatial magnetic correlation functions, including appropriate modifications for low temperatures.[3]

The magnetic contribution to the electrical resistivity at $H=0$ is given by

$$\rho_m(T=0,H=0)=\rho_M\left[c\,\frac{J}{J+1}+\frac{2\pi c^2}{(k_Fd)^3}\,F(2k_FR_f)\right]. \tag{3}$$

The first part represents the single ion contribution and the second one the effect of correlations, for which we define the function $F(x)=[\ln(1+x^2)-x^2/(1+x^2)]/x$. ρ_M is the spin disorder resistivity of the rare-earth magnetic ions (scattering at high temperatures), c is their concentration, k_F is the Fermi wave vector, and d is the average interatomic distance in the alloys. Notice that the magnetic correlations in random anisotropy systems always give rise to a positive contribution.

Under an applied magnetic field the expressions are more complex. In the FWA regime, where $R_H \propto 1/\sqrt{H}$ and as we have typically $(2k_FR_f)^2$, $(2k_FR_H)^2 \gg 1$, a considerable simplification can be achieved. One finally finds that the magnetoresistance $\Delta\rho/\rho$ has a logarithmic dependence on the magnetic field:

$$\Delta\rho(H)\approx \text{const}-\rho_M\,\frac{\pi c^2}{(k_Fd)^3k_FR_f}\,\ln H. \tag{4}$$

III. RESULTS

We present an experimental study of the low-temperature magnetoresistance of the random anisotropy amorphous series $(Dy_xGd_{1-x})Ni$ in which the $D/\mathcal{J}$ ratio can be varied from near zero (in GdNi) to about one (in DyNi) without sizeable structural and electronic changes. The characteristic magnetic parameters of these samples determined in previous studies[10,13,14] are presented in Table I. In Figs. 1 to 3 we present the magnetoresistance measured near 4 K in the samples $x=1$, 0.75, and 0.1. The logarithmic dependence is clearly observed, especially in the samples with larger $D/\mathcal{J}$ ratio. Notice that the magnetoresistance diminishes by a factor 15 from DyNi to $(Dy_{0.1}Gd_{0.9})Ni$.

To make a quantitative analysis of the results we note that the slope of the logarithmic field dependence is

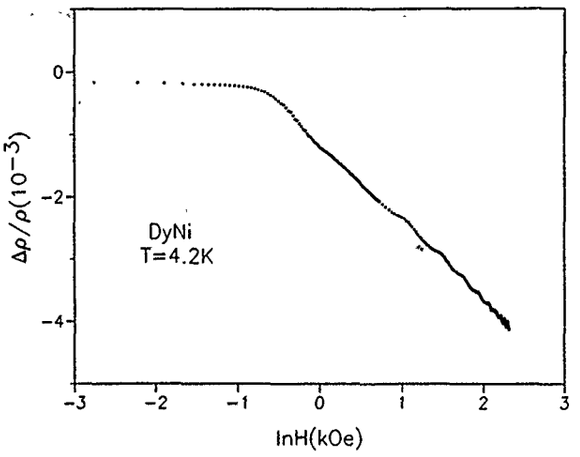

FIG. 1. Magnetoresistance of the sample DyNi as a function of the logarithm of the applied magnetic field.

$S_H=\Delta\rho/\rho \ln H=-\pi c^2\rho_M/\rho(0)(k_Fd)^3k_FR_f$, where $\rho(0)$ is the electrical resistivity of the samples (formally at $T=0$), for which we can take the room temperature value, 200 $\mu\Omega$ cm.[13]

To determine R_f we need to estimate the values of ρ_M and k_F for these alloys, and take the concentration of magnetic ions $c=0.5$. We assume that the magnetic ion contribution ρ_M varies linearly with x between the two ends of the series $\rho_M(\text{Gd})=125$ $\mu\Omega$ cm and $\rho_M(\text{Dy})=71$ $\mu\Omega$ cm, the experimental values for polycrystalline metals.[15] We use $\rho_M(x)=71x+125(1-x)$ $\mu\Omega$ cm. The value of k_F is estimated in a free electron approach as $k_F^3=3\pi^2z^*/d^3$, where z^* is the number of free-like electrons per atom[16] and d^3 is the average atomic volume. While in simple metals (Na, Cu, etc.) one can take z^* equal to the number of s electrons in their valence atomic orbitals ($z^*=1$ for Na, Cu, $z^*=2$ for Mg), in the case of transition metals or rare-earth metals with an incomplete d band (as Ni, Gd, Dy) the estimate of z^* is more delicate. In the Friedel band model, in which the d band density of states is approximated by a constant, one

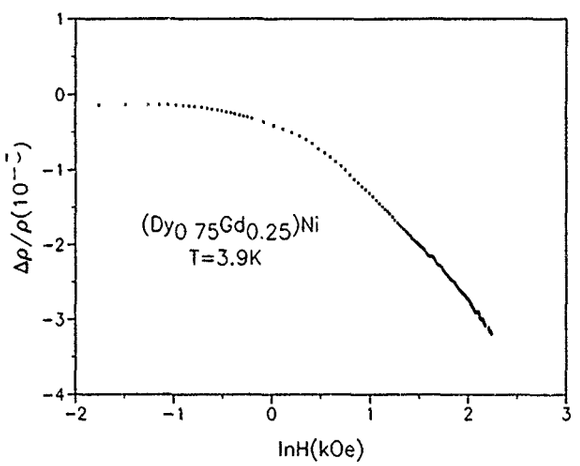

FIG. 2. Magnetoresistance of the sample $(Dy_{0.75}Gd_{0.25})Ni$ as a function of the logarithm of the applied magnetic field.

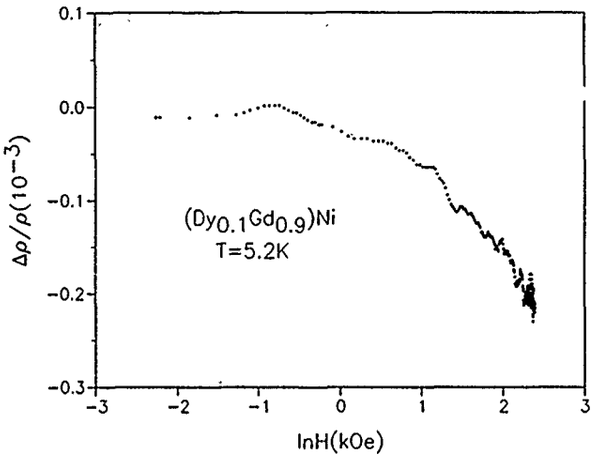

FIG. 3. Magnetoresistance of the sample $(Dy_{0.1}Gd_{0.9})Ni$ as a function of the logarithm of the applied magnetic field.

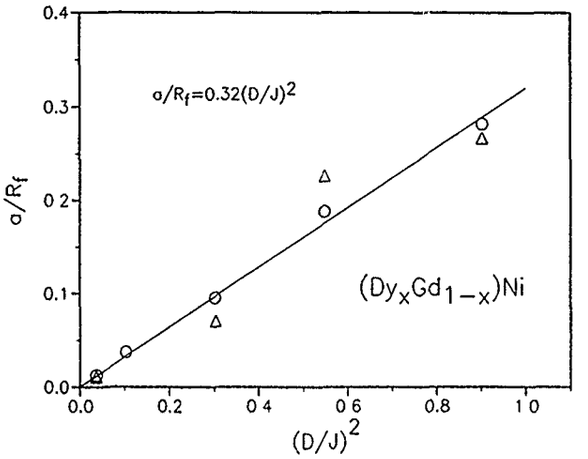

FIG. 4. Variation of the ferromagnetic correlation length R_f with $D/\mathscr{T}$. Circles and triangles represent the values obtained from magnetization and magnetoresistance studies, respectively. The linear dependence shows that the structural correlation volume Ω_c is the same throughout the series ($\Omega_c = 16a^3 \approx 510$ Å^3).

obtains the following values for the number of electrons in parabolic bands ($z^*=0.81$ for Ni and $z^*=0.54$ for La, which is adequate for Gd and Dy). Values of z^* lower than the chemical valence are experimentally confirmed by transport properties, like the Hall effect in Fe–Au and Ni–Au alloys[17] which give $z^*=0.6$ for Fe and Ni. We therefore estimate $z^*=0.6$ for all the samples, and from this we obtain $k_F d=2.6$.

The values of R_f determined from magnetoresistance are presented in Table II. The normalization R_f/a is obtained by noting that $d^3=0.5a^3$.

We notice a remarkable agreement between the values of the magnetic correlation lengths obtained from both procedures. This is clearly apparent in Fig. 4, where we present both values as a function of $(D/\mathscr{T})^2$. Both data sets have the best fitted straight line, $a/R_f=0.32(D/\mathscr{T})^2$. Using Eq. (2) and number of nearest neighbors $z^*=6$, we also find that the structural correlation volume Ω_c is constant through the series $\Omega_c=16a^3\approx 510$ Å^3, in agreement with x-ray determinations.[10]

IV. CONCLUSIONS

We have shown that the characteristic magnetic correlations in random anisotropy alloys can also be related to electron transport properties and that the magnetic correlation length R_f and the structural correlation volume Ω_c can be obtained directly from magnetoresistance measurements. These results give additional confirmation of the approach developed by Chudnovsky *et al.* in which transverse magnetic correlations decay exponentially with the correlation length $R_H \propto 1/\sqrt{H}$ under an applied field. Furthermore they show the relevance of transport measurements in the study of disordered magnetic systems.

This work was partially supported by the JNICT/CNRS scientific exchange program.

In situ magnetic and structural analysis of epitaxial $Ni_{80}Fe_{20}$ thin films for spin-valve heterostructures

I. Hashim and H. A. Atwater
Thomas J. Watson Laboratory of Applied Physics, California Institute of Technology, Pasadena, California 91125

We have investigated structural and magnetic properties of epitaxial (100) $Ni_{80}Fe_{20}$ films grown on relaxed Cu/Si(100) seed layers. The crystallographic texture and orientation of these films was analyzed *in situ* by reflection high energy electron diffraction (RHEED), and *ex situ* by x-ray diffraction and cross-sectional transmission electron microscopy (XTEM). In particular, RHEED intensities were recorded during epitaxial growth, and intensity profiles across Bragg rods were used to calculate the surface lattice constant, and hence the film strain. XTEM analysis indicated that the epitaxial films had atomically abrupt interfaces. The magnetic properties of these epitaxial films were measured *in situ* using magneto-optic Kerr effect magnetometry. Large H_c (10–20 Oe) was observed for epitaxial $Ni_{80}Fe_{20}$ (100) films less than 10.0 nm thick whereas for larger thicknesses, H_c decreased to a few Oe with the appearance of a uniaxial anisotropy. Correlations were made between magnetic properties of these epitaxial films and the strain in the film.

INTRODUCTION

Permalloy ($Ni_{80}Fe_{20}$) heterostructures are of great interest for magnetoresistive devices based on anomalous antiferromagnetic (AF)-coupling and giant magnetoresistance (GMR) in $Ni_{80}Fe_{20}$/Cu multilayers[1] and spin-valves.[2] To date, all investigations of such $Ni_{80}Fe_{20}$ heterostructures have employed polycrystalline films with atomically rough interfaces where the interface roughness is of the same order as the nonmagnetic spacer layer thickness.[1,2] Since AF-coupling and GMR depend sensitively on $Ni_{80}Fe_{20}$/Cu interface structure and the film morphology, the magnetotransport properties of atomically abrupt epitaxial films should more clearly elucidate the underlying physics. With atomically abrupt film interfaces, it would be possible to fabricate thinner nonmagnetic spacer layers without the interface roughness being the limiting factor.[1] Furthermore, the growth of epitaxial single layer $Ni_{80}Fe_{20}$ films on silicon would be potentially of great interest for studying magnetotransport and for applications to magnetoresistive devices because of reduced interfacial and grain-boundary scattering.[3] Finally, the growth of epitaxial magnetic films and the effects of coherency strain on magnetic properties especially anisotropy and magnetic moment have been the object of many previous investigations.[4] In particular, magnetic properties of epitaxial Fe and Ni thin films on Cu(100) have been studied recently[5,6] whereas strain relaxation in epitaxial Ni(100) films on Cu(100) has been examined in the past by Matthews and Crawford.[7] However, unlike Ni and Fe, $Ni_{80}Fe_{20}$ possesses very little magnetocrystalline anisotropy ($\sim 10^3$ ergs/cm^3) and the primary source of anisotropy is uniaxial anisotropy induced during deposition.

Epitaxial $Ni_{80}Fe_{20}$(100) films were grown on relaxed Cu(100) seed layers, 10–50 nm thick, oriented epitaxially with respect to Si(100). Because of the relatively small lattice mismatch between $Ni_{80}Fe_{20}$ and Cu (1.85%), the $Ni_{80}Fe_{20}$ layers were semicoherent with the Cu seed layer. The epitaxy of Cu(100) at room temperature on H-terminated Si(100) has been the object of earlier investigations and has been successfully demonstrated to occur in high-vacuum and UHV conditions.[8–10] The crystallographic orientation for this epitaxy was found to be Cu(100) ‖ Si(100) with Cu[100] ‖ Si[110].[10] Furthermore, FeMn, which is typically used in spin valves to exchange bias one of the ferromagnetic layers,[2] has an epitaxial relationship with $Ni_{80}Fe_{20}$. Hence, epitaxial spin-valve heterostructures consisting of FeMn/$Ni_{80}Fe_{20}$/Cu/$Ni_{80}Fe_{20}$ were grown on Cu/Si(100). The magnetotransport properties of these heterostructures will be reported elsewhere.[12]

EXPERIMENTAL PROCEDURES

The basic elements of the sputtering system used for deposition, x-ray diffraction analysis, electron microscopy, magneto-optic Kerr effect (MOKE) system for magnetic *in situ* characterization, and RHEED measurements to determine the surface lattice constant and the strain in the films, are described elsewhere.[10,11] In particular, $Ni_{80}Fe_{20}$ films were deposited in the presence of an external magnetic field to induce a uniaxial anisotropy.[13]

EPITAXIAL STRAIN AND MAGNETIC PROPERTIES

For growth of an overlayer B on substrate A and for small misfit f ($\leq$10%) between lattice constants for A and B, the lattice of B may expand or contract to form a coherent interface with that of A. However, formation of such an interface is associated with a strain energy in the overlayer B. For large enough thicknesses, it becomes energetically more favorable to relieve this coherency strain energy by generation of misfit dislocations at the interface. The critical epitaxial thickness h_c for which this transition takes place is obtained by solving the transcendental equation:[14]

$$h_c = \frac{b}{8\pi f \cos\alpha}\left[\frac{1-\nu\cos^2\beta}{1+\nu}\right]\ln\left(\frac{4h_c}{b}\right), \qquad (1)$$

where b is the misfit dislocation Burger's vector, ν is the Poisson's ratio, β and α are the angles that the Burger's vector makes with the dislocation line and the direction normal to the dislocation line lying within the plane of the in-

 0021-8979/94/75(10)/6516/3/$6.00 © 1994 American Institute of Physics

terface, respectively: Substituting the lattice constant of $Ni_{80}Fe_{20}$ for b, $\alpha=\beta=60°$ which is often the case for fcc crystals, ν of 0.31 for Ni and misfit f for $Ni_{80}Fe_{20}$/Cu, h_c was found to be 4.1 nm from solving Eq. (1). With the onset of misfit dislocations above the critical thickness, the elastic strain in the film decreases as given by:[14]

$$\epsilon_{\parallel}=\frac{b^2}{8\pi h\cos\alpha}\left[\frac{1-\nu\cos^2\beta}{1+\nu}\right]\ln\left(\frac{4h_c}{h}\right). \tag{2}$$

As the above equation indicates, the elastic strain falls off approximately inversely with thickness h of the film. Thus, residual strain may persist in the film for thicknesses much larger than the critical thickness h_c.

Among the effects of coherency strain on magnetic properties, it has been well known that a perpendicular anisotropy can be induced in ultrathin films due to interaction with strain.[15] Furthermore, coherency strain can give rise to a biaxial in-plane stress which can couple to magnetic anisotropy via magnetostriction λ_{ij} of the thin film. However, it is well know that for Ni-Fe composition of 81% and 19%, respectively, the magnetostriction of NiFe thin films is near zero and isotropic, but nevertheless, still sensitive to the exact composition and texture of the film.[16]

Using linear elasticity theory, the in-plane stress due to coherency strain along ⟨100⟩ cubic axes in a coherent thin film can be expressed in terms of the elastic constants c_{ij} and the in-plane strain $\epsilon_{\parallel}$:[17]

$$\sigma_{\parallel}=\left[(c_{11}+c_{12})-\frac{2c_{12}^2}{c_{11}}\right]\epsilon_{\parallel}. \tag{3}$$

Substituting the elastic constants for Ni and the misfit f for $\epsilon_{\parallel}$, and λ for $Ni_{80}Fe_{20}$ (100)-textured films obtained from that reported by Klokholm and Aboaf,[16] $\sigma_{\parallel}$ was calculated using Eq. (3) and substituted in:

$$E_{me}=\tfrac{3}{2}\lambda\sigma\sin^2\theta \tag{4}$$

to estimate magnetoelastic energy E_{me} of $\sim 10^5$ ergs/cm^3 where θ is the angle between σ and the magnetization vector. This can be compared with the induced uniaxial anisotropy energy E_k for $Ni_{80}Fe_{20}$ which is typically $\sim 10^3$–10^4 ergs/cm^3. The fact that magnetoelastic energy associated with coherency strain is significantly higher than uniaxial anisotropy energy, suggests that for coherent films of $Ni_{80}Fe_{20}$, the former would be an important factor in governing magnetic anisotropy.

RESULTS AND DISCUSSION

Surface lattice constant measurements using RHEED shown in Fig. 1, were employed to observe the relaxation of the coherency strain in $Ni_{80}Fe_{20}$ films on Cu/Si(100). Due to the relatively small mismatch between Cu and $Ni_{80}Fe_{20}$ (1.85%) and the limited resolution of the camera used for recording RHEED images, it was difficult to accurately calculate the strain in the $Ni_{80}Fe_{20}$ film using this technique. Nevertheless, it can be observed from these studies that the $Ni_{80}Fe_{20}$ film relaxes to its bulk lattice constant after 4.5 nm.

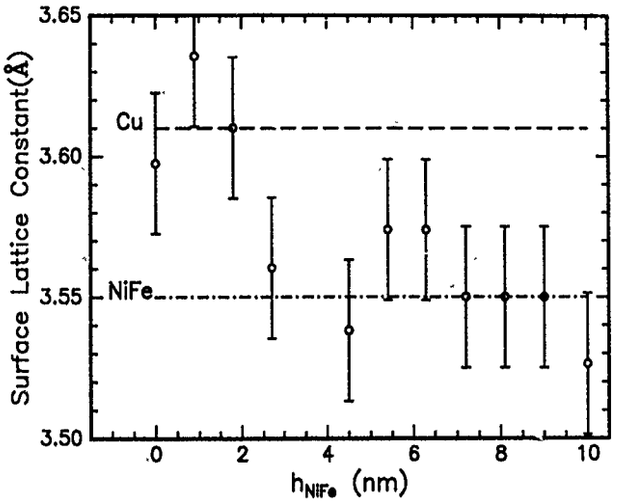

FIG. 1. Surface lattice constants as calculated from RHEED measurements of (100) $Ni_{80}Fe_{20}$ film grown on Cu/Si(100) as a function of film thickness.

No change in the RHEED intensity profiles was observed during epitaxial growth of $Ni_{80}Fe_{20}$ on Cu suggesting a layer-by-layer growth mechanism.

Figure 2 shows an x-ray scan for $\theta_i=30°$ for a $Ni_{80}Fe_{20}$ (30 nm)/Cu(30 nm)/Si(100) film which indicates that the (100) texture in the films is 2–3 orders of magnitude stronger than other fcc textures, notably (111). Furthermore, the lattice constants calculated from the diffraction spectrum confirm that the Cu and the $Ni_{80}Fe_{20}$ films are strain-relieved; i.e., have the bulk lattice constants.

Figure 3 shows a high resolution cross-sectional transmission electron micrograph of an epitaxial $Ni_{80}Fe_{20}$(50 nm)/Cu(50 nm)/Si(100) film along [110] Si in which metal lattice fringes can be seen extending from the Cu/Si interface to $Ni_{80}Fe_{20}$ film surface. The inset shows the selected area diffraction pattern due to (100) $Ni_{80}Fe_{20}$/Cu films and the Si substrate. The $Ni_{80}Fe_{20}$/Cu interface cannot be clearly seen in Fig. 3 due to lack of Z-contrast between $Ni_{80}Fe_{20}$ and Cu. However, it is discernible by the presence of Moiré fringes and misfit dislocations indicating a semicoherent interface between Cu and $Ni_{80}Fe_{20}$. Furthermore, a mosiac spread of

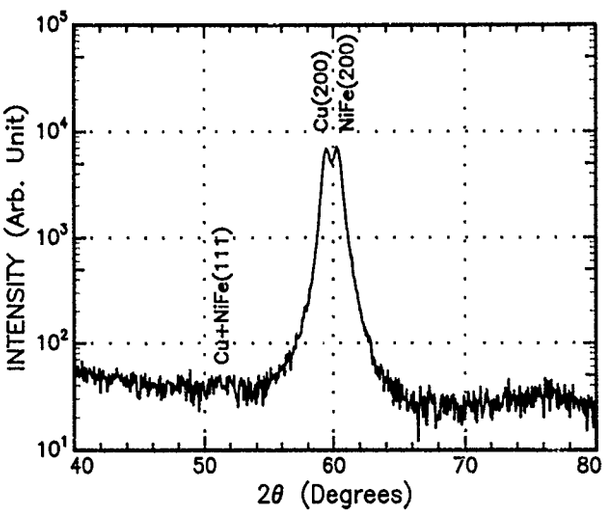

FIG. 2. Co K_α x-ray diffraction spectrum of epitaxial (100) $Ni_{80}Fe_{20}$(30 nm)/ Cu(30 nm)/Si(100).

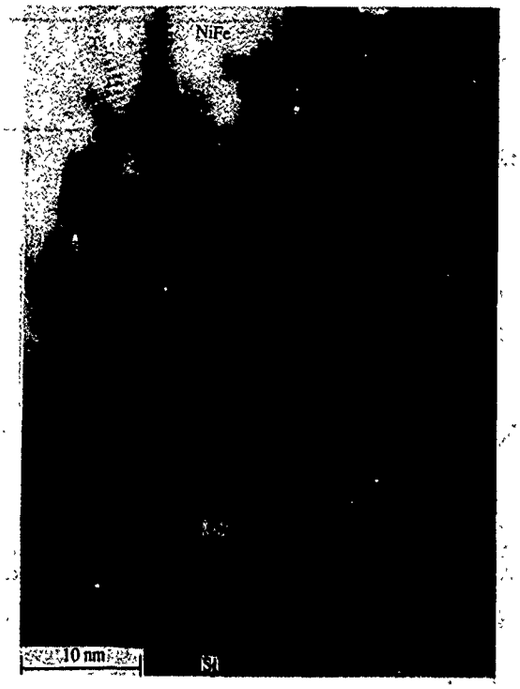

FIG. 3. High resolution cross-sectional transmission electron micrograph of epitaxial $Ni_{80}Fe_{20}$/Cu/Si(100) film along the Si[110] zone axis. The inset shows the diffraction pattern due to the film and the Si substrate.

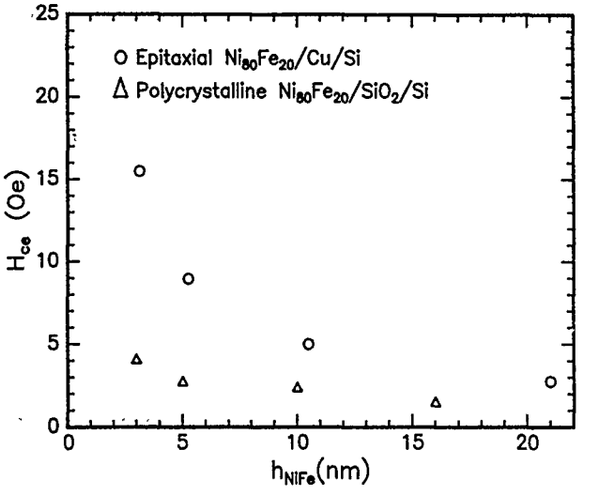

FIG. 4. Variation of H_c with $Ni_{80}Fe_{20}$ film thickness for epitaxial films on Cu/Si and polycrystalline films on SiO_2/Si.

up to ±6 ° in the (100) texture can be observed in the lattice fringes as well as the diffraction pattern due to the film. The smooth $Ni_{80}Fe_{20}$ film surface and the atomically abrupt Cu/Si interface suggest that the r.m.s. roughness of the epitaxial $Ni_{80}Fe_{20}$/Cu interface is few atomic layers. However, interdiffusion of Ni or Fe into Cu or vice-versa cannot be ruled out.

Magnetic properties of the epitaxial $Ni_{80}Fe_{20}$/Cu films, 2.0–20.0 nm thick, were measured using MOKE magnetometry. No MOKE signal could be detected for $Ni_{80}Fe_{20}$ films less than 2.0 nm thick. For films with thicknesses ≤10.0 nm, a biaxial anisotropy of ~10 Oe along the [100] crystallographic directions of $Ni_{80}Fe_{20}$ was observed which could be due to interaction with coherency strain as discussed earlier and/or magnetocrystalline anisotropy of $Ni_{80}Fe_{20}$. The coercivity for these films was 10–20 Oe which is rather high for $Ni_{80}Fe_{20}$. For random polycrystalline films deposited under the same conditions on SiO_2/Si, it was 1–2 Oe; see Fig. 4 for variation of H_c with film thickness for $Ni_{80}Fe_{20}$ films grown on Cu/Si and SiO_2/Si. Thicker epitaxial $Ni_{80}Fe_{20}$ films (≥ 10.0 nm) had an induced uniaxial anisotropy due to the external magnetic field applied during deposition. Furthermore, these films had relatively soft magnetic properties (H_{ce}=2.04 Oe, H_{ch}=0.22 Oe, and H_k=12.3 Oe) which were comparable to those of random polycrystalline $Ni_{80}Fe_{20}$ films. This indicates that these films are relatively strain-free and devoid of defects or pinning sites for domain walls. It is plausible that the thinner epitaxial films have voids or sources of localized stresses due to coherency strain, which cause domain wall pinning and hence, higher H_c. Investigations are currently under way to identify the nature of these defects using atomic force microscopy.

Magnetic and magnetoresistive properties of inhomogeneous magnetic dual-layer films

John O. Oti, Stephen E. Russek, and Steven C. Sanders
Electromagnetic Technology Division, National Institute of Standards and Technology, Boulder, Colorado 80303

Magnetic and magnetoresistive properties of sputtered Co alloy dual-layer films are compared with micromagnetic simulations. The simulations elucidate the details of the switching behavior of the dual-layer films as a function of the interlayer exchange and magnetostatic interactions. The simulations have led to a conceptual understanding of the coercive field splitting caused by the interlayer interactions. A calculation of the anisotropic magnetoresistance (AMR) has been included in the simulations. The AMR provides a second independent macroscopic quantity (in addition to the average magnetization) which can be measured and compared with the micromagnetic simulations. The AMR is more sensitive to the micromagnetic structure perpendicular to the applied field and is a better test of the accuracy of the micromagnetic model. The simulations qualitatively describe the measured AMR data on CoNi–Cr–CoNi dual layers.

INTRODUCTION

Magnetic multilayer thin films are becoming increasingly important in the development of high coercivity media[1] and low coercivity magnetic sensors.[2] Magnetic interactions within and between the layers of multilayer magnetic films play an important role in determining the properties of these films.[3] In this article we use our micromagnetic model[4,5] to analyze the micromagnetics of coercive field splitting (CFS) of the major hysteresis loops and introduce magnetoresistance calculations as a tool to provide further verification of the micromagnetic model. The results of the model simulations are compared with experimental data on sputtered $Co_{0.75}Ni_{0.25}$–Cr–$Co_{0.75}Ni_{0.25}$ dual-layer films.

In the micromagnetic model each magnetic layer is simulated by a rectangular array of discrete parallelepiped elements representing the grains of the layers. Each grain has a fixed magnitude magnetic moment which is allowed to dynamically relax (in three dimensions) in the presence of an external field, an effective exchange field, an effective anisotropy field, and a magnetostatic field. The magnetic layers are characterized by distributions of exchange, anisotropy, and magnetostatic parameters among the grains. The distribution of interlayer exchange coupling parameters, intralayer exchange coupling parameters, and magnetostatic interaction parameters are specified relative to certain mean values denoted, respectively, by $\langle C_e' \rangle$, $\langle C_e \rangle$, and $\langle C_{eh} \rangle$.[6] The parameters that are assigned to the grains are selected at random from an interval centered about the mean values. Ferromagnetic interlayer exchange coupling is simulated using positive interlayer exchange parameters, and antiferromagnetic interlayer exchange coupling is simulated using negative parameters.

The films discussed in this paper are ones with moderate intragranular exchange, strong uniaxial anisotropy, and strong disorder. The disorder in these films (principally the random distribution of anisotropy axes) acts to reduce the coercive field by providing nucleation centers for the magnetization reversal. One of the most prominent features of dual-layer magnetic thin films of this type is a splitting in the coercive fields as the two layers are brought together and allowed to interact through magnetostatic forces. At large separations, two statistically identical films will switch at approximately the same coercive field. As the films are brought closer, one film will switch first, as seen in the calculated and experimental $M-H$ curves shown in Figs. 1(a) and 1(c). We define the coercive field splitting as the difference between the top and bottom layer switching fields as determined by the distance between the peaks in the derivatives in the $M-H$ curves. The mechanism for CFS will be described in the next section.

The anisotropic magnetoresistance (AMR) can be simply modeled by assuming that each element has a change in resistance determined by the orientation of the magnetic moment relative to the current.[7] The normalized sheet resistance of the sample is

$$R_{\mathrm{AMR}} \approx \left[\sum_{j,\mathrm{par}} \left(\sum_{i,\mathrm{ser}} 1 + \delta r_{\mathrm{AMR}} (\hat{m}_{i,j} \cdot \hat{J})^2 \right)^{-1} \right]^{-1},$$

where $\hat{m}_{i,j}$ is a unit vector along the magnetic moment of the i,jth element, $\hat{J}$ is the direction of the current density, and δr_{AMR} is the normalized size of the anisotropic magnetoresistance. The inner summation sums the serial resistances in the direction of the current, and the outer summation sums them, reciprocally, transverse to the current. This formula does not include the effects of current redistribution and is appropriate only for systems, such as those discussed in this paper, in which the AMR is small. The average magnetization **M** and the AMR form a set of two independent macroscopic quantities which can be computed from the micromagnetic model and compared to experimental data. Examples of computed and measured AMR for a CoNi dual-layer film are shown in Figs. 1(b) and 1(d). The AMR is quadratic in **M** and measures the magnitude of the projection of **M** along the current direction. In particular the AMR can probe the degree of magnetization perpendicular to the applied field and is sensitive to the details of the magnetization reversal such as the formation of vortices.

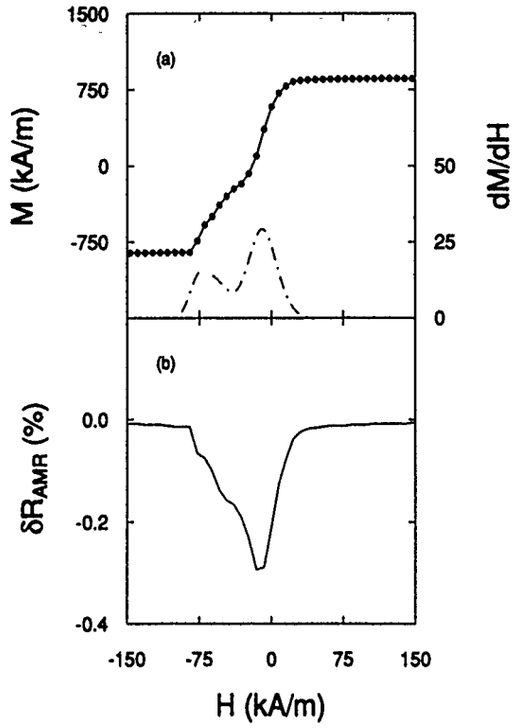

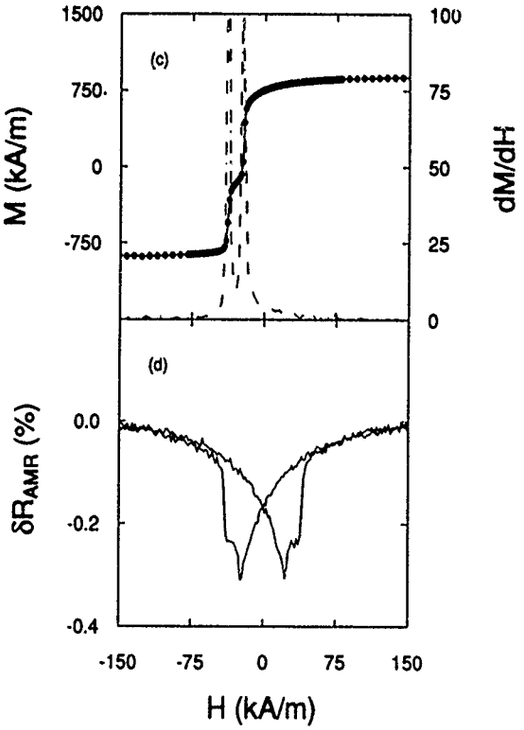

FIG. 1. (a) Calculated $M-H$ data of CoNi dual-layer film with an 8 nm Cr separation layer showing coercive field splitting (CFS). The CFS is equal to the distance between the peaks of the derivative of the magnetization (dotted curve). (b) Calculated AMR with **H** parallel to **J** for the same film. (c) Measured $M-H$ data for CoNi dual-layer film with 5 nm Cr separation layer showing CFS. The derivative of the magnetization is shown in the dotted curve. (d) Measured AMR with **H** parallel to **J** for the same film. Note that for clarity only one branch of the hysteresis loops are shown except for (d) which shows the full loop.

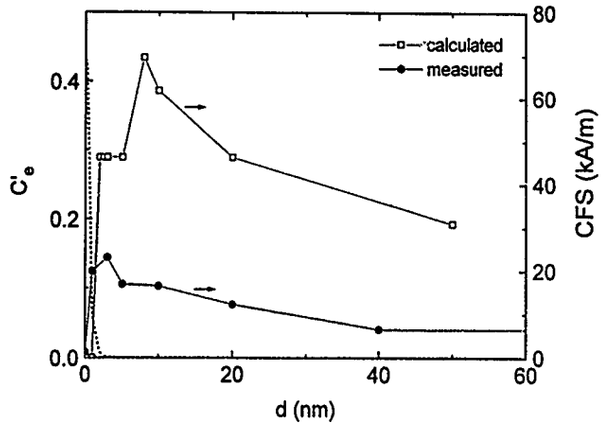

FIG. 2. Calculated and measured coercive force splitting as a function of interlayer separation d. The dotted curve on the left of the diagram represents the variation of C_e' with d.

SIMULATION AND EXPERIMENT

$Co_{0.75}Ni_{0.25}$–Cr–$Co_{0.75}Ni_{0.25}$ dual-layer films were sputter-deposited onto silicon substrates. The magnetic layers were each 30-nm thick, and the Cr layer thickness was varied from 1 to 80 nm. Details of the film preparation and the film microstructure are described in Ref. 4. The magnetic films are simulated by assuming a random distribution of the magnetic anisotropy axes with a uniaxial anisotropy field of H_k=193 kA/m (2420 Oe) and a median grain size of 22 nm. In Ref. 4, an array of 20×20 closely packed elements was used in simulating each magnetic layer of the sample. We have repeated the calculations using an array size of 50×50 elements. Periodic boundary conditions are used in the calculations to simulate the large experimental samples which have dimensions of 6×12 mm. The interlayer exchange coupling is a short-range interaction and drops off rapidly with increasing Cr spacing-layer thickness. We adopt a positive exchange constant (ferromagnetic coupling) with an exponentially decreasing form $\langle C_e' \rangle = 0.43 \exp(-2.0d)$, where d is the Cr spacing-layer thickness in nanometers. The dependence of the exchange coupling constant on spacer-layer thickness is shown in Fig. 2 (dotted curve). The same value of C_e' equal to the mean value was assigned to all the grains.

The simulations show that the magnetization reversal modes of the CoNi films are characterized by the formation and propagation of vortices in the magnetic layers. The vortices in the two layers form at different locations and different points in the hysteresis loops because of differences in their detailed microstructure. The centers of the vortices act as nucleation sites for local magnetization reversals, allowing the magnetization reversal to proceed along a low-energy path. The number of vortices in each layer initially grows with increasing externally applied field with little displacement from their original locations. Beyond a certain critical field, the vortices become extremely mobile and quickly self-annihilate, leading to complete reversal of the magnetization.

As the magnetic films are brought together they interact predominantly magnetostatically: free charges on one film attract opposite charges on the other film. The coercive fields

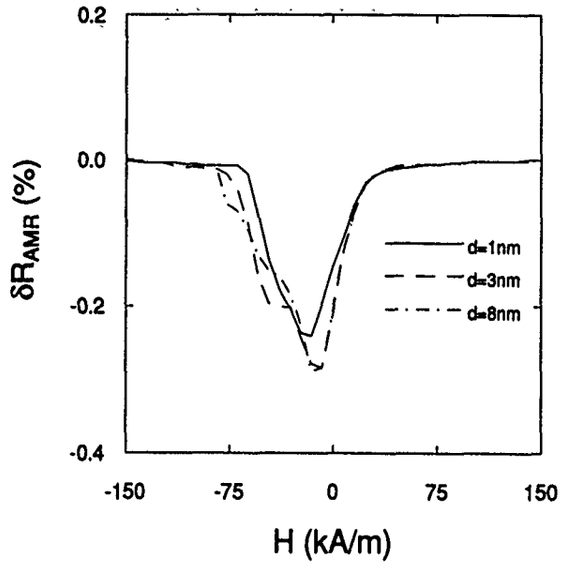

FIG. 3. Calculated AMR as a function of H for interlayer separations of 1, 3, and 8 nm (**H** is parallel to **J**).

split as shown in Figs. 1(a) and 1(c). The calculated and experimental dependence of CFS on the separation d between the magnetic layers is shown in Fig. 2. Agreement is seen in the trends of the calculated and experimental curves although magnitudes of the CFS differ. The magnitude of the CFS increases as the layers are brought together and the magnetostatic interaction increases. When the layers are sufficiently close that the exchange coupling dominates, the layers' moments are locked together and the CFS rapidly disappears.

The simulated AMR with **H** parallel to **J** is shown in Fig. 3 for different separations. The size of the AMR is directly related to the amount of magnetization perpendicular to the applied field. For smaller spacings, when the exchange interaction becomes important, the size of the AMR decreases because the layer that switches first, forces the other layer to have better registry and not have its moments lie outside the field direction.

DISCUSSION

The origin of the CFS can be understood by noting that the interlayer magnetostatic energy is a minimum in the disordered state when one of the layers has just switched and the other layer is about to switch. In this state, the disordered distribution of charges on one layer effectively compensate the disordered distribution of charges on the other layer. This magnetostatic energy minimum leads to the observed CFS, which consists of an extended stable region in which only one film has switched. An alternative approach to understanding the CFS is to realize that, as the layers begin to interact, they necessarily frustrate the other layer's ability to switch. When one layer begins to form a vortex in an energetically favorable location, it will cause, through the magnetostatic interaction, the other layer to reconfigure and not allow it to proceed along its lowest energy path. Therefore, when one layer switches it forces the other layer to proceed along another higher-energy path which requires a higher coercive field to switch the layer.

The coercive field splitting in the micromagnetic simulations is clearly magnetostatic in origin. The similarity of the hysteresis loops, AMR, and the dependence of the CFS on the separation layer thickness strongly suggests that the CFS seen in the experimental samples is also magnetostatic in origin. However, the interlayer exchange has not been measured in these samples, and a longer-range exchange interaction or an antiferromagnetic exchange interaction might be responsible for the observed behavior in the sputtered films. The observed splitting in the coercive fields can suggest that there is some stabilization of the antiferromagnetically aligned state and that there is antiferromagnetic exchange coupling between the layers. Often features similar to those seen in Fig. 1 have been interpreted as evidence of an antiferromagnetic exchange interaction. The results of this paper indicate that in many types of bilayer films these features can be of magnetostatic origin.

Further work needs to be done to quantify the output of the simulations (determining the correct energies and correlation functions to calculate) to obtain a better conceptual understanding of the effects of interactions in dual-layer magnetic thin films. The addition of AMR greatly improves our ability to test the accuracy of the simulations. While in the present work there is a size mismatch between the simulated sample (1 μm) and the measured sample (6 mm), this can be remedied in the future by fabricating and measuring micrometer-size samples. In this case there will be additional magnetostatic effects when the periodic boundary conditions are removed. The details of the reversal process in the range where the exchange and magnetostatic interactions are of comparable importance are still not clear, and a closer look at the micromagnetics in this range may be rewarding.

The enormous magnetoresistance effect at low temperatures in various uranium-based intermetallic compounds, which exceeds by far the effect found in magnetic-multilayer systems, is a consequence of the strong $5f$ conduction electron hybridization. The consequences of spin-dependent scattering for the giant magnetoresistance (GMR) effect in uranium intermetallics will be discussed and compared with the behavior in multilayer systems. Possible changes of the model parameters to achieve giant magnetoresistance (GMR) effects at higher temperatures, which are desirable for practical applications, are considered.

I. INTRODUCTION AND MOTIVATION

The occurrence of a large reduction of the electrical resistance upon application of a magnetic field in some magnetic-multilayer systems has attracted much attention in view of the possible applications (e.g., magnetic field sensor devices). As this reduction is much larger than the usual magnetoresistance effect in nonmagnetic and magnetic metals, one usually speaks about "giant magnetoresistance" (GMR) in this context. The GMR effect was originally discovered in Fe/Cr multilayers.[1] Since then, several other magnetic multilayer systems exhibiting the GMR effect have been found, which may be as large as $\Delta\rho/\rho=(\rho_{AF}-\rho_F)/\rho_F=65\%$ at room temperature and may exceed 110% at low temperatures (e.g., in Co/Cu multilayers[2]). The strong dependency on the layer thickness and interface mixing (roughness, etc.) reported (for a review see Ref. 3) request several special preparative conditions for multilayer "growth" like ultrahigh vacuum, good layer thickness control, etc. This is a serious drawback with respect to possible applications, because at present such conditions can be achieved only in rather specialized laboratories, so that applications seem to be far from practice.

On the other hand, there exists a second class of materials exhibiting the GMR effect, which was hardly noticed by research groups actually dealing with the GMR in multilayers. Recently, we have reported on the GMR in various uranium-based compounds, which crystallize in layered-like structures.[4–7] By driving these compounds through a metamagnetic transition towards an induced ferromagnetic alignment, a drastic reduction of the electrical resistivity is found, which exceeds that of multilayer systems by far and is as large as $\Delta\rho/\rho=650\%$ at 4.2 K in the case of UNiGa.[4,8] Although the GMR in the uranium compounds studied up to now is only present at low temperatures and (in most cases) relatively high magnetic fields, a deeper understanding of the mechanism responsible of the GMR effects in these materials could yield a considerable impetus in materials research.

In this contribution, we review the magnetoresistance effects observed in different UTX compounds (T=transition metal and X=p electron metal), which have been studied extensively on single crystals. The GMR effect found in UNiGa,[4,8] UNiAl,[5,8] UPdIn,[6,8] and UNiGe[7,8] will be compared with the effect in multilayer systems. The mechanism responsible for GMR in both types of systems and their main differences will be discussed.

II. EXPERIMENTAL RESULTS

Within an extensive research program on UTX compounds, we have studied the compounds crystallizing in the hexagonal ZrNiAl structure in most detail. The structure is built up by alternating U–T and T–X basal plane layers. For the compounds crystallizing in this structure, we find the uranium magnetic moments coupled ferromagnetically within the U–T planes, while the weaker interplane coupling is ferro- or antiferromagnetic leading to ordering with magnetic moments pointing in the c direction. In magnetic multilayers as well, ferromagnetically ordered layers are found, but in contrast to the uranium compounds here the magnetic moments are confined to the plane.

A typical example of uranium compounds is UNiGa, which orders antiferromagnetically at 40 K. Its antiferromagnetic ground state is characterized by a sequence of (++−−+−) orientations of equal magnetic moments. At low temperatures, UNiGa aligns ferromagnetically upon application of a magnetic field of about 1 T along the c axis. In the configuration $i\|B\|c$ axis, the metamagnetic transition toward the induced ferromagnetic alignment is accompanied by a drastic decrease of the resistivity, which exceeds 120 $\mu\Omega$ cm at 4.2 K (Fig. 1). This means a change of the resistivity $\Delta\rho/\rho$ equal to 650%. The effect in the perpendicular configuration $i\perp B\|c$ axis $\Delta\rho/\rho$ is smaller, but it still amounts to 200%. In both configurations, we observe a considerable hysteresis of about 0.25 T at 4.2 K (above 10 K there is no hysteresis observed), which reflects the hysteresis seen in the magnetization curves. No metamagnetic transition is observed for the

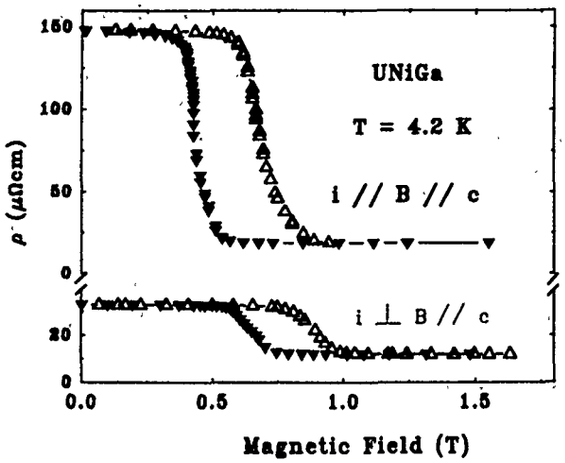

FIG. 1. Field dependence of the electrical resistivity of UNiGa at 4.2 K in the configuration $i \| B \| c$ axis and $i \perp B \| c$ axis. The open symbols represent the result obtained with increasing field, while the full symbols represent the one obtained with decreasing field. The lines are guides to the eye.

$B \perp c$ axis. As a consequence, there is also no comparable field effect in the electrical resistivity.

Another antiferromagnet with the ZrNiAl structure is UNiAl (Fig. 2), which orders antiferromagnetically at 18 K. At 4.2 K, the ferromagnetic alignment in this compound is achieved in fields above 11 T. Again, we find the metamagnetic transition to be accompanied by a drastic reduction of the electrical resistivity for fields applied along the c axis ($\Delta\rho/\rho$=425% for the $i \| B \| c$ axis and $\Delta\rho/\rho$=330% for the $i \perp B \| c$ axis). In UNiAl, the slow saturation tendency in the ferromagnetically aligned phase may originate from spin fluctuations present in this compound. In contrast to the previous compound, we do not observe any hysteresis.

Giant magnetoresistance effects in uranium intermetallics are not limited to pure antiferromagnets, which is illustrated by UPdIn, where an uncompensated antiferromagnetic structure with the stacking sequence (++−+−) is found

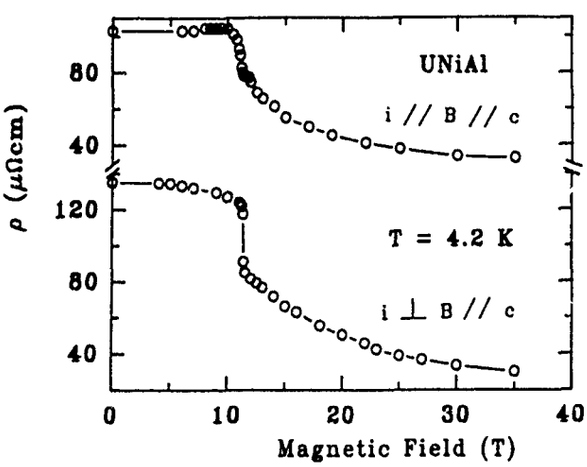

FIG 2. Field dependence of the electrical resistivity of UNiAl at 4.2 K in the configuration $i \| B \| c$ axis and $i \perp B \| c$ axis. The symbols represent the data points measured in fields, which were kept constant for at least 150 ms. The lines are guides to the eye.

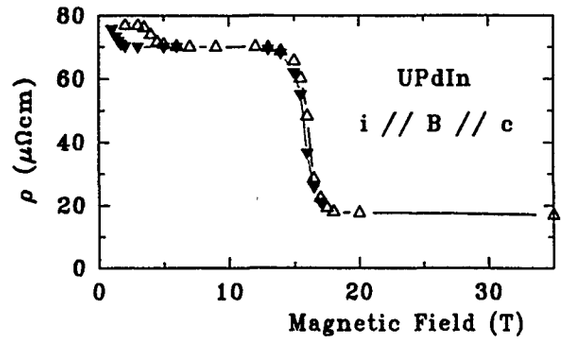

FIG. 3. Field dependence of the electrical resistivity of UPdIn at 4.2 K in the configuration $i \| B \| c$ axis. The open symbols represent the data points measured in fields, which were kept constant for at least 150 ms. below 8.5 K. At 4.2 K, the application of a magnetic field ($B \| c$ axis) yields a transformation of the magnetic structure of UPdIn to a structure with a stacking sequence (++−) in a field of about 3 T, which displays a hysteresis of about 1 T. The full ferromagnetic alignment is achieved above 17 T. Again, we find both metamagnetic transitions to be accompanied by a reduction of the electrical resistivity (Fig. 3). The total effect $\Delta\rho/\rho$ amounts to 350%.

The example of the antiferromagnet UNiGe, which crystallizes in the orthorhombic TiNiSi structure, shows that GMR effects are not restricted to a ZrNiAl structure-type of compounds. At 4.2 K, the destruction of the antiferromagnetic structure of UNiGe is reflected by two metamagnetic transitions at 3 and 9 T for the $B \| c$ axis (Fig. 4). For this compound, the total effect $\Delta\rho/\rho$ is equal to 290%. However, in contrast to the previous example an increased electrical resistivity is found for the intermediate phase between 3 and 9 T.

III. DISCUSSION AND CONCLUSIONS

In the ZrNiAl-type of compounds, the closer U–U distance and the stronger $5f$-d hybridization within the U–T layers lead to a much stronger magnetic coupling of the ura-

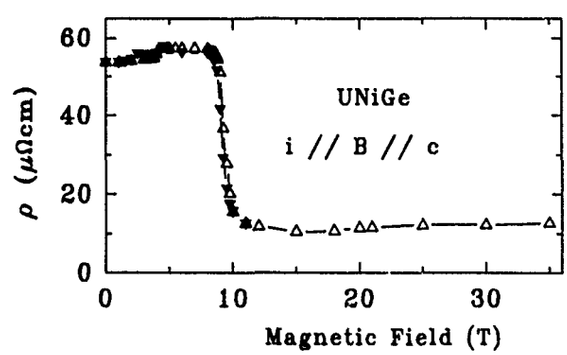

FIG. 4. Field dependence of the electrical resistivity of UNiGe at 4.2 K in the configuration $i \| B \| c$ axis. nium magnetic moments within the basal plane than along the c axis. For these compounds, the hybridization-induced exchange yields a strong ferromagnetic coupling within the plane, while the coupling along the c axis is much weaker. For TiNiSi-type of compounds, a similar situation is found, in this case with strong coupling along the a axis. In magnetic multilayers, one also finds strong ferromagnetic intralayer coupling and "weak" interlayer coupling, although in these systems the direction of the moments is confined within the layers. On the other hand, similar to the situation in magnetic multilayers, in the uranium antiferromagnets the weak antiferromagnetic coupling can be overcome by relatively low external magnetic fields, which is a necessary prerequisite of the GMR effect. The occurrence of GMR effects in multilayer systems is usually ascribed to spin-dependent scattering (for a review see Ref. 9). This raises the question, whether the GMR effect in uranium intermetallics also may be explained by this mechanism. In an antiferromagnetically ordered compound, spin-dependent scattering is thought to occur at defects. In particular, magnetic atoms occupying sites in the nonmagnetic layers may be effective scatterers (this is the analog of surface roughness in multilayer structures). However, in view of the expected number of such atoms and the estimated value of spin-disorder scattering per atom make this an unlikely mechanism to account for the observed effects. Therefore, the origin of such a spin-dependent scattering term in the electrical resistivity remains unclear. A possible mechanism would be electron–electron interactions. In order to understand why the GMR effect is larger in uranium compounds than in the multilayers, we have to consider the differences of both systems in this context. The most obvious difference is the "layer" thickness and quality (determined by the crystal structure). In contrast to multilayers, in uranium intermetallics we are dealing with a perfect sequence of monolayers. Therefore, we cannot invoke the picture of subband conductivities, where crossing an interface is said to lead to a switching between majority and minority bands, resulting in resistance. Instead, the influence of the antiferromagnetic order on the band structure has to be considered.

In this picture, the electrical resistivity in the antiferromagnetic state in the uranium intermetallics is determined by a term involving impurity scattering and by the presence of new Brillouin zone boundaries, which eliminate parts of the Fermi surface. In the ferromagnetically aligned state, the electrical resistivity of the uranium compounds is thought to be mainly determined by the impurity term, which might be reduced with respect to its value in the antiferromagnetic state, due to the alignment of impurity spins. An analogous reduction must occur in multilayers, so that this cannot explain the large GMR effect in uranium compounds. A drastic change in the topology of the Fermi surface, in the effective number of carriers and in the Fermi velocities would be necessary to account for the spectacular effects observed. If this explanation is correct, one may doubt whether the large GMR effects discussed above can ever be achieved in multilayer systems.

With respect to possible applications, the compounds discussed in this contribution incur some problems. Quite apart from the problem of introducing uranium in the household or office environment, these compounds have low ordering temperatures and (in some cases) high magnetic fields are necessary to obtain ferromagnetic alignment. However, it may be expected that upon substitution and variation of the composition these parameters can be modified easily. A second difficulty may be that the production of good-quality single crystals is sometimes even more difficult than the production of multilayers. However, to obtain the GMR effect there is no need for single crystals, which is indicated already by the large reduction of the electrical resistivity for current both parallel and perpendicular to the magnetic field. Palstra *et al.*[10] have indeed reported a reduction of the electrical resistivity of UNiGa polycrystal by 60%, which means $\Delta\rho/\rho=150\%$. Furthermore, it should be noted that neither uranium nor a layered-like structure appear to be really necessary ingredients for the occurrence of GMR effects, which was demonstrated by Schinkel *et al.* on FeRh alloys, where the electrical resistivity drops from 22 to 2 $\mu\Omega$ cm upon application of a magnetic field.[11]

In conclusion, the occurrence of GMR effect in uranium compounds emphasizes that there exist alternatives for application with respect to magnetic multilayers. At this stage, we try to get a deeper insight in the mechanism responsible for GMR effects in uranium systems, which could guide the search for compounds suitable for applications.

Preparation of Ni–Fe/Cu multilayers with low coercivity and GMR effect by ion beam sputtering

Masahiko Naoe, Yasuyoshi Miyamoto, and Shigeki Nakagawa
Department of Physical Electronics, Tokyo Institute of Technology, 2-12-1 O-okayama, Meguro, Tokyo 152, Japan

Multilayers composed of 30 [Ni–Fe/Cu] bilayers deposited on a 50-Å-thick Fe buffer layer were prepared by ion beam sputtering. The magnetoresistance (MR) ratio $\Delta\rho/\rho_0$ of the multilayers took high value at the Cu layer thickness δ_{Cu} of 10, 20, and 32 Å for the multilayers with Ni–Fe layer thickness δ_{Ni-Fe} of 10 Å. It was observed that (100) orientation of Ni–Fe and Cu crystallites were enhanced at δ_{Cu} of 20 and 32 Å. The multilayered film with δ_{Cu} of 10 Å exhibited $\Delta\rho/\rho_0$ as high as 12%. The multilayered film possessed good soft magnetic properties, and exhibited coercivity H_c and relative permeability μ_r of about 4 Oe and 800, respectively. The saturation magnetic field H_s was about 300 Oe. $\Delta\rho/\rho_0$, H_c, and H_s at δ_{Cu} of 20 Å, i.e., at the "second peak," were 6%, 10 Oe, and 25 Oe, respectively. The δ_{Cu} dependence of $\Delta\rho/\rho_0$ seemed to be correspondent to that of the preferential orientation of the (100) plane. Ni–Fe/Cu multilayers with the same construction but without an Fe buffer layer did not reveal apparent (100) preferential orientation and did not exhibit $\Delta\rho/\rho_0$ as high as detectable. Then, $\Delta\rho/\rho_0$ was strongly dependent not only on interlayer thickness, such as δ_{Cu}, but also (100) crystallite orientation.

I. INTRODUCTION

Giant magnetoresistance (GMR) effect has been successfully investigated for several multilayers such as Fe/Cr,[1] Co/Cu,[2,3] and Ni–Fe/Cu.[4–6] However, these GMR multilayers have exhibited high coercivity H_c above several hundreds Oe and saturation magnetic field H_s above 1 kOe. They should exhibit H_c and H_s as low as possible in order to apply them to MR heads and magnetic field sensors. Ni–Fe/Cu multilayers seemed to be applicable for these devices because of their soft magnetism with GMR effect. If the GMR multilayers possess soft magnetic properties applicable for the inductive recording heads, it seems to be very convenient to construct high efficient heads. Then, it is required to prepare GMR films with soft magnetic properties. There are several studies regarding low H_s in GMR multilayers.[7,8] In this study, the multilayers composed of Ni–Fe and Cu layers were prepared by an ion beam sputtering apparatus which can deposit the Ni–Fe layer with low coercivity H_c and saturation magnetic field H_s and the Cu layer without defects on plasma-free substrate at low gas pressure.

II. EXPERIMENTAL PROCEDURE

Specimen multilayers were deposited on Si(100) wafer substrates by sputtering $Ni_{81}Fe_{19}$ alloy and Cu metal targets alternately by the ions extracted from a Kaufman-type of ion source. Ar gas pressure and acceleration of the ions for sputtering were set at 0.1 mTorr and 500 V, respectively. 50-Å-thick Fe buffer layers were predeposited on the substrates before preparation of the multilayers. Deposition rates of Ni–Fe and Cu layers were 14 and 23.5 Å/min, respectively. Multilayers were composed of 30 [Ni–Fe/Cu] bilayers. Crystallographic structure was analyzed by x-ray diffractometry (XRD). Magnetic characteristics, such as H_c and the saturation magnetization M_s were evaluated by a vibrating-sample magnetometer (VSM). The relative permeability μ_r were measured at 4 MHz by the shunt core method. The MR of the multilayers was measured by the four probe method at room temperature.

III. RESULTS AND DISCUSSION

It is well known that the GMR effect is sensitive to the thickness of the interlayer between ferromagnetic layers. Then, multilayered films were constructed with 30 bilayers composed of Ni–Fe layers with thickness δ_{Ni-Fe} of 10 Å and Cu layers with thickness of δ_{Cu} in the range of 5–34 Å. Figure 1 shows the variation of XRD patterns of multilayered films with various δ_{Cu}. These patterns implied that the preferential orientation of crystallites in Ni–Fe and Cu layers were so sensitive to δ_{Cu} for δ_{Ni-Fe} of 10 Å. It seemed that the (100) orientation of Ni–Fe and Cu crystallites were enhanced at δ_{Cu} of 20 and 32 Å. The enhancement of the (100) preferential orientation seemed to follow certain periodicity. Figure 2 shows the δ_{Cu} dependence of the ratio of the (200)

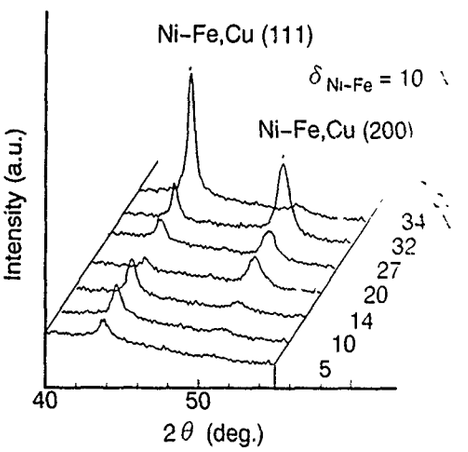

FIG. 1. Variation of XRD patterns of multilayered films for films with various δ_{Cu}.

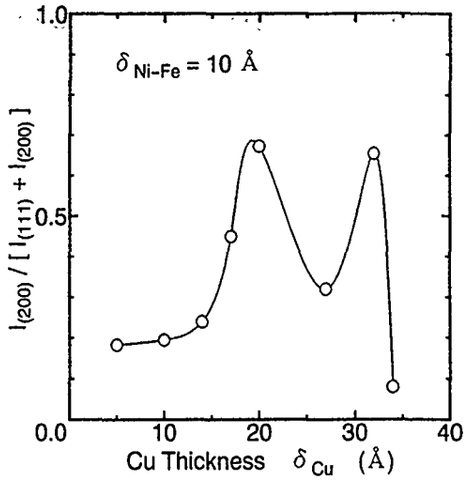

FIG. 2. δ_{Cu} dependence of the ratio of (200) diffraction intensity $I_{(200)}/[I_{(111)}+I_{(002)}]$.

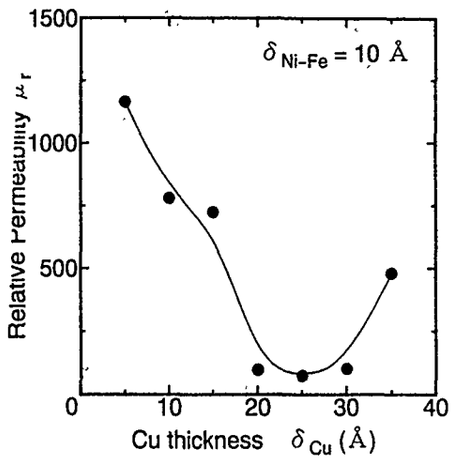

FIG. 4. δ_{Cu} dependence of μ_r multilayers.

diffraction intensity $I_{(200)}$ to the total of diffraction intensities of $[I_{(111)}+I_{(002)}]$. It was clearly found that the enhancement of (100) orientation occurred at δ_{Cu} of 20 and 32 Å.

Figure 3 shows the δ_{Cu} dependences of the MR ratio $\Delta\rho/\rho_0$ and the coercivity H_c. $\Delta\rho/\rho_0$ took a high value at δ_{Cu} of 10, 20, and 32 Å. Such a high $\Delta\rho/\rho_0$ seemed to be attained in the film with (100) orientation in crystallites as shown in Fig. 2. $\Delta\rho/\rho_0$ at δ_{Cu} of 10 Å, i.e., at first peak, was 12%. H_c as low as about 4 Oe at δ_{Cu} of 10 Å. The $\Delta\rho/\rho_0$ saturation magnetic field H_s was about 300 Oe. It had been confirmed that these multilayers exhibited almost the same $\Delta\rho/\rho_0$ and quite low H_c compared with other multilayers. The δ_{Cu} dependence of $\Delta\rho/\rho_0$ seemed to be correspondent to that of preferential orientation of the (100) plane as mentioned above. On the other hand, $\Delta\rho/\rho_0$, H_c, and H_s at δ_{Cu} of 20 Å, i.e. "at second peak," were 6%, 10 Oe, and 25 Oe, respectively. The films with δ_{Cu} larger than 20 Å possessed revealed slightly semihard magnetism. Figure 4 shows the δ_{Cu} dependence of the relative permeability μ_r of the multilayers. The films with δ_{Cu} lower than 20 Å seemed to exhibit relatively high μ_r. It should be very attractive that the film with δ_{Cu} of 10 Å, i.e., at first peak, exhibited μ_r as sufficiently high as about 800. Figure 5 shows the typical $M-H$ hysteresis loops of the film at first peak, namely with δ_{Cu} and δ_{Ni-Fe} of 10 and 10 Å, respectively. Although a little magnetic anisotropy was detectable, the coercivities H_c were low enough in any direction. It was confirmed that the multilayers at first peak exhibited not only high $\Delta\rho/\rho_0$, but also good soft magnetism applicable for magnetic recording heads.

On the other hand, the Ni–Fe/Cu multilayers with the same construction but without an Fe buffer layer did not reveal apparent (100) preferential orientation and did not exhibit sufficiently high $\Delta\rho/\rho_0$. Then $\Delta\rho/\rho_0$ seemed to be strongly dependent not only on interlayer thickness, such as δ_{Cu}, but also on (100) orientation of both crystallites. In other words, the Fe buffer layer had played an important role for promotion of (100) orientation and enhancement of GMR effect in the multilayers. Figure 6 shows the XRD patterns for two types of films. One is a thick Ni–Fe single layer with δ_{Ni-Fe} of 1000 Å and the other is a double layer composed of a thick Ni–Fe layer with δ_{Ni-Fe} of 500 Å and an Fe buffer

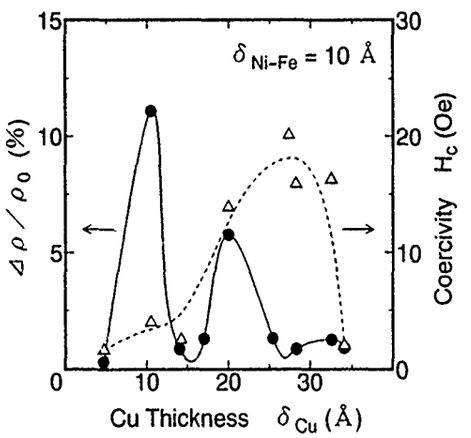

FIG. 3. δ_{Cu} dependences of the MR ratio $\Delta\rho/\rho_0$ and coercivity H_c.

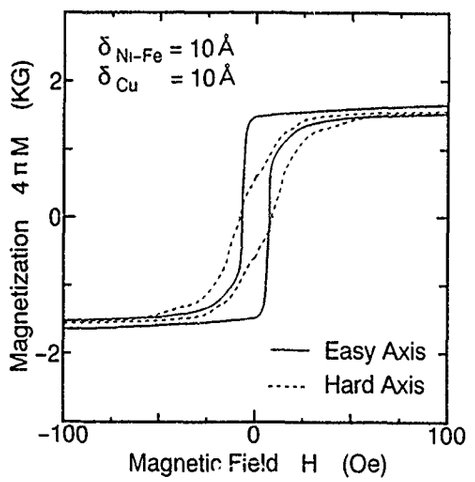

FIG. 5. Typical $M-H$ hysteresis loops of film at first peak, namely with δ_{Cu} and δ_{Ni-Fe} of 10 and 10 Å, respectively.

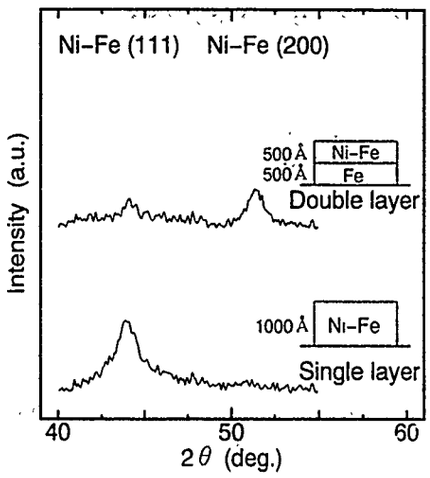

FIG. 6. XRD patterns for films of Ni–Fe single layer and Ni–Fe/Fe double layer.

layer with thickness of 500 Å. Although the Ni–Fe single layer revealed only apparent (111) orientation, the Ni–Fe layer with an Fe underlayer revealed (100) orientation. It was concluded that the Fe buffer layer promoted the (100) orientation in Ni–Fe fcc crystallites deposited on it.

IV. CONCLUSIONS

Multilayers composed of 30 [Ni–Fe/Cu] bilayers deposited on a 50-Å-thick Fe buffer layer were prepared by ion beam sputtering in order to attain a high MR ratio and possess a soft magnetism applicable to recording heads. The results obtained are as follows:

(1) (100) orientation of Ni–Fe and Cu crystallites in the multilayers were enhanced at δ_{Cu} of 20 and 32 Å. The δ_{Cu} dependence of $\Delta\rho/\rho_0$ seemed to be correspondent to that of a preferential orientation of the (100) plane.

(2) $\Delta\rho/\rho_0$ took a high value at δ_{Cu} of 10, 20, and 32 Å. For example, $\Delta\rho/\rho_0$ at δ_{Cu} of 10 Å was as high as 12%. H_c and μ_r were about 4 Oe and 800, respectively. $\Delta\rho/\rho_0$, H_c, and H_s at δ_{Cu} of 20 Å, i.e., at second peak, were 6%, 10 Oe, and 25 Oe, respectively.

(3) Ni–Fe/Cu multilayers with the same construction but without an Fe buffer layer did not reveal apparent (100) preferential orientation and did not possess $\Delta\rho/\rho_0$ as high as detectable. $\Delta\rho/\rho_0$ was strongly dependent on not only interlayer thickness, such as δ_{Cu}, but also (100) crystallites orientation.

As a result, we have succeeded in prepare, GMR multilayers with sufficiently soft magnetic properties suitable not only for detecting as a MR head but also for writing it as an inductive head. Then these multilayers seemed to be applicable for a core layer in inductive-MR hybrid type of recording heads.

Novel magnetoresistance behavior in single trilayer spin valves

M. Patel, T. Fujimoto, E. Gu, C. Daboo, and J. A. C. Bland
Cavendish Laboratory, University of Cambridge, Madingley Road, Cambridge CB3 0HE, United Kingdom

Single trilayer spin valves consisting of uncapped FeNi(60 Å)/Cu(60 Å)/Co(40 Å) have been grown using ultrahigh vacuum (UHV) electron beam evaporation methods. Room temperature magnetoresistance (MR) measurements exhibit well defined plateaux corresponding to the full antiparallel alignment of the FeNi and Co magnetizations. This sharp switching behavior and precisely defined antiferrimagnetic state is in contrast with the corresponding behavior reported for FeNi/Cu/Co multilayers.

INTRODUCTION

The discovery of the giant magnetoresistance (GMR) effect[1] has fuelled intense research into the properties of artificially engineered magnetic multilayers. Soft magnetic multilayers such as $Fe_{20}Ni_{80}$/Cu/Co[2] are of particular interest for their GMR behavior in low fields, in contrast with systems such as Fe/Cr and Co/Cu which saturate at high fields. In the present work we have utilized UHV electron beam evaporation growth techniques together with *in situ* magneto-optic Kerr (MOKE) magnetometry and reflection high-energy electron diffraction (RHEED) studies. We report the observation of sharp, independent magnetic switching for the two layers in the trilayer system $Fe_{20}Ni_{80}$/Cu/Co, corresponding to plateaux in the magnetoresistance (MR). In our samples a field of about 10 Oe aligns the layers antiparallel, and we believe this is the first direct observation of a definite antiparallel state in this system. We attribute the realization of the antiferrimagnetic state to the uniaxial anisotropy induced by using MBE growth techniques. We show that the single trilayers exhibit very different properties from the work reported on multilayers. The independent switching and well defined antiferrimagnetic state give rise to near ideal spin-valve[3] behavior in our samples, which we investigate in detail.

The samples we have studied in all cases consist of a single trilayer of FeNi (60 Å)/Cu(60 Å)/Co(40 Å) grown on Si(100) and As-capped GaAs(001) substrates in a UHV chamber using electron beam evaporation techniques. *Ex situ* transmission electron microscopy (TEM) was used to characterize samples post growth, and revealed a polycrystalline structure with a grain size of 10 nm. In addition the MOKE measurements revealed that the first 30 Å of the FeNi was nonmagnetic, and RHEED and cross section transmission electron microscopy (XTEM) have indicated that a reaction occurs with the Si substrate to form a rough, amorphous layer consistent with other reports.[4,5] Samples were deposited at ambient temperature (~50 °C) onto Si(100) and GaAs(001) wafers at a pressure not exceeding 5×10^{-8} mbar. Substrates were cleaned in an ultrasonic bath using IPA prior to insertion into the vacuum system. The depostion rates were typically 1, 5, and 2 Å/min for FeNi, Cu, and Co, respectively. The chamber was then vented and a CoO layer was allowed to form by oxidation of the Co surface layer. The thickness of the CoO layer was determined to be 20 Å by both SQUID magnetometry and polarized neutron reflectometry (PNR) measurements.[6]

Ex situ MR measurements were carried out using a four-point in-line geometry, at both room temperature and below using a continuous flow He cryostat. Room temperature measurements were also carried out by varying the angle between the two layer magnetizations to investigate the spin-valve effect, from which the GMR and anisotropic magnetoresistance (AMR) terms can then be isolated.

RESULTS

Figure 1 shows the *in situ* MOKE loops obtained during the growth of the sample. The loops obtained on the completed sample (a) show that the separate layers switch independently along the [100] axis, in contrast to the results of other studies on this system.[2] This sharp switching is realized by the presence of a uniaxial anisotropy in both layers, as evidenced by the [010] axis behavior. The anisotropy axes for the two layers are found to be rotated slightly from each other, and their directions are independent of any magnetic fields applied during growth or the substrate orientation. The abrupt switching behavior has been observed to deteriorate with increasing number of periods of the trilayer, and this suggests that the increasing waviness or roughness of the successive interfaces has a dramatic effect on the coupling between the ferromagnetic layers. This is consistent with recent reports on sputtered samples.[7]

From Fig. 1(b), the presence of a weak ferromagnetic exchange coupling between the FeNi and Co layers is also indicated by the increase of the FeNi layer coercivity upon Co deposition on the Cu interlayer. Figure 1(c) shows the effect of the CoO layer which forms almost instantaneously upon venting the chamber. The Co layer coercivity is seen to increase due to either weak exchange coupling to the paramagnetic oxide (the Néel temperature for CoO is 293 K)[8] or pinning by structural defects formed during the oxidation process.

Figure 2(a) shows the superimposed MR and MOKE loops for a trilayer grown on Si(100). At point A, the layer magnetizations are both aligned parallel. At point B, the applied field is greater then the saturating field of the FeNi layer, but less than the coercive field of the Co layer. As a result, the layers are aligned antiparallel, and a true antiferrimagnetic state is realized as has also been confirmed by SQUID and vibrating-sample (VS) magnetometry. At point C, the Co layer has also switched and so the layers are aligned parallel again. The MR behavior shows that when the layers are aligned parallel the resistance is a minimum, and that when the trilayer is in the antiferrimagnetic configuration the MR exhibits plateaux. Figure 2(b) shows the sensi-

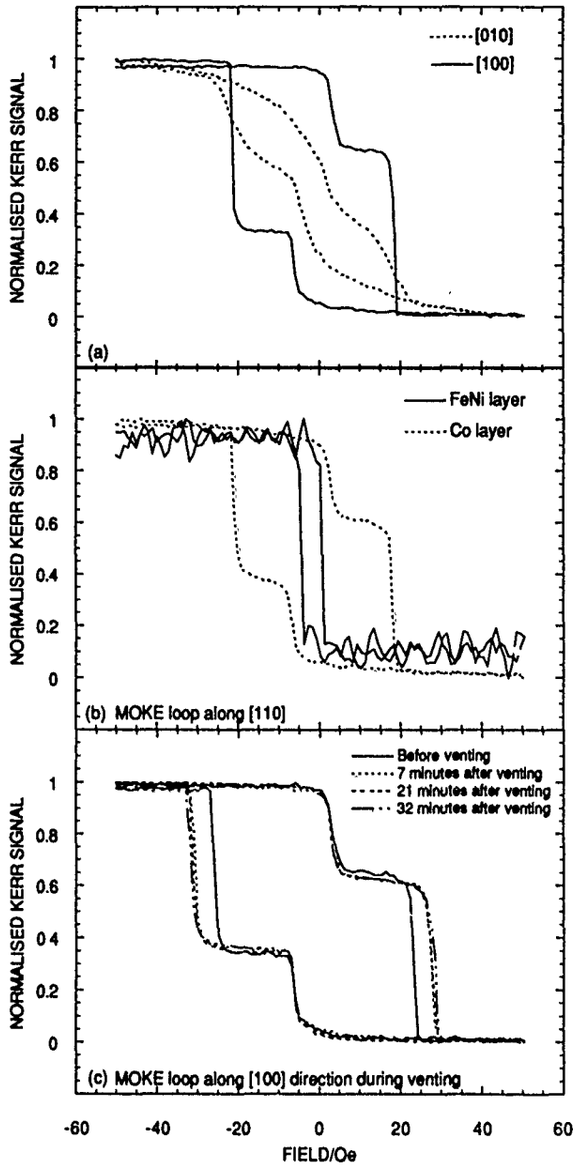

FIG. 1. *In situ* MOKE loops obtained for growth of single trilayer on a Si(100) substrate. See the main text for explanation.

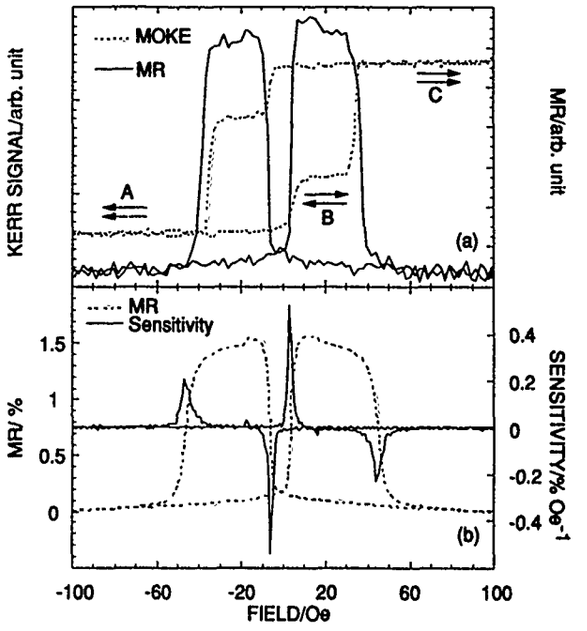

FIG. 2. *Ex situ* MOKE and MR loops for a trilayer grown on Si(100): (a) MR and MOKE loops for sample immediately after growth; (b) MR and sensitivity measured on the same sample on more sensitive equipment after 50 days.

tivity of a trilayer sample, which is defined as the change in MR per unit applied field. A maximum value of 0.51%/Oe is obtained for a sample with a total MR effect of 1.6%, which is larger than the sensitivity for FeNi fibers.[9] This sample shows a slightly different MR–H characteristic due to prolonged exposure to air compared to the sample for Fig. 2(a).

Measurements were also carried out using the same method as reported by Miller[10] in order to isolate the GMR and AMR terms and evaluate the spin-valve behavior of the trilayers. Samples were first saturated with an applied field of 200 Oe in the easy axis. The applied field was then reduced and rotated with respect to the sample. Figure 3 shows the resistance as a function of angle between the applied fields of 22, 28.6, and 37.4 Oe and the initial saturation direction. The resistance behavior is found to very closely follow a $\cos(\theta)$ dependence and shows one peak corresponding to antiparallel layer alignment. When the field is large enough to rotate the Co layer magnetization as well, true antiparallel alignment is never achieved so the resistance change is much smaller, and two peaks are observed. The AMR term is estimated to be roughly 1/15th of the GMR term, which is consistent with previously reported values.[3,10,11]

Figure 4 shows the temperature variation of the maximum and minimum resistance and the MR ratio with temperature. Below 50 K the samples can no longer be saturated so the minimum resistance cannot be measured. The peak in the resistance at 250 K is due to increased shunting in the Si substrate. Between 50 and 250 K the MR decreases linearly by 63%, while the FeNi layer magnetizations only decrease by 7%. The presence of the CoO layer complicates further

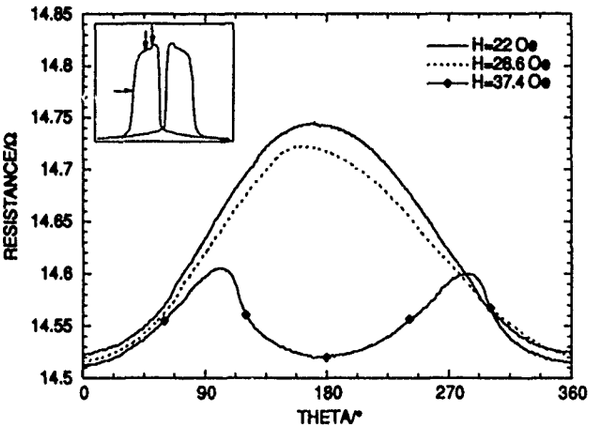

FIG. 3. Angular dependence of the MR for a trilayer grown on Si(100). The inset shows the values of the rotating applied field in relation to the MR loop along the [100] direction.

analysis of the data and the decrease in the Co layer magnetization cannot be measured accurately, but experiments on capped samples will be reported in a future publication.[6] However, it can still be inferred that the change in the MR is strongly dependent on the temperature dependence of the magnon scattering, since the minimum resistance changes by only 21%.

DISCUSSION

The above results observed for the angle-dependent MR show that the samples exhibit near ideal spin-valve behavior. It is possible to simulate the MOKE response of the samples if the magnetization reversal is assumed to be a single domain coherent rotation process. The energy of the system can be expressed as

$$E=-t_1\mathbf{M}_1\cdot\mathbf{H}-t_2\mathbf{M}_2\cdot\mathbf{H}+K_{u1}\sin^2(\theta_1-\alpha_1)$$
$$+K_{u2}\sin^2(\theta_2-\alpha_2)-2A_{12}\cos(\theta_1-\theta_2). \quad (1)$$

The first and second terms are the usual Zeeman terms for the interaction of a region of magnetization M and thickness t in an external field H for the two separate layers. The following two terms are the uniaxial anisotropy terms for each layer, where $(\theta-\alpha)$ is the angle between the magnetization and the easy axis. The final term is the bilinear exchange coupling term between the two magnetic layers. The calculation then gives the direction of the magnetization of each layer which can be used to approximate the hysteresis loop. Once the directions of the magnetizations are known, it is then possible to approximate the shape of the MR by using the following equation:

$$R=R_0+R_{\mathrm{AMR}}\cos^2\theta_1+R_{\mathrm{GMR}}\cos(\theta_1-\theta_2), \quad (2)$$

where it is assumed that the GMR and AMR terms are added in series and R_{GMR} and R_{AMR} are their amplitudes. The results for this simulation are shown with experimental results for a trilayer grown on GaAs(001) in Fig. 5. The values for the anisotropy constants used for the simulation were 3.1×10^3 and 1.4×10^5 erg/cm^3 for the FeNi and Co, respectively, which are larger than the experimentally determined values from the $M-H$ loops. In addition, the switching fields for the 45° axis are less than those observed experimentally.

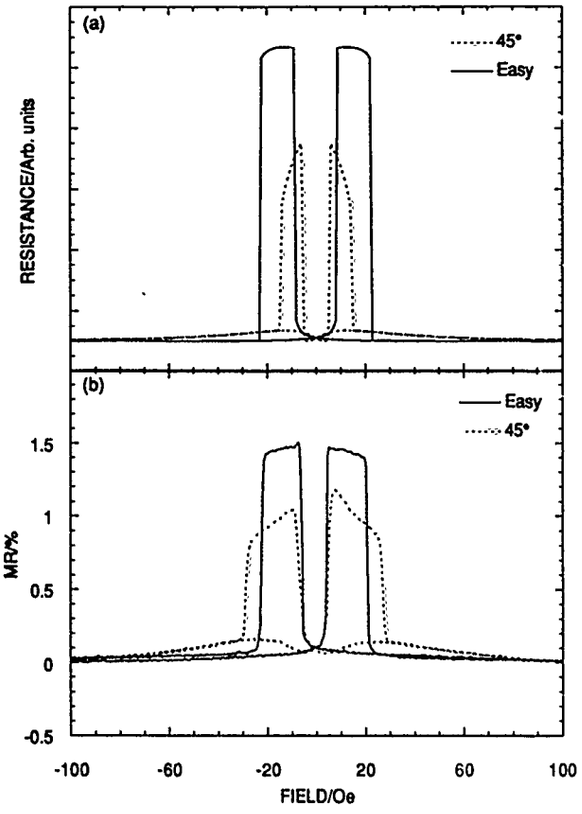

FIG. 5. MR loops for a trilayer grown on GaAs(001): (a) Simulated loops along the easy axis and the axis at 45°; (b) experimentally observed loops along the easy axis and the axis at 45°.

This indicates that domain wall sweeping rather than magnetization rotation is taking place at these fields and that there may be internal fields in our polycrystalline samples that need to be included in the calculation. However, the qualitative agreement between the simulation and the experimentally observed MR curves is still extremely good, and it can be concluded that if the field is applied along the Co easy axis, antiparallel alignment of the complete layer magnetizations can be achieved.

The main source of $1/f$ resistance noise in materials exhibiting giant magnetoresistance (GMR) is the GMR effect itself. Large $1/f$ noise from fluctuations in the parallel vs antiparallel alignment appears when $|dR/dH|$ is large. We have studied this noise as a function of the number of Co/Cu bilayers in multilayer samples and discuss the implications for devices. Barkhausen noise in the resistance as the field is swept through the GMR transition is used to estimate coherent domain sizes between 0.1 and 10 μm^2 for a single Co layer in the multilayers. GMR noise is also seen in a Co/Ag granular system.

Materials exhibiting giant magnetoresistance (GMR) are generating great interest in part because of their potential for technical applications in magnetic recording.[1] Realization of this potential will require understanding the limits set on detector sensitivity by intrinsic noise of the materials. We have characterized a large source of $1/f$ noise in Co/Cu multilayers exhibiting GMR and have studied its dependence on the number of layers. In addition, measurements of the resistive noise while the magnetic field is swept allow us to characterize the effective domain size for the GMR dynamics.

We also report GMR $1/f$ noise in preliminary measurements on a CoAg granular system. Such measurements potentially offer information to help determine the mechanism for the GMR effect in granular systems.[2,3]

The Co/Cu multilayers were prepared at IBM and consist of varying numbers of sputtered bilayers. Each Co layer is 10-Å thick and in the samples denoted "A" ("B") each Cu spacer layer is 19-Å (9-Å) thick. The various samples are described in Table I. Each sample is photolithographically patterned into a bridge of four parallel arms. A constant current is applied to the sample and the resulting fluctuations in voltage across the bridge are amplified with commercial low-noise amplifiers, anti-alias filtered and then digitally sampled and Fourier transformed (and squared) by a standard PC to give the noise spectrum.

All the measurements discussed employ dc currents because ac probe currents were found to completely alter the noise spectra and ac GMR response. The techniques are more fully described elsewhere.[4] All of the multilayer measurements were made at room temperature.

The data for each noise spectrum are collected while a constant magnetic field, H, is applied in the plane of the sample. After H is changed several minutes, at least, are allowed for the magnetization to reach quasiequilibrium before taking a spectrum. For the Barkhausen measurements, on the other hand, H is ramped continuously and voltage fluctuations are recorded directly as a function of time without Fourier transforming.

Figure 1 shows the form of the noise power and resistance as a function of H. The noise is plotted in the form of the dimensionless parameter α defined by $\alpha(f) \equiv f S_R(f) N/R^2$,[5] where $S_R(f)$ is the power spectral density of fluctuations in R and N is the number of atoms in the sample. We have previously shown that $\alpha(H)$ can be predicted, except near $H=0$, via the fluctuation dissipation theorem from the out-of-phase response of the resistance to an ac magnetic field, using the assumption that R is a function only of the magnetization M.[4]

While H is being swept, the noise power at fields with large $|dR/dH|$ is much greater than in equilibrium, as illustrated in Fig. 2. Since essentially every layer pair must rotate from antiparallel (AP) to parallel (P) alignment as H increases from zero, this nonequilibrium (Barkhausen) GMR noise allows some characterization of the domains beyond that possible from the quasiequilibrium noise, for which the fraction of the sample fluctuating is not known.

It is easy to set an upper limit to the size of any domain whose P–AP order changes significantly in a step simply by looking for the maximum step sizes in the Barkhausen noise, and applying the relation[6,7]

TABLE I. Sample characteristics.

Sample	A39	A30	A16	A10	A5	B
Cu thickness (Å)	19	19	19	19	19	9
Number of bilayers	39	30	16	10	5	39
Zero-field R (Ω)	166	125	115	127	275	323
$\Delta R/R_p$	0.26	0.235	0.149	0.114	0.067	0.45
Peak α	17	7.1	6.7	2	0.3	0.21
ΔH_M (Oe)	5	2.7	5.3	2.5	2	1

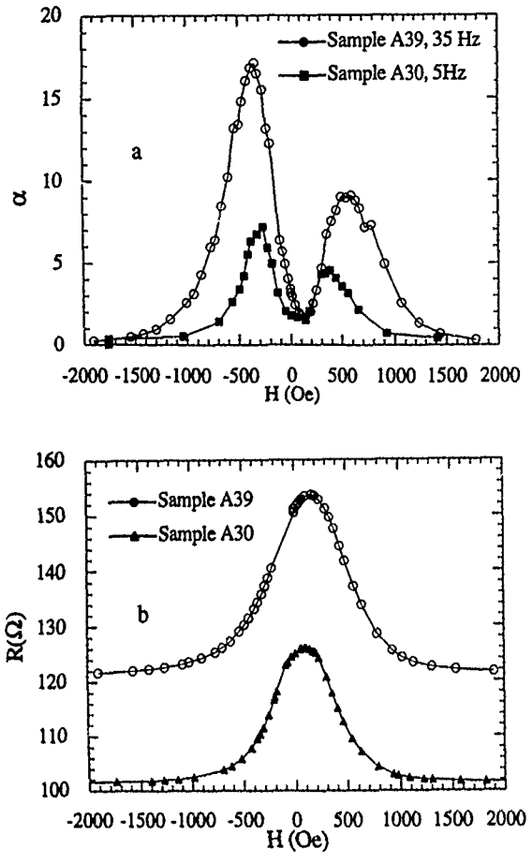

FIG. 1. (a) The dimensionless noise parameter α as a function of field, starting at large negative fields, for samples with two different numbers of bilayers. (b) Resistance as a function of field for the same two samples. Note that these resistances are measured across the sample bridges while the numbers in Table I are for a single branch of each sample.

$$R=R_{AP}-(M/M_S)^2\Delta R, \tag{1}$$

where M_S is the saturation M and ΔR is the maximum decrease in R from R_{AP}, the antiparallel R. We find no obvious discrete domain switches, indicating that no layer pair with area greater than 10 μm^2 reorders coherently.

The Barkhausen noise also lets us set a minimum typical domain size. The sweeps shown in Fig. 2 show that a finite change in H is required before one obtains a new random R, indicating that the noise signal at any field comes from domains that have rotated within about 50 Oe of that field. (This field range, like the noise amplitude, depends somewhat on field history.) Thus about 10% of the layers in the sample are involved in the Barkhausen noise at the maximum value. Then at the maximum

$$\langle(\delta R)^2\rangle/R^2\leq 0.1(V_D/V)(\Delta R/R)^2/4 \tag{2}$$

by simple statistics, where V_D is a typical domain volume and V is the sample volume. The inequality arises because domains probably do not all switch from AP to P in single steps.

Equation (2) gives $V_D\geq 2\times 10^{-4}$ μm^3 or a domain area in one magnetic layer of ≥ 0.1 μm^2. The number is somewhat dependent on whether $|H|$ is being increased or decreased. The limits on the domain area in sample B were

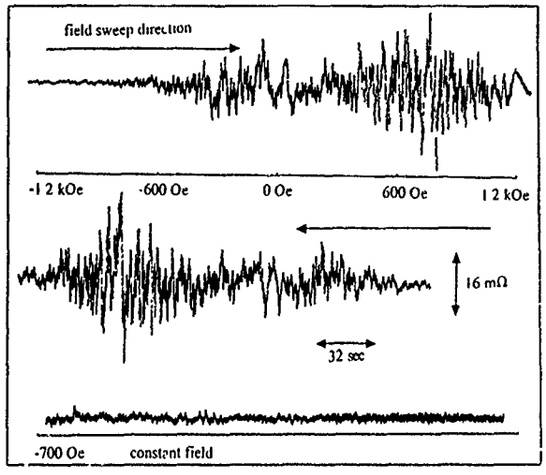

FIG. 2. Barkhausen noise in sample A39. Here the sample has 1-mA dc current in each branch. The −700-Oe constant field trace was taken after cycling to a large positive field—it corresponds to the region of largest noise when the field is continuously swept.

about an order of magnitude smaller. These rather large domains may limit the uniformity of the GMR in collections of small devices.

The size of the GMR effect ($\Delta R/R$) is well known to decrease when the number of multilayers is reduced. However, for practical applications in small devices the field sensitivity would be determined not only by the size of the GMR effect but also by the sample noise. At very high frequencies, Johnson noise rather than $1/f$ noise becomes the limiting background. However (for example), in 39-layer sensors operated at high current densities (e.g., 3×10^6 A/cm^2) the average GMR $1/f$ noise will exceed the Johnson noise up to frequencies on the order of 10^7 Hz. In thinner samples a higher current density can be sustained, keeping the frequency below which the GMR $1/f$ noise becomes importantly high.

We have rated the samples (with various numbers of multilayers) according to the minimum field change ΔH_M, required to produce a change in R discernable above the GMR $1/f$ noise in any octave bandwidth. More precisely, we define ΔH_M by

$$(\Delta H_M)^2=\alpha R^2/(dR/dH)^2N. \tag{3}$$

The results are listed in Table I.

Although both $\Delta R/R$ and N become smaller for thin samples, the reduction in the characteristic field together with the strong reduction in α give a slightly higher sensitivity (vs intrinsic $1/f$ noise) in the thinnest samples. The role of detailed sample properties, e.g., layer roughness, in determining the noise of each sample has not yet been sorted out. The deviation of sample A16 from the trend of the other samples suggests that some such individual differences may affect the comparisons of these samples. We also note that sample B, with 9-Å Cu layers has better incremental sensitivity than the samples with 19-Å layers, although at larger absolute H.

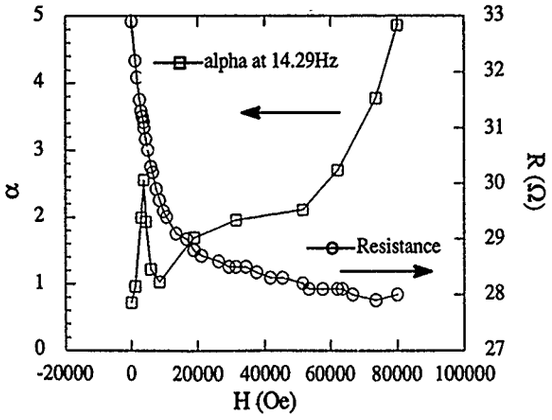

FIG. 3. α and resistance as a function of field, starting at high field, for the CoAg granular sample at 4.2 K.

Because noise measurements help characterize the couplings of the spins to R in their local environments, before averaging over the ensemble of environments, they can also be used to provide information on how the GMR itself works in inhomogeneous materials. Figure 3 shows a preliminary measurement of the $1/f$ noise and resistance in a granular Co/Ag GMR sample as a function of applied field at about 4.2 K.

The 294-nm-thick sample of Ag and (nominally 20 at. %) Co was prepared using two independent sputtering guns with rotating substrates at an Ar pressure of 5×10^{-3} Torr.[8] α increases substantially to a peak near the maximum in $|dR/dH|$, as in the multilayers. The residual α at $H=0$ is less than 30% of the peak value. There is also a very gradual increase in α at high H, whose origin (perhaps connected with enhancement of universal conductance fluctuations by the suppression of spin-flip scattering) remains undetermined.

This $\alpha(H)$ curve may have some implications for the GMR mechanism in an inhomogeneous material, since the noise depends on the mean square local sensitivity to magnetization, rather than the mean sensitivity. We believe that these variations in local sensitivity will prove to be different in the spin disorder scattering model[3] and the d-band density-of-states model.[2]

In conclusion, we have shown that the GMR effect is accompanied by large $1/f$ noise, which may limit the sensitivity of GMR devices. Surprisingly, the thinner structures appear to have slightly better intrinsic field sensitivity. Preliminary experiments show that similar noise appears in a granular GMR material, for which it may provide evidence bearing on the GMR mechanism.

Co/Cu multilayers with the form of glass/Cu 50 Å[Co11.5 Å/Cu(t_{Cu})]$_{30}$/Cu50 Å, prepared by rf triode sputtering, exhibit oscillatory magnetoresistance (MR), as a function of the Cu layer thickness with a period of ≈12 Å and maximum MR values of 36.8% and 22.3% at 77 and 295 K, respectively. In order to study the effect of annealing on the structural and magnetic properties, five samples with Cu thicknesses between 9 and 34 Å were heat treated at temperatures up to 300 °C and analyzed by low- and high-angle x-ray diffraction, MR, and mageto-optic Kerr effect measurements. Annealing at moderate temperatures for the samples with Cu thicknesses around the second and third MR peaks leads to an initial increase in the MR. In contrast, annealing causes only a monotonic MR decrease for the sample at the first peak with a Cu thickness of 9 Å.

INTRODUCTION

The recent discoveries of giant magnetoresistance (GMR) and oscillatory exchange coupling in a wide variety of magnetic multilayers have stimulated a great deal of interest.[1,2] In particular, sputtered Co/Cu multilayers exhibit the largest MR value and a well-defined oscillatory exchange coupling at room temperature.[2–4] It is now generally agreed that GMR is associated with the reorientation of the magnetic moments in neighboring magnetic layers and has been interpreted on the basis of spin-dependent electron scattering at the magnetic/nonmagnetic interface and in the bulk of the magnetic layer.[5] Studies demonstrate that in Fe/Cr[6,7] and Co/Re[8] multilayers the GMR is enhanced by the presence of interfacial roughness due to either changing preparation conditions[6] or annealings[7,8] while it decreases in some other Cu-based systems upon annealing.[9,10]

In this paper, we report the effect of relatively low-temperature annealing up to 300 °C on the structural and magnetic properties of Co/Cu multilayers sputtered onto Cu buffer layers for a wide range of Cu thicknesses in order to follow the effect of structural modifications on the GMR.

EXPERIMENTAL DETAILS

Co/Cu multilayers with the form of glass/Cu50 Å[Co11.5 Å/Cu(t_{Cu})]$_{30}$/Cu50 Å were prepared using a modified single-source rf triode sputtering system[11] with a base pressure of less than 2×10^{-7} Torr. Depositions were carried out under 3.25 mTorr of pure argon at a rate of approximately 2 Å/s, the exact rates being calibrated by the layer thicknesses determined by low-angle x-ray diffraction. A sample shape of 8×4 mm^2 was chosen as suitable for both transport and x-ray measurements and was defined by a mask overlaid on the substrate during deposition. The structure of the samples was determined using low- and high-angle x-ray diffraction measurements with CuK_α radiation.[11] The MR was measured in magnetic fields up to 10 kOe using a high-resolution ac bridge[12] and the magnetic hysteresis loop was determined by means of the magneto-optic Kerr effect (MOKE) with the magnetic field applied in the film plane. All experiments were performed on the same samples to ensure accurate comparison of the data after each thermal treatment.

Annealing was carried out in a temperature-controlled tube furnace with the sample placed in a quartz probe which was continuously evacuated to a pressure of $\sim5\times10^{-6}$ Torr. In order to follow the structural and magnetic evolution progressively, samples were annealed at each temperature step and cooled to room temperature for x-ray diffraction, MOKE, and transport measurements. This cycle was repeated at the same annealing temperature until the behavior stabilized before proceeding to a higher temperature.

RESULTS AND DISCUSSION

Figure 1 summarizes the variation of the MR magitude as a function of the Cu thickness for the as-deposited multilayers with a 50-Å Cu buffer at 77 and 300 K. Three oscillation peaks are identified at t_{Cu}=9.2, 21.7, and 33.6 Å with a period (≈12 Å) and phase similar to values reported in other Co/Cu studies.[2–4] The MR values at the first peak are smaller than those found for the Co/Cu multilayers grown on a 50-Å Fe buffer layer.[2–4] This reduction can be ascribed partly to an incomplete antiferromagnetic coupling in our samples resulting from uneven layer growth on the Cu buffer layer[3,13] and partly to a larger shunting effect of the 50-Å Cu buffer/cap layers which reduces the maximum MR by about 10%.[3]

Five samples, marked A–E in Fig. 1, were selected for annealing studies. High-angle x-ray measurements show that all our samples are polycrystalline with a (111) texture, as presented in Fig. 2 for sample D. The dominant feature is a

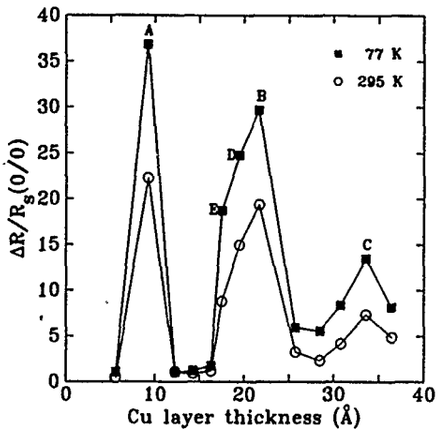

FIG. 1. Dependence of the saturation MR at 77 and 295 K on the Cu layer thickness for multilayers with the form glass/Cu50 Å[Co11.5 Å/Cu(t_{Cu})]$_{30}$/Cu50 Å. The five samples A, B, C, D, and E were selected for annealing studies.

strong (111) peak ($2\theta \simeq 44°$) situated between the fcc Cu and Co (111) Bragg peaks at 43.3° and 44.2°, respectively. A weak (200) peak (at about 51°) is also present but no evidence for interlayer coherence is apparent in these spectra. The (111) and (200) linewidths were found to decrease monotonically with each annealing step although the peak positions remain unchanged (see Table I), suggesting that the films have developed larger textured grains with no evidence for formation of phase segregated regions. This suggestion is consistent with the decrease of the zero-field resistance R_0 observed after each anneal (Table I). Low-angle x-ray reflectivity spectra for the same sample are presented in the inset of Fig. 2. Since there is no significant change in the superlattice peaks after annealing, we conclude that the composition modulation persists, consistent with the high-angle data. The slight change in the reflectivity below the 2θ value of the

first Bragg peak for the annealed film arises from the growth of an oxide overlayer during annealing. Similar behavior was observed for the other annealed samples.

Representative MR data at 295 K for samples A (t_{Cu}=9.2 Å), C (33.6 Å), and D (19.5 Å), as-deposited and after annealing are displayed in Fig. 3. The MR is defined here as the ratio $(R_0 - R_s)/R_s$, where R_0 is the maximum value of the resistance and R_s, the high field saturated value. The MR of sample A (t_{Cu}=9.2 Å) drops from 22.3% to 15.1% after annealing at only 150 °C for 2 h, whereas the MR of sample D (t_{Cu}=19.5 Å) increases slightly from 14.8% to 18% after the more intense treatment at 200 °C for 20 h. From the MR data in Table I it can be seen that for the samples with thicker Cu layers (B to E), the MR and ΔR_s initially pass through a maximum before decreasing. In contrast, for sample A with small t_{Cu}=9.2 Å, the $\Delta R_s/R_s$ and ΔR_s decrease progressively with increasing temperature and time. It appears that the atomic mixing and disorder within the very thin Cu layer of the as-deposited multilayer results in a relatively poor Co layer coupling. This conclusion is consistent with the fact that the first peak in Fig. 1 is much narrower than the second and not much higher.

The magnetic behavior of the films was also monitored after each annealing step. Figure 4 shows hysteresis loops for

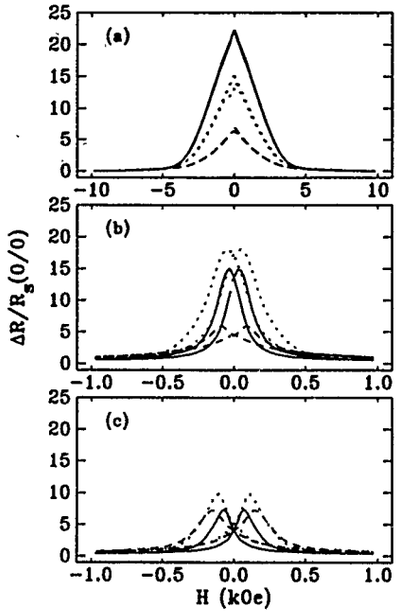

FIG. 3. Resistance vs field curves at 295 K before annealing (solid curves) and after annealing: (a) sample A, 150 °C for 2 h (dotted line), 200 °C for 1 h (dashed line); (b) sample D, 200 °C for 20 h (dotted line), 300 °C for 1 h (dashed line); (c) sample C, 250 °C for 2 h (dotted line), 300 °C for 1 h (dashed line).

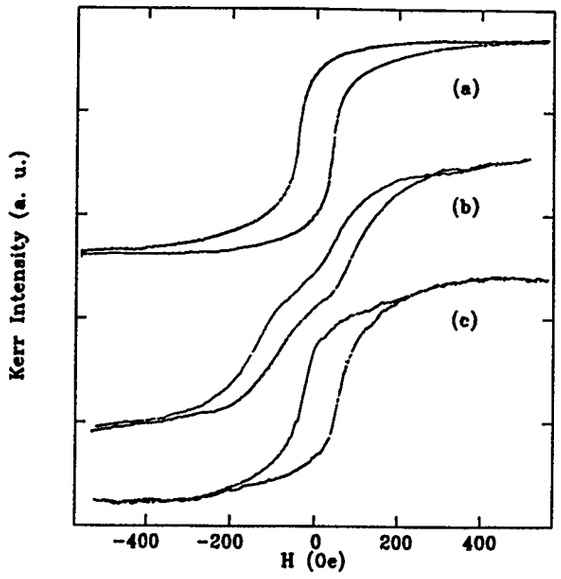

FIG. 4. MOKE hysteresis loops for sample D with t_{Cu}=19.5 Å: (a) as-deposited; (b) annealed at 200 °C for 20 h; (c) annealed at 300 °C for 2 h.

sample D as-deposited and after annealing. For the as-deposited material, the Kerr rotation indicates a large remanence at zero field and a slow approach to saturation, suggesting that only a fraction of the layers is antiferromagnetically coupled. Annealing at a moderate temperature results in a nearly zero remanence and a wasp-waisted curve characteristic of a film with substantial antiferromagnetic coupling. Further annealing gives rise to an almost square loop typical of a ferromagnetic film. Samples C and D followed the same behavior. Combining the structural, transport, and magnetic results, we conclude that the initial increase in the MR can be ascribed to the larger grain size which, in turn, results in an increase of the antiferromagnetically coupled fraction of the film. On the contrary, for sample A there was only a monotonic increase in the remanence upon annealing, indicating a monotonic decrease of the interlayer antiferromagnetic coupling, as inferred from the MR results.

In summary, oscillatory MR has been observed in sputtered Co/Cu multilayers grown on glass substrates with 50-Å Cu buffer and cap layers. Annealing of samples at moderate temperatures leads to larger grain sizes with no loss in the multilayer periodicity. Annealed samples at the second and third MR peaks show an initial increase of the MR arising from an enhancement of the antiferromagnetically coupled fraction of the films. No MR increase is observed for the sample at the first peak probably because the very thin Cu layer is initially too disordered.

Magnetoresistance and exchange effects of NiCo/Cu sandwich films with oxide overlayer

T. R. McGuire and T. S. Plaskett[a)]
IBM Research Division, T. J. Watson Research Center, Yorktown Heights, New York 10598

Giant magnetoresistance (GMR) of 8% at 4.2 K is found in sandwich films having the composition $Ni_{0.7}Co_{0.3}$(50 Å)/Cu(t)/NiCo(50 Å)/NiCoO(40 Å) where NiCoO is a mixed oxide overlayer that exchange couples with the NiCo alloy layer. These films show a MR temperature dependence quite similar to that previously reported for Co/Cu/Co/CoO where the MR becomes small above 200 K. When bilayers of CoO/NiO are placed on the NiCo layer, the temperature dependence of MR extends to 250 K. The magnitude of the MR at 4.2 K scales with the magnitude of the saturation magnetization in the NiCo and Co films.

I. INTRODUCTION

Giant magnetoresistance (GMR) found in multilayers[1,2] is also found in sandwich layers[3,4] composed of two magnetic layers, M_1 and M_2, separated by a single layer of a nonmagnetic metal as shown in Fig. 1. Initial work by Dieny *et al.*[3] described sandwiches of NiFe/Cu/NiFe with an FeMn overlay. The observed changes in resistivity with applied magnetic field was called a "spin-valve" effect because it depends on the relative angle between the directions of magnetization of the two magnetized NiFe layers. Speriosu *et al.*[4] have also reported on Co/Cu/Co sandwiches also with an FeMn overlay that have MR of 4% at room temperature.

The importance of the FeMn alloy layer comes about because it is antiferromagnetic and exchange couples with either the FeNi or Co upper layer. This inhibits the rotation of the magnetization of the upper layer M_1 with respect to the lower magnetic layer M_2. When the two magnetic layers in the sandwich are antiparallel at low magnetic fields (H) the sandwich film resistivity is a maximum (ρ_{max}). For large H when M_1 and M_2 are parallel, minimum (ρ_{min}) is measured. This resistivity effect is caused by polarized conduction electrons from one layer which are scattered by the antiparallel magnetic layer as well as any disordered magnetic moments. Magnetic saturation minimizes this scattering.

In our previous study[5] of Co/Cu/Co we often obtained large MR (up to 12% at 4.2 K) with no special overlayers or underlayers. Subsequently it was found[6] that consistently large values of MR could only be obtained if a CoO overlayer is deposited on the Co/Cu/Co sandwich. The antiferromagnetic CoO served the same purpose as the FeMn. Although the CoO is antiferromagnetic with a transition at 290 K, the exchange coupling was only effective to about 200 K above which the MR<1%.

Since the antiferromagnetic transition of NiO is 520 K, in the present work sandwiches of $Ni_{0.7}Co_{0.3}$(50 Å)/Cu(t)/NiCo(50 Å)/NiCoO were made in an attempt to increase the value of MR at room temperature. In addition $Ni_{0.7}Co_{0.3}$ bulk alloys are known to be magnetically soft similar to permalloy, hence NiCo films might make a more sensitive magnetic probe.

II. EXPERIMENTAL RESULTS AND DISCUSSION

The films are prepared on glass substrates by magnetron sputtering in a 3-mTorr Ar atmosphere using Cu and $Ni_{0.7}Co_{0.3}$ targets. The substrates, at ambient temperature, are moved sequentially over each gun to deposit film on the substrate. Film structure is shown in Fig. 1 and the layer thicknesses are listed in Table I. The $Ni_{0.7}Co_{0.3}O$ overlay is added by depositing additional NiCo on the upper magnetic layer M_1 and simultaneously introducing oxygen to the sputtering system. We do not know the exact composition of the oxide layer, however since the substrate temperature is ≈50 °C, the oxide may be amorphous. The last three films listed in Table I are made with a double oxide overlay. Cobalt and nickel targets are used to first form a reactively sputtered CoO of 50 Å followed by a NiO layer of 50 Å.

Magnetization of the films was measured with a Quantum Design SQUID magnetometer. As seen in Table I values of magnetic saturation M_s at 4.2 K vary from 800 to 900 emu/cm^3. Many of our films are about 10% higher than the value for bulk $Ni_{0.7}Co_{0.3}$ (812 emu/cm^3). In our previous work[5,6] with Co sandwich films, M_s was 10% to 15% lower than Co bulk values. We attribute the lower magnetization of Co to oxygen penetration of the upper Co layer, a condition which is apparently not present in the NiCo film.

Magnetoresistance is measured by the van der Pauw method on 2-cm-diam films with in-plane H and current. As listed in Table I, MR varies from 6% to 9%; also listed are ρ_{max}, ρ_{min}, and ΔH and these are obtained from resistivity field data as marked in Fig. 2. The MR (%) column is calculated from $(\rho_{max}-\rho_{min})/\rho_{min}$.

Figure 2 shows resistivity and also M vs H for film (a) of Table I and both curves have the characteristic plateau found for sandwich films. A plateau represents some sort of

		NiCoO						
a	16	40	905	31.7	29.0	2.7	2.5	9.3
b	20	40	876	28.3	26.2	2.1	2.5	8.0
c	28	40	870	24.7	23.2	1.5	1.5	6.5
		CoO, NiO						
d	16	50,50	765	39.5	36.6	2.9	···	7.9
e	20	50,50	828	27.8	26.1	1.7	···	6.5
f	28	50,50	820	35.5	32.7	2.8	···	8.6

stable nonparallel orientation of M_1 and M_2. The field region ΔH of ρ_{max} extends not only over the magnetization plateau but to a portion of the magnetization curve where magnetic saturation takes place. We interpret this to mean that only a small amount of unsaturated magnetization is needed to obtain ρ_{max}. Scattering of polarized conduction electrons from a disordered magnetic layer, e.g., at an interface may be as important as bulk scattering within the magnetic layer. The relation of the scattering mechanism to the magnetic state of the sample is a complex problem.

Figure 3 shows the temperature dependence of ρ_{max} and ρ_{min} for films (a). The difference $\Delta\rho=\rho_{max}-\rho_{min}$ becomes small for $T>200$ K. This temperature dependence is almost identical to that found for Co/Cu/Co/CoO films.[6] The temperature dependence of MR for films (a) and (d) are plotted in Fig. 4. Film (d) which has a bi-layer CoO/NiO has a higher MR in the temperature range 125 to 250 K as compared to film (a). Possibly there is some exchange coupling between the NiO and CoO to extend the temperature range.

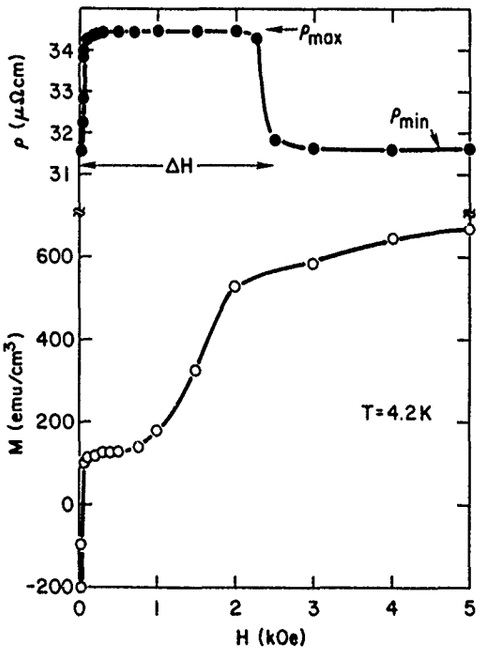

FIG. 2. Sandwich film (a) of the $Ni_{0.7}Co_{0.3}$ (50 Å) with Cu(16 Å) and overlayer of NiCoO(40 Å). Upper curve is resistivity with ρ_{max}, ρ_{min}, and ΔH specified and lower curve is magnetization.

Interacting CoO–NiO superlattices with NiFe have been reported by Carey and Berkowitz.[7] The larger MR found at 4.2 K for film (a) may be related to M_s; M_s of film (a) is 10% greater than M_s of film (d).

A measure of the exchange coupling of the antiferromagnetic oxide overlayer to M_1 is given by the width of the plateau of ρ_{max} (Fig. 2) as listed by ΔH in Table I. The largest value of ΔH for the single layer oxide overlayer is about 2500 Oe as shown in Fig. 2. This is, however, about half that observed for Co/Cu/Co/CoO films where $\Delta H \approx 5000$ Oe.[6] Figure 5 shows ρ vs H for film (d) which has a CoO/NiO overlayer. The shape at 4.2 K makes it difficult to specify ΔH, however it is not larger than 2500 Oe. At higher temperatures the width of the plateau narrows considerably even though MR remains large. In Fig. 3 ΔH vs T for film (a) is plotted which shows that ΔH vs T decreases more rapidly than the MR vs T decreases. This Curie-type dependence for ΔH is similar to that reported for Co/CoO. It is possible that the antiferromagnetism of the CoO or NiCoO is decreasing as $1/T$ perhaps because the oxide is off stoichiometry and also amorphous.

The magnitude of MR in the NiCo sandwich is about 7% to 8% and M is about 800 emu/cm^3. This compares with 15% to 16% and 1400 emu/cm^3 for Co sandwich films[6] thus showing scaling of MR with M for these two systems. At 4.2

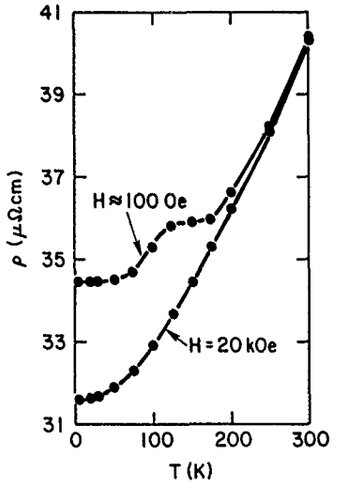

FIG. 3. Resistivity as a function of temperature for the NiCo sandwich (a) with Cu(16 Å) and NiCoO(40 Å) overlayer.

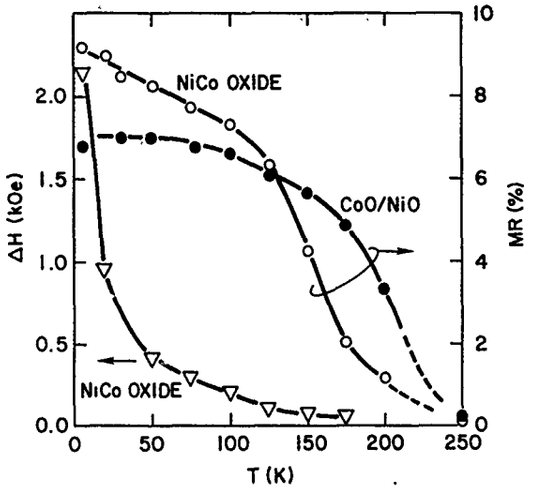

FIG. 4. Temperature dependence of MR for the NiCo sandwich (a) with NiCoO(40 Å) overlayer and film (d) CoO(50 Å)/NiO(50 Å) overlayer both with Cu(16 Å). The plateau width ΔH vs T is shown for the NiCoO overlayer film (a).

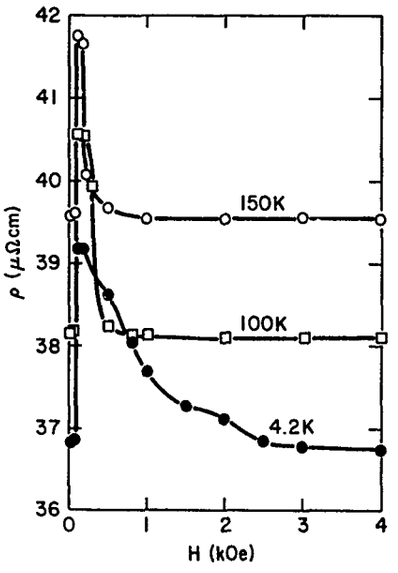

FIG. 5. Resistivity vs H for three temperatures for film (d) in Table I which has bilayer CoO(50 Å)/NiO(50 Å) overlayer and Cu(16 Å).

K, data for the b, c, e, and f films where the Cu thickness is 20 and 28 Å are quite similar to the Cu(16 Å). However, we do not have extensive temperature measurements on b, c, e, and f films.

III. SUMMARY

(a) Reactively sputtered overlayers of NiCoO and CoO/NiO are exchange coupled to $Ni_{0.7}Co_{0.3}$ sandwich films and cause nonparallel magnetic layers having high resistivity.

(b) The temperature dependence of magnetoresistance decreases faster for the mixed oxide NiCoO overlayer than for the bilayer CoO/NiO.

(c) The exchange coupling of the oxide to the NiCo layer decreases as $1/T$.

(d) The temperature dependence of MR and ΔH for the mixed oxide overlayer with Ni Co is almost the same as found previously[6] for Co/Cu/Co/CoO sandwich films.

(e) The magnitude of MR in the NiCo and Co series scales linearly with the value of saturation magnetization in the two series.

Effect of oxygen incorporation on magnetoresistance in Co/Cu multilayers

K. Kagawa, H. Kano, A. Okabe, A. Suzuki, and K. Hayashi
Sony Corporation Research Center, 174 Fujitsuka-cho, Hodogaya-ku, Yokohama 240, Japan

The background pressure dependence of magnetoresistance (MR) ratio of Co/Cu multilayer films and the effect of the Fe buffer layer were studied. Secondary ion mass spectrometry (SIMS) measurement of the films and *in situ* quadrupole mass spectrometry (QMS) analysis in conjunction with background pressure dependence of MR ratio confirmed that the oxidation of Co/Cu gives a crucial influence to the giant magnetoresistance (GMR) effect. The oxidation of Co/Cu weakens the antiferromagnetic coupling, and results in the low MR ratio. The Fe buffer layer absorbs the residual oxygen, and this leads to the increase of the MR ratio. The MR ratio of $(Co_{1\ nm}/Cu_{1\ nm})_{100}/Fe_{2.5\ nm}$ film deposited under low background pressure and high deposition rate so as to suppress oxidation reached over 80% at RT and 160% at 2 K.

INTRODUCTION

The giant magnetoresistance (GMR) of the Co/Cu multilayer has been intensively studied, from the motivation of both scientific interest and the application to magnetic sensors. But it has not been clarified yet what is the critically important condition for the GMR effect, which causes disagreement among the reported magnetoresistance (MR) ratios.[1,2] The analysis of the Fe buffer layer effect that is known to make a large MR ratio and better reproducibility may provide clues to the question. Some groups report that an Fe buffer layer changes the texture of Co/Cu and that the crystalline orientation may play a significant role for the GMR effect.[3] The increase of the small-angle x-ray diffraction peak intensity by the Fe buffer layer is also reported.[4] However, it has not been specified yet what is the major role of the Fe buffer layer for the increase of the MR ratio.

In this work, we clarify that the oxidation of Co/Cu has a significant influence on the MR ratio by investigating the background pressure dependence of the MR ratio. The effect of the Fe buffer layer is also explained on this line.

EXPERIMENTAL PROCEDURE

Co/Cu multilayers with/without a 2.5–5-nm-thick Fe buffer layer were prepared on water-cooled[5] glass and Si substrates by dc magnetron sputtering. Ar gas pressure during sputtering was 0.5 Pa. Substrates were moved sequentially over each gun to deposit a Co or Cu layer and the deposition rate was around 2.3 nm/s. The background pressure before deposition was varied from 9×10^{-4} to 5×10^{-5} Pa. The atmosphere during deposition was monitored by quadrupole mass spectrometry (QMS). The magnetic properties of Co/Cu multilayers were measured with a vibrating-sample magnetometer (VSM) at RT. The crystalline orientations of Co/Cu multilayers were investigated by x-ray diffraction (XRD) with Cu$K\alpha$ radiation. The MR measurements were made by the dc four-terminal method at RT and 2 K with the maximum magnetic field of 15 kOe. Sample size was 5×25 mm^2. The oxygen content of Co/Cu multilayers were investigated by secondary ion mass spectrometry (SIMS). The oxygen content was estimated as the relative oxygen ion intensity to the Cu ion intensity of the film, assuming the Cu content to be constant specified otherwise.

RESULTS AND DISCUSSION

Figure 1 shows the background pressure dependence of the MR ratio of $(Co_{1\ nm}/Cu_{1\ nm})_{100}$ multilayers with/without a 5-nm-thick Fe buffer layer. The MR ratio of Co/Cu becomes drastically larger as the background pressure is decreased below 10^{-3} Pa and then appears to saturate around 10^{-4} Pa. The Fe buffer layer works to increase the MR ratio, but the effect is relatively small for lower background pressure. The Fe buffer layered film shows six times larger MR ratio than film without a buffer for high background pressure (8.9×10^{-4} Pa), while the increase of MR ratio by Fe buffer layer is only 2%–3% for low background pressure (1.8×10^{-4} Pa). Figure 2 reveals the background pressure dependence of the x-ray diffraction intensity ratio $I_{200}/(I_{111}+I_{200})$ of $(Co_{1\ nm}/Cu_{1\ nm})_{100}$ of multilayers with/without a 5-nm-thick Fe buffer layer. The Fe buffer layer changes the texture of Co/Cu from (111) to (200) almost equally for the whole range of the background pressure. Therefore, the effect of texture change cannot account for the smaller increase of MR ratio by the Fe buffer layer for low background pressure (1.8×10^{-4} Pa). The MR ratio of Co/Cu appears to depend simply on background pressure,

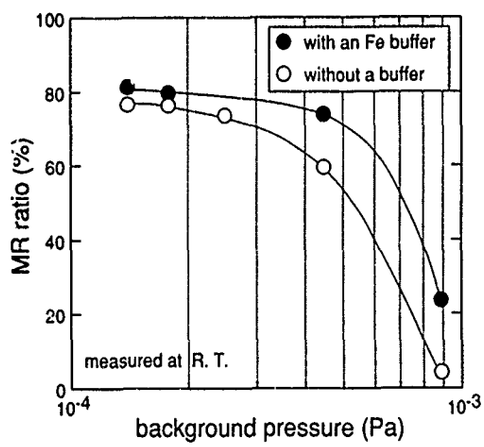

FIG. 1. Background pressure dependence of the MR ratio of $(Co_{1\ nm}/Cu_{1\ nm})_{100}$ with/without an Fe buffer layer at RT.

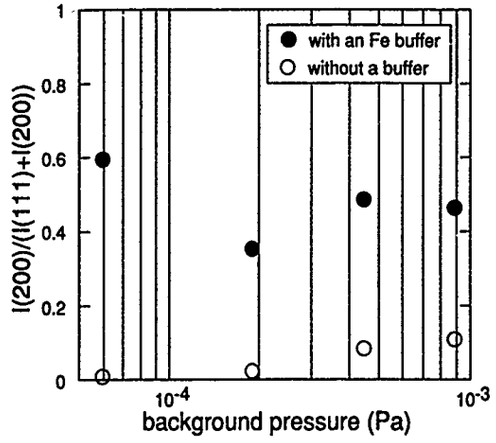

FIG. 2. Background pressure dependence of the x-ray diffraction intensity ratio $I_{200}/(I_{111}+I_{200})$ of $(Co_{1\ nm}/Cu_{1\ nm})_{100}$ with/without an Fe buffer layer.

rather than texture of the film. The background pressure is expected to have a direct relationship with the oxygen content of the film.

The relative oxygen ion intensity of Co/Cu multilayers measured by SIMS are shown in Fig. 3. The film deposition under low background pressure lowers the oxygen content of Co/Cu multilayers. The Fe buffer layered film has low oxygen content compared to the film without a buffer deposited under the same background pressure. The low oxygen content is shown to be necessary to cause the large MR change. The Fe buffer layer effect for the increase of MR ratio is attributed to reducing the oxygen content of the Co/Cu multilayers.

The oxidation of the film during deposition is monitored by *in situ* QMS analysis. As it is well-known that residual H_2O decomposes to O_2 and H_2 by sputtering, we paid attention to O_2 and H_2 partial pressure. Figures 4(a), 4(b), and 4(c) illustrate the change of residual gas partial pressure during deposition of Co/Cu multilayers with low background pressure (6×10^{-5} Pa), with high background pressure (4.5×10^{-4} Pa), and with high background pressure (4.5×10^{-4} Pa) with an Fe buffer layer. The H_2 partial pressure increases during sputtering, while O_2 partial pressure does not increase. That implies O_2 formed by decomposition of H_2O is absorbed concurrently in the growing film. Therefore, the increase of the H_2 partial pressure ΔP_{H_2} during sputtering is the measure of the oxidation of the film. The high peak of H_2 partial pressure at the beginning of Co/Cu deposition also implies the severe oxidation of the growing film. The deposition under low background pressure reduces both ΔP_{H_2} and the peak height at the beginning of Co/Cu. The oxidation of the Co/Cu during deposition is confirmed to influence the MR ratio significantly. The deposition of an Fe buffer layer also lowers ΔP_{H_2} and the peak height. The sputtered Fe buffer layer is thought to lower the effective background pressure as an oxygen absorber. This is consistent with the smaller Fe buffer layer effect to increase the MR ratio for lower background pressure. The major role of the Fe buffer layer for the increase of MR ratio is to absorb the residual oxygen and to suppress oxidation of Co/Cu multilayers rather than texture change.

The change of magnetization behavior as the background pressure changes is measured. Figure 5 shows the $M-H$ loops of Co/Cu multilayer films grown at various background pressure. The antiparallel spin alignment of the neighboring Co layers is responsible for the spin-dependent

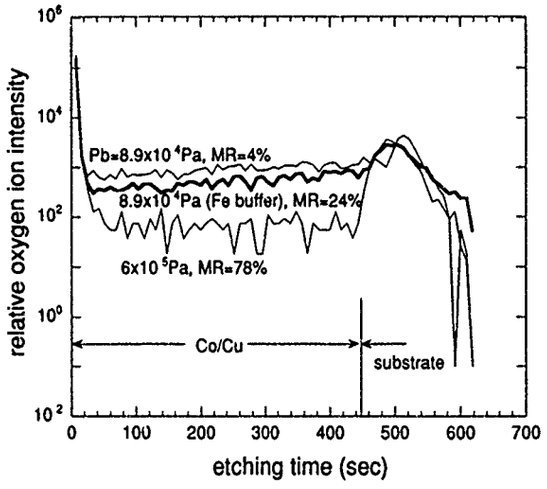

FIG. 3. Relative ion intensity of oxygen of $(Co_{1\ nm}/Cu_{1\ nm})_{100}$ films with background pressure $P_b=8.9 \times 10^{-4}$ Pa, 8.9×10^{-4} Pa with an Fe buffer layer, and 6×10^{-5} Pa.

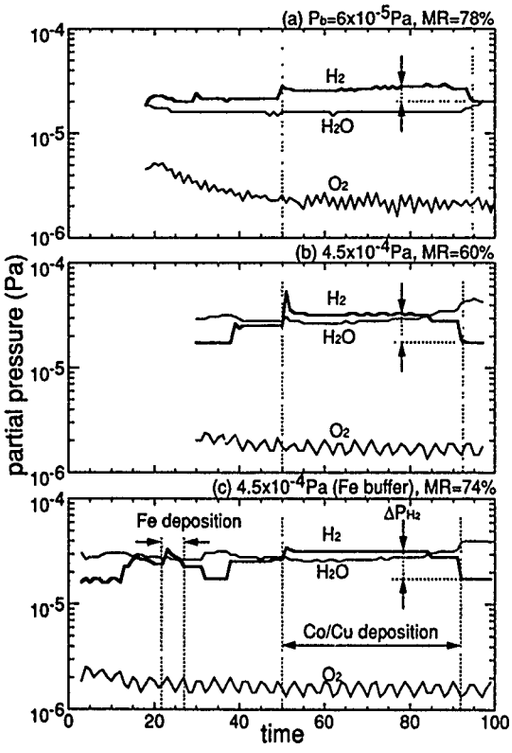

FIG. 4. Change of residual gas partial pressure during deposition of (a) $(Co_{1\ nm}/Cu_{1\ nm})_{100}$ with background pressure $P_b=6 \times 10^{-5}$ Pa, (b) 4.5×10^{-4} Pa, and (c) 4.5×10^{-4} Pa with an Fe buffer layer.

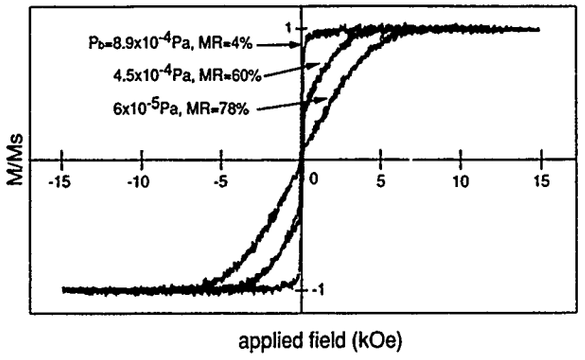

FIG. 5. $M-H$ loop of $(Co_{1\ nm}/Cu_{1\ nm})_{100}$ with background pressure P_b=8.9 $\times 10^{-4}$ Pa, 4.5 $\times 10^{-4}$ Pa, and 6 $\times 10^{-5}$ Pa.

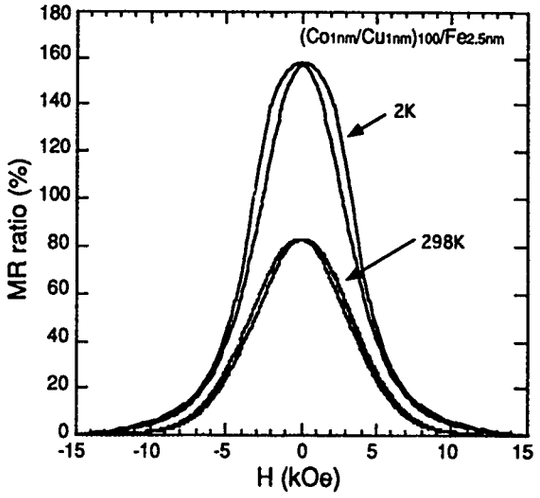

FIG. 6. MR change of $(Co_{1\ nm}/Cu_{1\ nm})_{100}/Fe_{2.5\ nm}$ with 5 $\times 10^{-5}$-Pa background pressure.

scattering at the interfaces between Co and Cu. The antiferromagnetic (AFM) coupling reduces the remanent magnetization, and increases the saturation field. The saturation field becomes smaller and the remanent magnetization increases for higher background pressure. The oxidation of the interfaces between Co and Cu makes the antiferromagnetic (AFM) coupling incomplete. As is reported in the case of FeNi/FeMn, the suppression of oxidation of the interfaces between Co and Cu is indispensable to strengthen the AFM coupling.

It becomes clear that the suppression of Co/Cu oxidation during deposition is a significant condition to cause large MR ratio. The film deposition under lower background pressure, with an Fe buffer layer are effective to prevent oxidation. Figure 6 shows the MR curve for $(Co_{1\ nm}/Cu_{1\ nm})_{100}/Fe_{2.5\ nm}$ film deposited with 5 $\times 10^{-5}$ Pa background pressure. The film exhibits an MR ratio of over 80% at RT and 160% at 2 K.

CONCLUSIONS

The effect of oxidation of Co/Cu was studied. The MR ratio is greatly improved by suppression of oxidation. The oxidation of the Co/Cu, especially the oxidation of the interfaces between Co and Cu, makes the antiferromagnetic coupling weaker, and that reduces the MR change. The Fe buffer layer effect for the large MR ratio was confirmed to be the residual oxygen absorption and lowering the oxygen content of Co/Cu, rather than texture change. The film deposition under low background pressure and the Fe buffer layer were confirmed to be effective to prevent oxidation. The difference of oxidation degree is thought to be one reason of the disagreement among the reported MR ratio. The MR ratio of $(Co_{1\ nm}/Cu_{1\ nm})_{100}/Fe_{2.5\ nm}$ film increased to a high of over 80% at RT and 160% at 2 K by careful suppression of Co/Cu oxidation.

ACKNOWLEDGMENTS

We are grateful to S. Miwa for the skillful SIMS measurement. We would like to thank Dr. Seto and Dr. Watanabe for continuous encouragement.

Giant magnetoresistance in electrodeposited Co–Ni–Cu/Cu superlattices

M. Alper, K. Attenborough, V. Baryshev,[a] R. Hart, D. S. Lashmore,[b] and W. Schwarzacher[c]
H. H. Wills Physics Laboratory, Tyndall Avenue, Bristol BS8 1TL, United Kingdom

We have electrodeposited a series of Co–Ni–Cu/Cu superlattices in which the Cu layer thickness was varied between 7 and 35 Å and the Co–Ni–Cu alloy layer thickness held constant. "Giant magnetoresistance" was observed for all films, with the magnitude of the effect decreasing with increasing Cu spacer layer thickness.

Giant magnetoresistance (GMR) is one of the most interesting properties exhibited by magnetically inhomogeneous systems. It was first observed in Fe/Cr superlattices with antiferromagnetic coupling between adjacent Fe layers[1] and subsequently found in other metal/metal multilayers with or without antiferromagnetic coupling.[2,3] Even single-layer heterogeneous alloy films can show GMR providing the magnetization varies on a length scale comparable to the conduction electron mean free path.[4]

Multilayers and single-layer heterogeneous alloy films have different perceived strengths with regard to possible technological applications of GMR. The alloy films are reasonably straightforward to fabricate, but the large fields generally required for such films to show a significant change in resistance make them less attractive than multilayers for use as magnetic field sensors. Most GMR multilayers, however, require a vacuum system (with the all the attendant cost and complexity) for their fabrication.

Recently we reported the first evidence for GMR in metal/metal superlattices grown by electrodeposition.[5] This process has the obvious advantage over techniques such as sputtering or molecular-beam epitaxy (MBE) that it does not require a vacuum system, and yet is still able to give clean *multilayer* films.[6] In this paper we present more detailed data on the Cu thickness dependence of GMR in electrodeposited Co–Ni–Cu/Cu superlattices.

Our films are grown from a sulfamate electrolyte in a cell with a standard three-electrode configuration using a process similar to that described by Lashmore *et al.*[7] Deposition was carried out with the electrolyte at 30±1 °C and pH=2.0±0.1. The electrolyte contains Co^{2+}, Ni^{2+}, and Cu^{2+} ions and we can alter the composition of the electrodeposited metal by controlling the cathode (substrate) potential. For example, when the cathode potential is −0.15 V relative to the saturated calomel reference electrode only Cu will be deposited, but when the cathode is at −1.8 V all three metals will be deposited to give a ferromagnetic Co–Ni–Cu alloy. Hence we can grow a Co–Ni–Cu/Cu superlattice by switching between these two potentials. A computer is used to monitor the deposition current, and switches from one potential to the other when the charge passed reaches the value corresponding to the desired layer thickness

The films used in this study were grown on (100) textured polycrystalline Cu plates and mounted on glass after their Cu substrates were dissolved away by means of a chromic/sulfuric acid selective electrochemical etch. This was done to prevent the highly conductive substrates from short-circuiting the superlattice during transport measurements.

After growth, x-ray diffraction was used to measure the repeat distances Λ of our superlattices, while their compositions were measured using an electron probe fitted with wavelength dispersive x-ray spectrometers, as described in a previous paper.[5] Some superlattices were measured by synchrotron radiation x-ray fluorescence analysis using beam line 3 on the storage ring VEPP-3 at the Institute of Nuclear Physics, Novosibirsk to determine the mass of Co, Ni, and Cu per unit area of film, and the compositions determined by this technique and using the electron probe agree quite well. The compositional measurements enable us to conclude that the ratio of Co to Ni in the ferromagnetic layers is between 3.6:1 and 3.8:1, while the Cu content of these layers could be as high as 25 at. %.[5] From the mass of each metal per unit area of the film m_x (x=Co, Ni, Cu) and its bulk density ρ_x it is also possible to calculate the equivalent thickness of that metal $t_x = m_x/\rho_x$, and hence the superlattice repeat distance $\Lambda = (t_{Co}+t_{Ni}+t_{Cu})/N$, where N is the number of repeats in the superlattice. Values of Λ obtained by this method and by x-ray diffraction agree to within ~15%.

To measure the magnetoresistance, point-like pressure contacts are applied to the corners of a square of film as shown in Fig. 1 (van der Pauw geometry[8]) and the in-plane applied magnetic field varied between −8 and 8 kOe (the maximum field available from our electromagnet). $R_{12,34}$ is defined as the potential difference $V_4 - V_3$ between contact 4

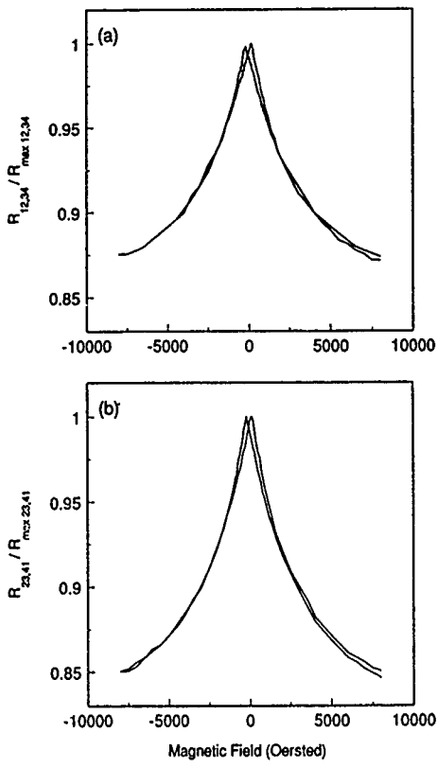

FIG. 2. Normalized magnetoresistances measured at room temperature for an electrodeposited superlattice consisting of 81 repeats of Co–Ni–Cu (~20 Å)/Cu (~7 Å). The resistance $R_{12,34}$ (a) is defined as the potential difference $V_4 - V_3$ between contact 4 and contact 3 per unit current flowing from contact 1 to contact 2, while $R_{23,41}$ (b) is defined analogously. The positions of the contacts are shown in Fig. 1. $R_{12,34}$ is predominantly a measure of the longitudinal magnetoresistance (current parallel to field) while $R_{23,41}$ is predominantly a measure of the transverse magnetoresistance (current perpendicular to field).

and contact 3 per unit current flowing from contact 1 to contact 2, and $R_{23,41}$ is defined analogously. $R_{12,34}$ is predominantly a measure of the longitudinal magnetoresistance (current parallel to field) while $R_{23,41}$ is predominantly a measure of the transverse magnetoresistance (current perpendicular to field).

Figures 2(a) and 2(b) show the results of such a measurement at room temperature on a superlattice consisting of 81 repeats of Co–Ni–Cu (~20 Å)/Cu (~7 Å). The size of the effect and the fact that both the "longitudinal" ($R_{12,34}$) and the "transverse" ($R_{23,41}$) magnetoresistance decrease when the magnitude of the applied field is increased show that we have observed GMR. Anisotropic magnetoresistance (AMR) of the kind observed in bulk alloys of the $3d$ transition metals[9] also appears to make a significant contribution to the observed magnetoresistance, since the percentage change in $R_{12,34}$ is rather less than the percentage change in $R_{23,41}$—AMR generally causes the longitudinal magnetoresistance to increase and the transverse magnetoresistance to decrease with increasing applied field.

Figure 3 shows the variation of percentage change in $R_{12,34}$ and $R_{23,41}$ as a function of the nominal Cu layer thickness (the Cu layer thickness calculated from the charge passed during deposition of each layer) for a series of superlattices with constant nominal Co–Ni–Cu thickness. The

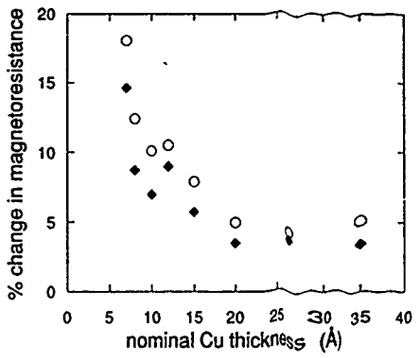

FIG. 3. Percentage change in $R_{12,34}$ ("longitudinal" magnetoresistance: (◆) and $R_{23,41}$ ("transverse" magnetoresistance: (○) for a series of electrodeposited Co–Ni–Cu/Cu superlattices with constant nominal Co–Ni–Cu thickness and total thickness ~0.3 μm. The percentage change in R is calculated as $[(R_{max} - R(8\text{ kOe}))/R(8\text{ kOe})] \times 100$.

true layer thickness is given by the product of the nominal layer thickness and the current efficiency, which is expected to be close to 100% for Cu. In each case the percentage change in R was calculated as $[(R_{max} - R(8\text{ kOe}))/R(8\text{ kOe})] \times 100$, and since our maximum field of 8 kOe was insufficient to saturate the magnetoresistance (see Fig. 2), larger percentage changes in the magnetoresistance would be possible at higher fields.

A number of points of interest are apparent from Fig. 3. Firstly, the percentage change in $R_{12,34}$ is consistently less than in $R_{23,41}$, implying a contribution from AMR in the observed magnetoresistance for all films. Second, the percentage change in magnetoresistance decreases with increasing Cu layer thickness, which is expected since increasing the Cu spacer thickness decreases the probability of the spin-conserving transmission of conduction electrons between two ferromagnetic layers required for GMR.[10] Third, although additional data points would be required to rule out the possibility, there is no obvious evidence of oscillations in the GMR as might be expected if it were due to oscillatory magnetic exchange coupling.[11] Such oscillations have been seen for sputtered Co–Ni/Cu superlattices.[12] Even so, the GMR in our samples may well be due to an antiferromagnetic exchange interaction, given the large applied fields required to saturate the magnetoresistance, although a large remanence at zero applied magnetic field measured using a vibrating-sample magnetometer (VSM) implies that only parts of the superlattice are so coupled.[13] The lack of oscillations could be due to fluctuations in the spacer layer thickness which damp them out, though this point requires further investigation.

To summarize, we have grown a series of electrodeposited Co–Ni–Cu/Cu superlattices and characterized them by x-ray diffraction, electron probe microanalysis, and x-ray fluorescence analysis. The magnetoresistance contains both an AMR and a GMR component and its magnitude decreases with increasing Cu spacer layer thickness.

Results for the temperature and magnetic-field dependence of melt-spun $Cu_{87}Co_{13}$ are presented and discussed. The magnetoresistance of the as-spun sample exhibits superparamagnetic behavior with a magnetoresistance of 18% at 0.4 K and in a field of 80 kOe. The magnetic-field dependence of the magnetoresistance is approximately proportional to the Langevin function. The microstructure of the sample was investigated by transmission electron microscopy and it appears that the giant magnetoresistance is due to the presence of small Co precipitates with an approximate mean diameter of 12 Å and a mean separation of 35 Å.

The magnetoresistance (MR) of magnetic materials has become a subject of much interest since the discovery of giant magnetoresistance (GMR) in magnetic multilayers.[1,2] It has recently been found that GMR is also a property of magnetic granular sputtered films.[3,4] When the randomly oriented magnetic moments of granules are aligned by an external magnetic field, the resistivity of the film decreases dramatically—by as much as 75% in the case of CoAg.[5] The microstructure of these films is complex, but all samples appear to have three things in common: (i) a nonmagnetic or spin-glass matrix; (ii) large precipitates of the magnetic element typically 200 Å in diameter or larger; (iii) smaller precipitates of less than 50 Å in diameter. At present it is not clear what the relative importance is of these three features determining the magnetic properties of these films.

We have studied $Cu_{87}Co_{13}$ produced by rapidly quenching the molten alloy using a melt-spinning technique. Most studies on GMR in granular systems have been based on sputtered samples[3,4] although a few groups are now working on melt-spun samples, also.[6,7] The alloy ingots were produced by arc melting 99.99% Co and 99.999% Cu in an argon arc furnace. Rapidly quenched ribbons were produced by means of a single copper rimmed wheel in 0.5 atm of helium gas. Part of the ribbon was used to measure the temperature and magnetic-field dependence of the resistance and part of the ribbon was thinned using a concentrated acid solution for transmission electron microscopy (TEM) studies. The TEM studies were carried out using a JEOL CX at 200 kV.

In Figs. 1(a) and 1(b) we show the TEM micrograph of the sample in bright and dark field. The grain size of the Cu matrix is about 1 μm and within the grain there are "large" Co precipitates of between 150 and 500 Å. In Fig. 1(c) we show the diffraction pattern. This shows spots consistent with the Cu matrix and twinned fcc Co precipitates, but most important we see a diffuse ring due to the presence of a high density of "small" Co precipitates. In Fig. 1(d) we show a micrograph highlighting the twinned structure within the large Co precipitates. In Fig. 1(e) we show a dark-field micrograph from the diffuse ring showing a large number of Co precipitates with a mean diameter of about 12 Å and spacing of about 35 Å. Parkin *et al.*[8] has observed similar results using small-angle neutron diffraction to determine the particle size distribution.

In Fig. 2 we show the magnetoresistance of the sample at various temperatures between 2 and 150 K. The maximum magnetoresistance is 18% at 0.4 K at 80 kOe, however, it is clear that at all temperatures the MR is not saturating. The MR decreases as the temperature rises and is only 2% at room temperature. In Fig. 3 we show the temperature dependence of the resistivity of the sample in zero field and in a 60 kOe field. The data in a field was the same whether the sample was zero-field cooled or field cooled.

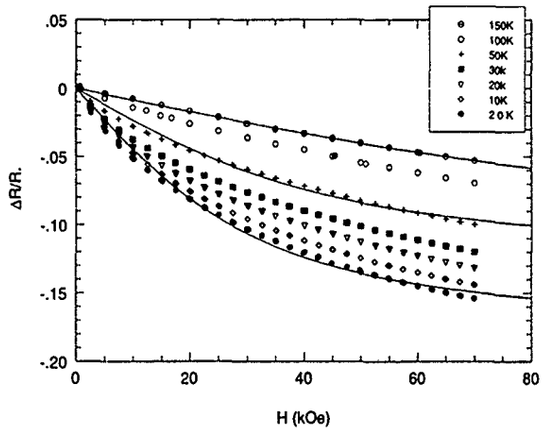

FIG. 2. The magnetoresistance of the sample at various temperatures. The solid lines are fits to the data assuming $\Delta\rho/\rho_0 \propto L(\alpha)$. For clarity the fits are only shown for 2, 50, and 150 K.

It appears that the magnetoresistance is due to the presence of the small 15 Å Co particles, and that these are superparamagnetic.[4] If we assume that the electron scattering probability is linearly dependent on the correlation of the magnetic moments of adjacent magnetic particles, then the magnetoresistance will be proportional to the square of the magnetization.[9] Hence, the resistivity would be proportional to the square of the Langevin function $L(\alpha)$, where $\alpha=\mu H/k_BT$ and μ is a measure of the magnitude of the moment on a particle. This assumes that the magnetic moments on each particle are uncorrelated. However, we find that we cannot fit MR data to the square of the Langevin function: The MR at low fields is very close to being proportional to $|H|$. The first point to be concerned with is the fact that if the MR is proportional to the modulus of H at low fields then there will be a nondifferentiable point at $H=0$. This is not actually a problem; all that is required of the MR is that it is an even function of H and is continuous. In Fig. 2 we show a fit to the data using $\Delta\rho/\rho_0 \propto L(\alpha)$.

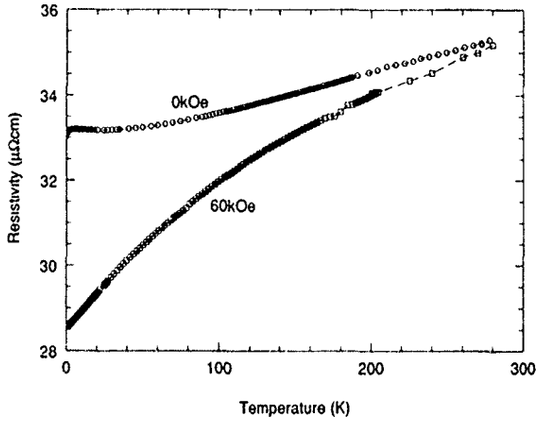

FIG. 3. The temperature dependence of the resistivity of the sample in zero field and in a 60 kOe magnetic field.

The reason the magnetoresistance is proportional to the Langevin function and not the square of the Langevin function is not clear. The result that the MR should be proportional to the square of the Langevin function is only strictly correct if the moments on the Co particles are uncorrelated. However, there are a number of ways they could become correlated: (i) the moments on the large "200 Å" Co particles will saturate at quite a low field and then the small superparamagnetic particles will interact with the field produced by the larger particles; (ii) the small particles may have a significant shape anisotropy which is oriented along the length of the ribbon; (iii) there may be some residual coupling between the particles.

A serious problem with our understanding of the field dependence of the magnetoresistance is that the values of μ extracted from the fits are temperature dependent varying from approximately 1 to 50 μ_B as the temperature is raised from 0.4 to 200 K for the sample. Interestingly, Barlett *et al.*[10] have argued that the MR in multilayer samples is also described by the Langevin function, although it is difficult to see what is the origin of the paramagnetic spins, but there is a similar problem with a temperature dependent μ. Such a temperature-dependent μ is not physically correct and this problem needs to be addressed for granular magnetic samples. However, the temperature dependence of the effective magnetic moment on a Co particle can be understood if we consider the possibility of coupling between the Co particles. Of course, the distance between the particles is of the right magnitude that there could be a residual antiferromagnetic average coupling between the particles. The possibility is being explored in depth at the moment.

We are grateful to the British Council and the Overseas Development Agency for partial funding of this project.

Temperature effect on magnetoresistance in Co/Ru sandwiches

A. Dinia, S. Zoll, and K. Ounadjela
ULP, IPCMS-GEMME, 4 rue Blaise, Pascal, F67070 Strasbourg, France

Evidence is given of a strong dependence of magnetoresistance on temperature in Co/Ru sandwiches. This dependence while weak for thin Ru layers is much stronger for thicker Ru layers. In fact, three oscillations in saturation magnetoresistance and saturation field as a function of the thickness of the Ru layer t_{Ru} are observed at 4.2 K while only one oscillation is found at 300 K. In addition, for thin Ru layers, $t_{Ru}<11$ Å, the saturation magnetoresistance is found to decrease between 4.2 and 300 K. In contrast, for Ru thickness in the range 11 Å$<t_{Ru}<$14 Å, the behavior is reversed, leading to the increase of the magnetoresistance at 300 K. This behavior is attributed to the spin disorder occurring at the interfaces at room temperature. Finally, for $t_{Ru}>14$ Å the magnetoresistance completely vanishes at 300 K while a relatively high value is still observed for large Ru thickness, $t_{Ru}=80$ Å, at 4.2 K. This indicates that the mean free path of the conduction electrons in the Ru layer is strongly reduced from about 100 Å at 4.2 K to approximately 14 Å at room temperature.

The study of magnetic layered systems consisting of ferromagnetic layers separated by a nonmagnetic interlayer has resulted in the discovery of a variety of fascinating phenomena.[1] In particular, reports of giant magnetoresistance (GMR) in Fe/Cr multilayers[2] have attracted great interest for fundamental physics as well as applications. The magnetoresistance (MR) has been found to be strongly dependent on the temperature, however the comprehension of this aspect remains still lacking. The decrease of MR with temperature has been recently reported and usually explained by a decrease of the mean free path of the electrons in the nonmagnetic layers.[3] Moreover, Parkin[4] has shown that the variation of the MR with temperature is strongly enhanced when the spacer layer thickness increases, suggesting that the main contribution to the MR comes from spin diffusion within the nonmagnetic layer.

Co/Ru sandwiches were grown by UHV evaporation onto mica substrate. A 150-Å-thick epitaxial Ru buffer layer was grown onto this substrate at 600 °C in order to provide a smooth and clean single-crystalline surface. After cooling the substrate to 120 °C, Co and Ru layers were subsequently grown and covered by 100 Å Ru (upper layer) to protect the sample against oxidation. For this study, a series of samples was prepared with fixed Co thickness $t_{Co}=32$ Å and varied Ru thicknesses from 5 to 80 Å. In the following, we refer to the nomenclature $(Co_xRu_y)_n$ superlattice, where x and y indicate the thicknesses in Å of Co and Ru sublayers and n the number of periods in which $n=2$ corresponds to sandwiches. The reflection high-energy electron-diffraction (RHEED) patterns obtained during the samples' growth reveal high crystalline quality with a (0001) hcp stacking of the Co and Ru layers.[5] For this series of samples in which $t_{Co}=32$ Å, the magnetization lies along the film plane as reported in previous work.[6]

The resistance was measured using the conventional four-point method, at liquid-helium temperature, with the external magnetic field applied along the film plane and parallel to the electric current direction. The magnetoresistance ratio $\Delta R/R$ was defined as the ratio of the total resistivity change ΔR to the resistivity at zero field. All MR curves were corrected for the classical parabolic magnetoresistance.

Figure 1 shows the MR curves obtained at 4.2 and 300 K for the strongly antiferromagnetically coupled sample $(Co_{32}Ru_5)_2$. For these two curves the maximum of resistance is observed at zero field, when the magnetizations of the two Co layers are antiparallelly aligned. The resistance decreases as the magnetic field increases and becomes constant when the applied field is sufficient to overcome the antiferromagnetic (AFM) exchange coupling and to align the adjacent magnetizations in its direction. For the curve measured at room temperature, we observe a shoulder at 500 Oe which is clearly explained by the anisotropic magnetoresistance (AMR) effect.[7] This anisotropic contribution of the MR was also deserved for all sandwiches and was taken into account for a precise determination of the spin-valve MR. The most interesting result is the temperature effect observed in this figure. In this sample, both MR and saturation field H_s obtained at 4.2 K ($\Delta R/R=0.36\%$ and $H_s=30$ kOe) are much larger than those found at 300 K ($\Delta R/R=0.11\%$ and $H_s=20$ kOe). This result indicates that the AFM exchange

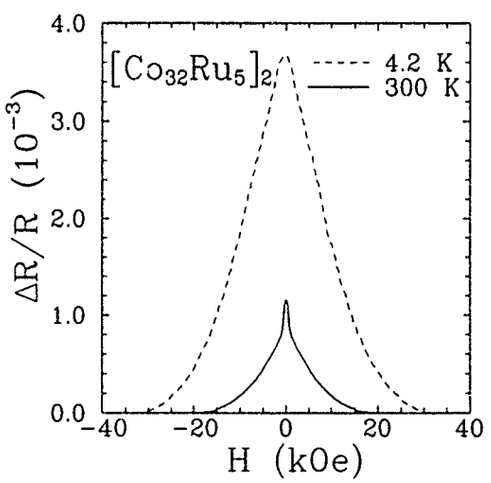

FIG. 1. Magnetoresistance curves of a $(Co_{32}Ru_5)_2$ sandwich with the applied magnetic field along the film plane and parallel to the current, respectively, at 4.2 K (dashed line) and 300 K (solid line).

 0021-8979/94/75(10)/6548/3/$6.00 © 1994 American Institute of Physics

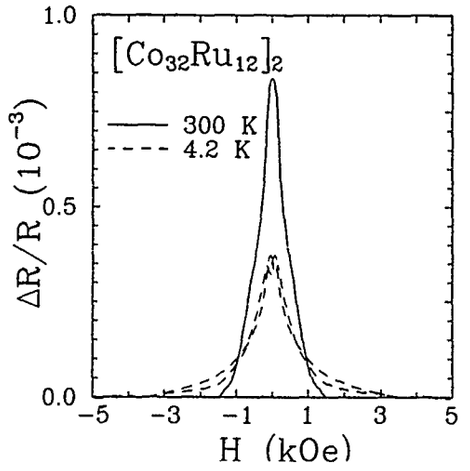

FIG. 2. Magnetoresistance curves of a $(Co_{32}Ru_{12})_2$ sandwich with the applied magnetic field along the film plane and parallel to the current, respectively, at 4.2 K (dashed line) and 300 K (solid line).

coupling strength J_{AF} decreases as the temperature increases. Its magnitude is related to the saturation field H_s by the following equation: $J_{AF}=H_sM_st_F/2$, where M_s and t_F are, respectively, the saturation magnetization and thickness, of the magnetic layer. Using the saturation field obtained in Fig. 1 and the saturation magnetization of the bulk Co, the J_{AF} values found for the $(Co_{32}Ru_5)_2$ bilayer are approximately equal to 6.72 erg/cm^2 at 4.2 K and 4.48 erg/cm^2 at 300 K. Such decrease of the AFM coupling by 33% between 4.2 K and room temperature is slightly higher than the reduction of 20% and 22% observed, respectively, in Fe/Cr (Ref. 3) and Co/Cu multilayers.[8] We explain this effect as being due to the thermal spin fluctuations occurring at room temperature. On the other hand, the decrease of the MR by 60% in this sample can be attributed to the strong decrease of the mean free path in the Ru layers at room temperature.

A similar study was performed on the $(Co_{32}Ru_{12})_2$ sandwich with larger Ru thickness than the corresponding value of the sample presented above. The magnetization hysteresis loop of this sample obtained at room temperature with the field along the film plane has shown a small coercive field and a small remanent magnetization which are characteristic of a ferromagnetic (FM) canted state.[7] This state was also confirmed by recent neutron-diffraction studies performed on the multilayer with the same Co and Ru thicknesses[9] where only a FM peak was found with relatively smaller intensity than the one corresponding to the ful' · ferromagnetically coupled layers. As a result the MR curves obtained at 4.2 and 300 K with H along the plane and parallel to the current I (Fig. 2) present an interesting behavior. Surprisingly the MR is found to increase at room temperature at the opposite of the other sample $(Co_{32}Ru_5)_2$ where the MR decreases at 300 K. This result was also obtained for the multilayer with the same Co and Ru thicknesses[7] and seems to be a characteristic of Co/Ru superlattices. In these superlattices the nuclear-magnetic-resonance (NMR) study has shown the evidence of some intermixing at the interfaces along three Co monolayers.[10] In these conditions the magnetization is lowered at the interfaces. This suggests a gradient in Curie temperature due to the concentration gradient of the interdiffused region and the appearance of a paramagnetic zone at the top of the layer where the concentration of Ru is higher than 37 at. % for Co atoms. As a consequence, the spin disorder is maximum at the interfaces at room temperature giving a contribution to the magnetoresistance due to the scattering within the Co layers which is much larger than the one obtained at 4.2 K. This contribution is relatively important for this Ru thickness, for which the MR due to the AFM exchange coupling is small, leading to the inversion of the MR behavior at 300 K. These results indicate that the dependence of the MR on temperature gives a fine information on the nature of the magnetic state as well as the one given by neutron diffraction.

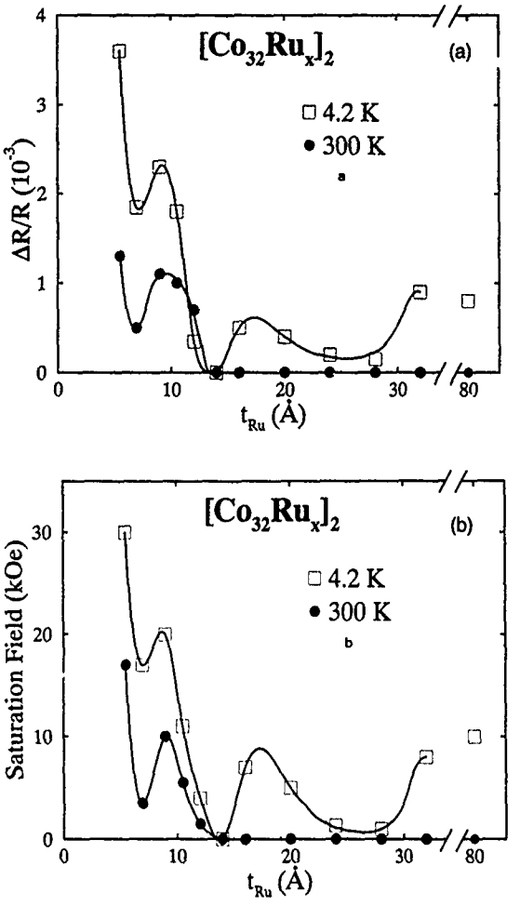

FIG. 3. Variation of the (a) magnetoresistance ratio and (b) saturation field as a function of the Ru thickness, respectively, at 4.2 K (square) and 300 K (circle). The magnetic field is applied along the film plane and parallel to the current. Solid curves are a guide to the eye.

Figures 3(a) and 3(b) show the variation of the saturation field H_s and saturation magnetoresistance $\Delta R/R$ of 14 sandwiches as a function of Ru thickness t_{Ru} both at 4.2 and 300 K. Three oscillations of $\Delta R/R$ and H_s are observed at 4.2 K while only one oscillation is found at 300 K. The oscillations obtained at 4.2 K are similar to those previously reported on Co/Ru multilayers[11–14] and are indicative of an oscillation in the indirect exchange coupling from antiferromagnetic to fer-

romagnetic state as the Ru layer thickness is varied. The maximum of these oscillations corresponds to the AFM state, where the coupling is strong, particularly for thin Ru thickness, and needs high magnetic field to change the relative orientation of the two magnetic layers from antiparallel to parallel.

The more striking result obtained in this figure is the strong dependence on the temperature of the magnetoresistance and saturation field. For the MR curve three different behaviors are clearly evidenced depending on the Ru thickness, as follows.

(i) For thin Ru spacer layers, $t_{Ru}<11$ Å, the MR is strongly reduced between 4.2 and 300 K. This reduction of MR is of 60% for $t_{Ru}=5$ Å and decreases as the Ru thickness is increased reaching 30% for $t_{Ru}=10$ Å. To explain this effect, we have to assume that the increase of the Ru thickness is accompanied by the reduction of the AFM exchange coupling, then the corresponding MR values are also reduced. In addition, the MR due to the spin disorder is found to increase at room temperature as explained above. As a consequence, the MR due to the spin disorder becomes relatively important which gives the decrease of the MR reduction between 4.2 and 300 K.

(ii) More interestingly, for 11 Å$<t_{Ru}<$14 Å the AFM exchange coupling is strongly decreased as confirmed by the small saturation field values. As a result, the MR due to this effect is smaller than the one due to the spin disorder at 300 K which leads to the inversion of the MR behavior where this latter is enhanced between 4.2 and 300 K.

(iii) for $t_{Ru}>14$ Å this effect is no longer observed, because the thickness becomes larger than the mean free path at 300 K and the MR completely vanishes; however, at 4.2 K two more oscillations of MR and H_s are observed for thicker Ru layers. The latter effect was also reported by Parkin[4] on $(NiFe/Cu)_n$ multilayers. The MR completely disappears for $t_{Ru}>10$ Å at room temperature while two oscillations of the MR are still observed at 4.2 K for larger Cu thicknesses. This result has been explained by the increased scattering in the Cu layers at room temperature for larger Cu thicknesses. For the variation of the saturation field with the Ru thickness reported in Fig. 3(b) the behavior is similar to the MR variation. However, the saturation field is always reduced at 300 K even for the Ru range thickness 11–14 Å where the MR was found to increase at 300 K.

Surprisingly, we find the presence of MR effect with slightly high saturation field ($H_s=10$ kOe) for a bilayer with Ru thickness of 80 Å, as reported in Fig. 4. This could indicate that the antiferromagnetic or ferromagnetic canted coupling persists for Ru thicknesses up to more than 80 Å and that the mean free path at this temperature is of the order of 100 Å.

In summary, we have shown that the dependence of the MR on the temperature gives fine information on the nature of the magnetic state and particularly at the interfaces. In fact, for thin Ru layers, where the AFM coupling is strong, the MR is important at 4.2 K and is sensitively reduced at 300 K due to the strong decrease of the mean free path. In contrast, for thicker Ru layers ($t_{Ru}=12$ Å) the coupling is small giving a small MR, then the enhancement of MR at 300 K is mainly due to the spin disorder at the interfaces. We find well-defined oscillations in the MR and the H_s at 4.2 K. However, only one oscillation was observed at 300 K indicating the strong dependence of the temperature effect on the Ru layer thickness. Consequently, for Ru layers larger than 14 Å both the MR and H_s vanish. The observation of a significant MR for a Ru thickness of 80 Å at 4.2 K suggests that the mean free path is of the order of 100 Å at this temperature, which is much larger than the value of about 14 Å obtained at 300 K.

Results are reported on the magnetothermopower of antiferromagnetically coupled Co-Re superlattices, obtained in a film of 150 Å Re/(Co 22 Å Re 5 Å)×16/50 ÅRe, from 10 to 300 K and in magnetic fields $0<H<10$ kOe. At low temperature the magnetothermopower, $\Delta S=S(H)-S(0)$, is positive reaching a maximum around 100 K ($\Delta S/S\cong 10\%$ at saturation), and fading away when $T>250$ K. At each temperature, the field dependence of ΔS is rather close to that observed in the magnetoresistance. The temperature dependence of ΔS is consistent with the model of Piraux *et al.* [J. Magn. Magn. Mater. **110**, L247 (1992)] based on a two-spin-channel conduction with electron spin mixing due to magnon scattering ($\rho_{\uparrow\downarrow}$). In this model the sign of ΔS depends on whether the parameter $\alpha=\rho_{0\downarrow}/\rho_{0\uparrow}$ is greater ($\Delta S<0$) or smaller than unity ($\Delta S>0$). The results for Co-Re superlattices, showing $\Delta S>0$, support this prediction, since $\alpha<1$ for Re impurities in Co, from previous studies.

I. INTRODUCTION

The two-current model, involving parallel conduction of spin-up and spin-down channels, and spin-dependent scattering at the interfaces or within the ferromagnetic layers, was successively used to explain the giant magnetoresistance in antiferromagnetically (AF) coupled Fe/Cu,[1] Co/Cr,[2] and Co/Re (Ref. 3) superlattices at low temperature. The observed decrease of the magnetoresistance when the temperature increases was first related to spin mixing by electron-magnon scattering.[4,5] This idea was then generalized and used to explain the observed temperature dependence of the magnetothermopower in Fe/Cr and Co/Cu multilayers.[6]

In this work we present a detailed experimental investigation of the magnetothermopower, $\Delta S=S(H)-S(0)$, in an AF coupled Co/Re superlattice with composition Re 150 Å/(Co 22 Å Re 5 Å)×16/Re 50 Å, exhibiting a large magnetoresistance at low temperature.[3] The temperature dependence of ΔS is analyzed in terms of the model of Piraux *et al.*,[6] and the field dependence of ΔS up to magnetic saturation is compared with the dependence of the magnetoresistance measured at the same temperature.

II. EXPERIMENT

The superlattice (Co 22 Å Re 5 Å)×16 was prepared by magnetrom sputtering in a high vacuum system with a base pressure of 1×10^{-7} Torr. The Co was deposited by rf, at a rate of 2 Å s^{-1}, and Re was deposited by dc magnetrom sputtering at a rate of 0.85 Å s^{-1}. These rates were monitored by *in situ* quartz crystals and the Ar pressure during deposition was kept at 8 mTorr (for Co) and 2.5 mTorr (for Re). In order to induce [001] crystal growth perpendicular to the plane of the films, a 150-Å-thick Re buffer film was used. It also reduces spurious effects of the glass substrate on the superlattice structure. To avoid effects from external exposure, a protective layer of Re, 50 Å thick, was deposited on the top of the film. Further details on sample preparation and characterization were given elsewhere.[3]

The thermopower S was measured with a four-wire dynamic method (two copper and two Chromel wires attached directly to the sample), based on the application, at each experimental temperature, of a transient temperature gradient giving a small difference of temperature across the sample, $\Delta T(t)$. This induces two time-dependent thermal emf (in the copper-sample and Chromel-sample circuits) which, for small ΔT, vary linearly with each other. The small voltages are measured with nanovolt resolution, and from the corresponding slope we can obtain S relative to copper (or Chromel). Further details on the experimental method are given elsewhere.[7]

III. RESULTS AND DISCUSSION

Figure 1 shows the temperature dependence of the thermopower for the reported Co/Re superlattice, from 10 up to 300 K and in zero magnetic field. $S(T)$ is negative and its magnitude increases with T, exhibiting great similarities with the corresponding curves measured in sputtered films of pure

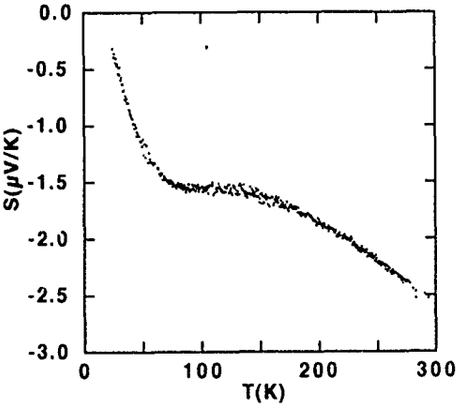

FIG. 1 Temperature dependence of the thermopower (S: Referred to copper) of the Re 150 Å/(Co 22 Å Re 5 Å)×16/Re 50 Å superlattice, measured in zero magnetic field.

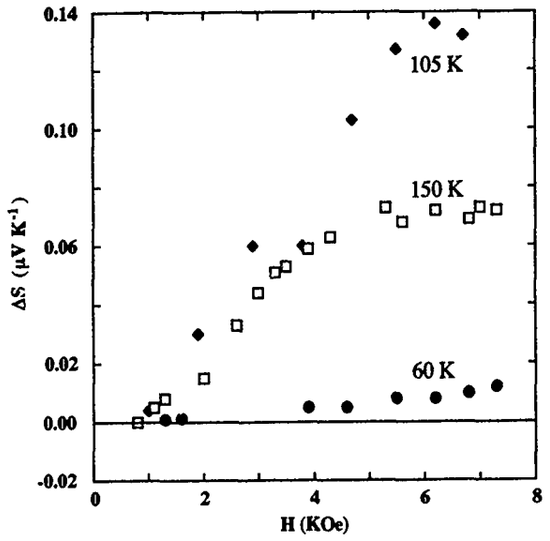

FIG. 2. Magnetic-field dependence of the thermopower, measured at three different temperatures: 60 K (●), 105 K (♦) and 150 K (○).

Co.[8] Thus, most of the observed thermal effects reflects the dominant role of Co in the Co 22 Å/Re 5 Å superlattice.

The application of a magnetic field produces a positive contribution in the thermopower, leading ultimately to magnetic saturation as illustrated in Fig. 2 for a few measured temperatures. The corresponding saturation fields $H_s(T)$, agree with those obtained from the magnetoresistance curves measured at the same temperature. As illustrated in Fig. 3 with data obtained at $T=100$ K an approximate linear relation exists between ΔS and $\Delta\rho/\rho$.

From the experimental $S(H)$ curves obtained at different temperatures, we can construct the magnetothermopower curve in the temperature range 10–300 K, as shown in Fig. 4. Here ΔS_m is the saturation magnetothermopower, obtained at fields $H>H_s(T)$.

This curve reveals the main features predicted in the model of Piraux *et al.*[6] based on the two-current model ($\rho_\uparrow$,$\rho_\downarrow$) and spin mixing due to magnon scattering ($\rho_{\uparrow\downarrow}$). It

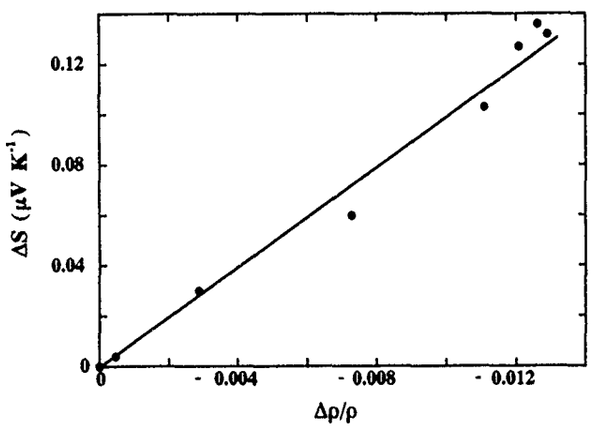

FIG. 3. An approximate linear relation exists between the changes with magnetic field of the magnetothermopower and magnetoresistance, as illustrated here for $T=100$ K.

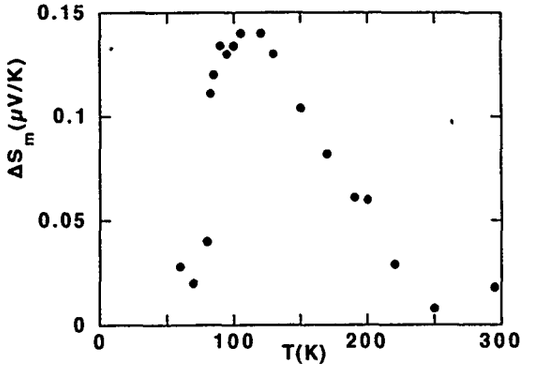

FIG. 4. Temperature dependence of the (saturation) magnetothermopower measured in the AF coupled Re 150 Å/(Co 22 Å Re 5 Å)×16/Re 50 Å superlattice.

gives a specific magnetothermopower contribution in AF coupled multilayered thin films with the form

$$\Delta S_m=\frac{\pi^2}{3}\frac{k}{|e|}R(T)\frac{\rho_\downarrow^2-\rho_\uparrow^2}{K}\rho_{\uparrow\downarrow}, \tag{1}$$

where $R(T)$ is a positive coefficient of the order of unity which varies slowly with temperature (except at very low temperature where R vanishes exponentially) and

$$K=[\rho_\uparrow\rho_\downarrow+\rho_{\uparrow\downarrow}(\rho_\uparrow+\rho_\downarrow)][\rho_\uparrow+\rho_\downarrow+4\rho_{\uparrow\downarrow}].$$

This anomalous thermopower contribution requires asymmetric conduction ($\rho_\uparrow\neq\rho_\downarrow$) and, simultaneously, spin-mixing mechanisms originating $\rho_{\uparrow\downarrow}$ (magnon scattering in the model). The addition of $3d$ impurities to the ferromagnetic elements (Co, Ni, and Fe) can induce large differences in $\rho_\uparrow$ and $\rho_\downarrow$. In the case of Re impurities in Co it is known that $\rho_\downarrow<\rho_\uparrow$,[9] which could explain the positive sign of ΔS_m in our Co-Re superlattice.

As a function of temperature, according to Eq. (1), $\Delta S_m=0$ at $T=0$ K ($\rho_{\uparrow\downarrow}=0$), increases with $\rho_{\uparrow\downarrow}$, goes through a maximum for $\rho_{\uparrow\downarrow}=0.5(\rho_\uparrow\rho_\downarrow)^{1/2}$ and decreases to zero for $\rho_{\uparrow\downarrow}\gg(\rho_\uparrow\rho_\downarrow)^{1/2}$. In contrast with the cases of Fe/Cu and Co/Cu multilayers,[6] where the expected maxima in $|\Delta S_m|$ are not observed below room temperature, in our Co/Re superlattice the maximum occurs well below room temperature. This suggests that the spin-mixing resistivity $\rho_{\uparrow\downarrow}$ in Co/Re reaches comparable values to $(\rho_\uparrow\rho_\downarrow)^{1/2}$ at considerably lower temperatures. From Ref. 9 we know the values of the partial residual resistivities caused by Re impurities in a Co matrix, for spin-up and spin-down conduction electrons, $\rho_{0\uparrow}=18$ $\mu\Omega$ cm and $\rho_{0\downarrow}=7.7$ $\mu\Omega$ cm, so $\alpha=\rho_{0\downarrow}/\rho_{0\uparrow}=0.43$ in this case; the behavior of $\rho_{\uparrow\downarrow}(T)$ in bulk Co was found to be similar to that of Ni. The suggested enhancement in $\rho_{\uparrow\downarrow}$ in our Co/Re superlattice film could be related to a smaller value of the D constant of the magnon dispersion curve in Co ($w=Dq^2$). A similar effect has been previously reported for $\rho_{\uparrow\downarrow}$ in Fe/Co multilayers.[6]

We should now comment the small magnitude of the thermoelectric power in our Co/Re multilayers. The zero-field thermopower S of pure Co is -30.8 μV K^{-1} at room temperature[10] and similar values have been observed at satu-

ration in Co/Cu multilayers. In contrast, S in our Co/Re multilayers is about one order of magnitude smaller. The magnetothermopower in Co/Cu samples with the largest magnetoresistance is about $-6\ \mu V\,K^{-1}$,[11–13] as opposed to the $+0.14\ \mu V\,K^{-1}$ observed in our Co/Re multilayer.

These differences could be due to the distinct role played by Cu and Re impurities in cobalt. For the transition-metal impurity, the large effective impurity potential, due to its incomplete d shell, is strong enough ($\Delta Z=2$ with respect to Co) to build up a virtual bound state $s_\uparrow d_\uparrow$(VBS) extending through the Fermi level, thus allowing extra conduction electron transitions, due to impurity scattering, into such VBS localized states.[14] In contrast, for Cu impurities, with their $3d$ band full, such a type of impurity scattering is not possible.

In pure Co (and also Co-Cu multilayers) we expect the dominance of the usual s-d transitions induced by phonons. Due to the high density of states in the d subband which goes through E_F, $N_{d\downarrow}(E_F)$, and to its rapid decrease with energy, a large negative thermoelectric power arises, $S\sim -30\ \mu V\,K^{-1}$ at room temperature.

As shown by Cadeville and Roussel,[10] 1% Re impurities in Co is sufficient to reduce the magnitude of the room temperature thermopower from about -30 to $-2\ \mu V\,K^{-1}$. Such dramatic reduction is due to the fact that the VBS density of states N has its maximum near E_F and so $dN/dE\sim 0$ leads to a small thermoelectric power (even to a change of sign, when we go from Os to Re).

Our results bring new information for the ongoing discussion of the physical origin of the magnetothermopower in magnetic multilayers as follows,

(i) Some authors[6] claim that electron-magnon, spin-mixing effects, are the dominant mechanisms. In this model the magnetothermopower is negligible both at low and high temperatures, so the ΔS_m anomalies occur only at intermediate temperatures.

(ii) More recent work, mainly concerned with Co-Cu multilayers,[11,12] emphasizes the dominant role of the phonon-induced non-spin-flip s-d transitions.

We believe that, due to the presence of the Re impurities and the high residual resistivity, s-d transition effects are not dominant in our Co-Re multilayers. It appears that the magnetothermopower essentially reflects the effects of the spin-mixing mechanisms, appropriately damped by the large residual resistivity (see below).[6] In contrast, s-d electron transitions seem to dominate in Co-Cu originating large thermopower and magnetothermopower values.[11,12] The temperature dependence of ΔS_m in Co/Re and Co/Cu multilayers is also consistent with the above considerations: The anomaly is concentrated at intermediate temperatures in Co/Re (as predicted by the electron-magnon model), whereas in Co/Cu it shows no sign of fading away up to 300 K (the density-of-states model gives an increase of ΔS_m with T, as the anomaly occurs through electron-phonon scattering).

Our previous characterization of the interfacial structure of Co/Re multilayers[15] indicates that interface Co-Re mixing occurs, at most, over about 5 Å (2.5 Å+2.5 Å) in each 22 Å Co layer. Nevertheless, if we recall that just 1% Re in Co decreases S by a factor of $\sim$10, it is not surprising that atomic disorder in Co/Re multilayers may lead to a large reduction of S. Apparently this is associated with a switch from the s-d (Refs. 11–13) to the electron magnon model.[6]

Structural properties of sputtered Si/Re 50 Å/(Co 20 Å/Re x Å)$_{40}$ superlattices have been investigated in detail by low- and high-angle x-ray-diffraction measurements. The low-angle x-ray reflectivity data have been analyzed using an optical model and the high-angle data have been treated on the basis of a trapezoidal model. The fitted results indicate that the films with small x_{Re}=3, 5, and 7 Å are essentially composed of pure Co layers and Re rich alloy (~80%) interfaces about 3–5 monolayers thick. The magnetoresistance (MR) data of the antiferromagnetically coupled films have been analyzed using a semiclassical MR model of interfacial spin-dependent scattering.

I. INTRODUCTION

Recently discovered giant magnetoresistance[1] (GMR) and oscillatory exchange coupling[2] in magnetic multilayers continue to attract intensive investigation because of their unusual underlying physics[1,2] and potential applications in magnetoresistive devices.[3] Since GMR has been found experimentally to be highly sensitive to the atomic structures of the individual layers as well as to the interfacial microstructures,[4–6] detailed structural characterization is necessary for understanding the anomalous magnetotransport property. In previous articles,[7,8] we have reported the GMR and oscillatory exchange coupling in sputtered Si/Re 50 Å/(Co 20 Å/Re x Å)$_{40}$ superlattices with x_{Re}=3–32 Å, and the annealing effect on the structure and GMR of the films. In this article, we analyze the low- and high-angle x-ray-diffraction data for the Co/Re superlattices on the basis of the structural models described in Ref. 9. In addition, the MR data of the antiferromagnetically (AF) coupled films are discussed in the light of a semiclassical MR model of interfacial spin-dependent scattering.[4]

II. EXPERIMENTAL DETAILS

The Co/Re superlattices with structures Si(oxidized)/Re 50 Å/(Co 20 Å/Re x Å)$_{40}$ were prepared using a modified single-source rf triode sputtering system.[7,9] Low- and high-angle x-ray-diffraction measurements have been taken using Cu$K\alpha$ radiation as detailed in Ref. 9. The MR was measured with the current in the film plane at temperatures from 1.5 to 325 K in magnetic fields up to 1 T, using a high-resolution ac bridge.[7]

III. RESULTS AND DISCUSSION

The reflectivity data of several films are shown in Fig. 1: Sharp superlattice peaks up to third order (except for the thinnest) are observed for all the films with Re thickness x_{Re} down to 3 Å. The reflectivity data of the films have been analyzed using an optical model[9] which includes both interfacial mixing and discrete layer-thickness fluctuations. The fitted results (dashed lines) are also shown in Fig. 1 for films B and E and the parameters for all five films are listed in Table I. As these values indicate, the rear and front interfaces in the small x_{Re} films extend across the entire Re layer, so that the films are essentially composed of Co layers and an alloyed interfacial region [3–5 monolayers (ML)]. For the film with the smallest x_{Re}~1 ML, successive Co layers may not be completely separated due to interfacial roughness. For films with $x_{Re} \geq 14$ Å, the fitted results indicate an asymmetric interface configuration as found in Co/Re bilayer and equal-thickness films.[9] Rear and front interface widths are found to be about 2 and 3 ML, respectively, somewhat smaller than found in the Co/Re equal-thickness films. This change can be understood on the basis of smaller cumulative layer roughness since the present films have only one-third the thicknesses of the previous series.

The high-angle x-ray-diffraction data for the same series of films show sharp superlattice peaks around the Bragg peaks corresponding to the Co and Re (002) average atomic spacing.[8] The strongest superlattice peak decreases in intensity and is displaced toward the Co (002) reflection position,

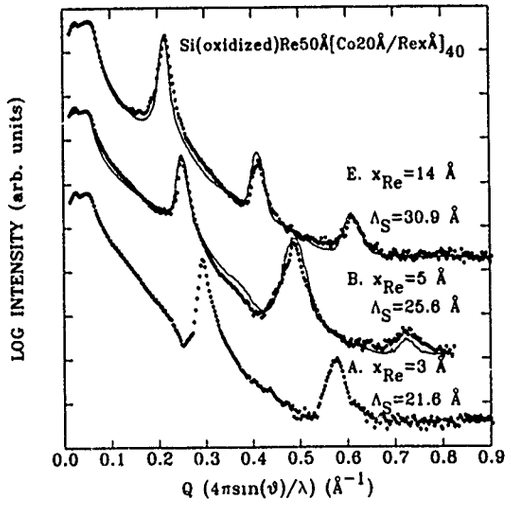

FIG. 1. Semilog plot for x-ray reflectivity data for Si/Re 50 Å (Co 20 Å/Re x Å)$_{40}$ films A, B, and E as a function of the scattering vector $Q = 4\pi \sin\theta/\lambda$. Solid lines are fitted results.

E 14	30.9	5.0	10.9	7.0	8.0	2.8	3.3

TABLE II. Derived parameters from fits to the high-angle diffraction data for the same films listed in Table I. x_{Re} is the nominal Re layer thickness; Λ_h is the modulation wavelength; $\bar{d}_{Co}$ and $\bar{d}_{Re}$ are the average atomic interplanar distances of Co and Re (002); n_{Co} and n_{Re} the corresponding atomic plane numbers, n_R and n_F the atomic layer numbers at the rear and front interfaces; L_c is the coherence length of the multilayer crystallite along the growth direction. The values in parentheses are the corresponding layer thicknesses.

x_{Re} (Å)	Λ_h (Å)	$\bar{d}_{Co}$ (Å)	$\bar{d}_{Re}$ (Å)	n_R (t_R) (Å)	n_{Co} (t_{Co}) (Å)	n_F (t_F) (Å)	n_{Re} (t_{Re}) (Å)	L_c (Å)
B 5	25.0	2 048	2.190	3 (6.4)	6 (12.3)	3 (6.4)	0	143
C 7	25.2	2.056	2.200	2 (4.3)	6 (13.2)	3 (6.4)	1 (2.1)	135
D 10	27.6	2.059	2.204	2 (4.3)	6 (12.4)	3 (6.4)	2 (4.4)	129
E 14	29.9	2.051	2.232	2 (4.3)	5 (10.3)	3 (6.4)	4 (8 9)	120

as the number of Re planes decreases. Quantitative analysis of the spectra was performed using a trapezoidal model which considers crystalline multilayers having extended interfaces with linear composition profiles.[9,10] The fitted results for the films B and E with x_{Re}=5 and 14 Å are shown in Fig. 2 and the structural parameters for films B, C, D, and E are listed in Table II. Due to the appreciable fraction of independent crystallites present in film A, it was not possible to fit its spectrum with adequate precision.

For the film with x_{Re}=14 Å, the values of $\bar{d}_{Co}$ and $\bar{d}_{Re}$ are found to be comparable to those obtained in the equal-thickness Co/Re films with similar Co layer thicknesses.[9] For films with $x_{Re} \leq 10$ Å, the $\bar{d}_{Co}$ decreases with decreasing x_{Re} from a $\bar{d}_{Co}$ value expanded by ~1.1% down to the Co bulk value, suggesting that the proportion of Co alloyed with the Re decreases due to the limited amount of Re available in these small x_{Re} films. On the other hand, the $\bar{d}_{Re}$ decreases significantly (~4%) compared to the values found for larger x_{Re} films (e.g., x_{Re}=14 Å), and becomes even smaller than the bulk value, indicating that almost all the Re layers are involved in alloying with Co. Using Vegard's law and the $\bar{d}_{Re}$ values listed in Table II, the average Re atomic concentration in the alloyed interfacial region is estimated to be ~80%.

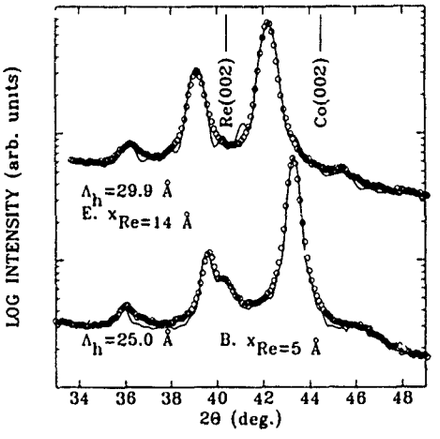

FIG. 2. High-angle x-ray-diffraction data (circles) and fitted results (solid line) for films B and E. The fitted results for film B include Re crystallites with d spacings close to that of the (002) plane. The positions corresponding to Co and Re reflections are indicated by the solid vertical lines.

Given that the trapezoidal model uses only integral monolayer thicknesses, there is good agreement between this model and the low-angle optical model as far as the individual layer thicknesses are concerned. Evidently, this conclusion also holds for the modulation wavelengths.

It is interesting to compare the MR shape,[7] in particular in low field, for two AF coupled films with x_{Re}=3 and 5 Å. For x_{Re}=3 Å, the maximum MR is observed at $\pm B_c$ (the coercive field), suggesting that there exists a remanent magnetization in zero field for this x_{Re}=3 Å film. As we know, for perfect AF coupling between identical magnetic layers, one expects no remanent magnetization as seen in Fe/Cr (Ref. 1) and Co/Ru.[2] From the structural analysis, we know that the successive Co layers are in partial contact due to pinholes in this film, which will result in a partial ferromagnet (FM) alignment of adjacent Co layers (direct exchange) and therefore a remanent magnetization in zero field. The triangular shape of the TMR curve in low field is also indicative of incomplete AF alignment of the Co layers.[2] In contrast, for films with x_{Re}=5 Å, the TMR curve shows a plateau shape at very low field,[7] decreases slowly as the field increases, and saturates at higher B_s, very similar to the MR behavior found in perfectly AF coupled films Fe/Cr,[1] and Co/Ru.[2] This form suggests that the remanent magnetization of the Co layers becomes practically zero, indicative of almost 100% AF coupling. Indeed, low- and high-angle x-ray-diffraction studies give evidence for Co layers separated by an interface region (~4 ML) with a Re atomic concentration about 80%, a nonmagnetic alloy layer. Hence, the MR properties for these two samples agree very well with the x-ray structural results.

The MR studies on these films showed oscillatory MR and interlayer magnetic coupling as a function of the Re layer thickness x_{Re} with a period of about 12 Å and a maximum MR magnitude of ≃1.2% at 4.2 K for x_{Re}=5 Å. In order to analyze the MR data (at 4.2 K) more quantitatively, we have fitted the experimental data of the AF coupled films with x_{Re}=5, 7, 16 Å using an equation derived from the semiclassical MR model,[4]

$$\frac{\Delta R}{R(F)} = \frac{R(\mathrm{AF}) - R(F)}{R(F)} = A\left[\mathcal{G}_3\left(\frac{x_{Re}}{\lambda}\right) - \mathcal{G}\left(\frac{x_{Re}}{\lambda}\right)\right]. \quad (1)$$

The prefactor A depends on the mean free path (MFP) λ

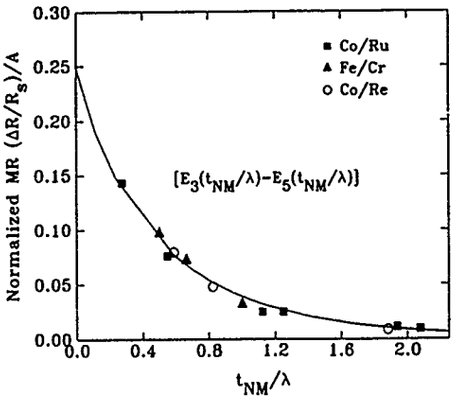

FIG. 3. Normalized MR $(\Delta R/R_F)/A$ plotted as a function of t_{NM}/λ for AF coupled multilayers: (△) Fe/Cr, $\lambda=20$ Å, $A=4.5$ (Ref. 4); (□) Co/Ru, $\lambda=15$ Å, $A=0.3$, (Ref. 4); (○) Co/Re, $\lambda=9$ Å, $A=0.14$.

(which is assumed, for simplicity, to be the same in Co and Re layers), the coherent interface transmission coefficients for spin-down and spin-up electrons $T_\downarrow$, $T_\uparrow$, and the Co thickness x_{Co}, but not on the thickness of the nonmagnetic layer x_{Re}, $\mathscr{E}_n$ are exponential integral functions.[4] Figure 3 shows that the series of experimental data on Fe/Cr,[4] Co/Ru,[4] and Co/Re at 4.2 K can be plotted on the same curve $\mathscr{E}_3(x_{Re}/\lambda)-\mathscr{E}_5(x_{Re}/\lambda)$ when the normalized MR, $\Delta R/R$ divided by the normalization factor A, is plotted versus t_{NM}/λ ($t_{NM}=t_{Cr}$, t_{Ru}, and t_{Re}). Analysis gives $\lambda\simeq 9$ Å for Co/Re, which is smaller than λ(Fe/Cr)=20 Å; and λ(Co/Ru)=15 Å.[4] This smaller λ in Co/Re can be ascribed to the high resistivity of the Re spacer. The decrease in λ values is consistent with the decreasing MR found in the Fe/Cr, Co/Ru, and Co/Re systems. In addition, as indicated in Ref. 5, for x_{Re} larger than the MFP λ (=9 Å in Re/Co), the MR vanishes as $\exp(-x_{Re}/\lambda)$, which explains the much smaller second AF peak observed at $x_{Re}\sim 16$ Å.[7]

In summary, the results obtained from the analyses of low- and high-angle diffraction data unambiguously indicate that the films with small x_{Re} are composed of Co layers and Re-rich alloy interfaces about 3–5 ML thick. The MR data of the AF coupled films can be well described by the semiclassical MR model of interfacial spin-dependent scattering.

A Cu/Fe granular film, formed from a multilayer film and composed of particles of Fe imbedded in Cu, has had several of its important properties investigated. Measurements include ferromagentic resonance, magnetoresistance, Mössbauer effect, magnetic viscosity, and magnetization. The two-phase behavior of these immiscible alloy systems, and the effect of multilayering on the shape of the magnetic precipitates, can explain some of these properties. An explanation of the ferromagnetic resonance line shape is proffered. An extraordinary macroscopic quantum tunneling effect is found to govern the magnetic relaxation at the lowest temperatures.

I. MAGNETORESISTANCE

We have manufactured a Cu/Fe multilayer, [Cu(50 Å)/Fe(10 Å)]×50 (and a Cu/Dy multilayer [Cu(100 Å)/Dy(40 Å)]) on Kapton. The samples were prepared by thermal evaporation in a high-vacuum system. Due, in part, to the low miscibility of Fe in Cu, this process can produce samples with small granular particles of Fe imbedded in the Cu matrix, instead of the usual layered structures. A similar process was recently used by IBM to produce their discontinuous (granular) $Ni_{80}Fe_{20}$/Ag multilayer films which currently hold the record for the largest sensitivity in any giant magnetoresistive (GMR) structure.[1] Although our Cu/Fe has only modest GMR, and Dy/Cu has almost none, our study of granular multilayers should provide insights into the magnetic structure of $Ni_{80}Fe_{20}$/Ag.

The 4.2 K magnetoresistance of the Fe/Cu granular multilayer is plotted as a function of external applied magnetic field in Fig. 1, along with the 4.2 K magnetic moment of the sample, obtained with a superconducting quantum interference device magnetometer. The magnetoresistance is large, decreases monotonically with field, and is independent of the field direction. These are the telltale characteristics of GMR, a phenomenon often found in multilayers and granular materials. GMR is associated with magnetically inhomogeneous material, and is caused by the magnetic scattering of conduction electrons by the nonaligned magnetic entities.[2] At 4.2 K and 60 kOe, the fractional change of resistance $\Delta\rho/\rho = -15\%$, but neither the magnetoresistance nor the magnetic moment is completely saturated yet. This failure to saturate is not due to ordinary magnetic hardness, but is caused by the existence of a paramagnetic component, most likely Fe singlets, dimers, or trimers dissolved within the Cu matrix, which coexist with the Fe precipitates. Further evidence for the existence of a paramagnetic iron moment in the as-deposited Fe/Cu film will become apparent in the Mössbauer effect results, presented in Sec. IV.

Unlike Fe/Cu, the Dy/Cu sample showed only ordinary magnetoresistance, characterized by both a nonmonotonic field dependence and a sensitivity to the magnetic-field direction.

II. FERROMAGNETIC RESONANCE

We have obtained the ferromagnetic resonance (FMR) spectrum of the Cu/Fe granular multilayer sample at 9.55 GHz with the magnetic field both parallel and perpendicular to the film plane. (The Dy/Cu spectrum was not detected.) The spectra depend hardly at all on temperature, and the room-temperature parallel and perpendicular absorption-derivative spectra are shown in Fig. 2. The parallel resonance is centered at 1.43 kOe and has a linewidth $\Delta H_{\parallel}=0.975$ kOe, while the perpendicular resonance is centered at 7.87 kOe with a linewidth $\Delta H_{\perp}=1.95$ kOe. Kittel[3] has derived the fields for resonance in the parallel and perpendicular configuration of thin magnetic films, H. In the absence of magnetic anisotropy they are given by the equations

$$f/\gamma=(H)^{1/2}(H+4\pi M)^{1/2} \quad \text{(parallel resonance)},$$
$$f/\gamma=H-4\pi M \quad \text{(perpendicular resonance)}, \qquad (1)$$

where f is the microwave frequency, γ is the gyromagnetic ratio, and M is the magnetization. (For a pure iron film, $\gamma=3.2$ GHz/kOe and $4\pi M=21.5$ kOe.)

Using the Kittel equations for the Cu/Fe sample, we obtain $g=2.18$ and $4\pi M=4.87$ kOe using the data shown in

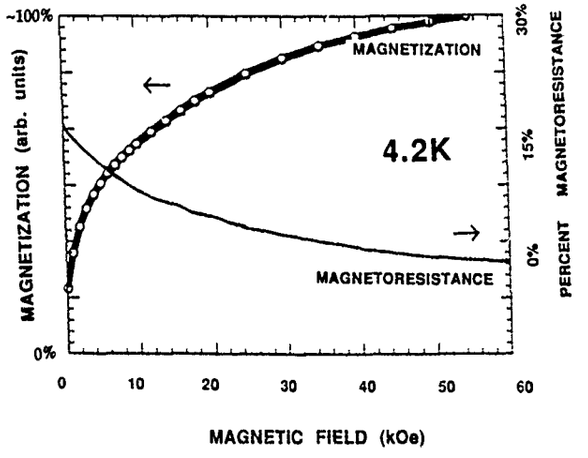

FIG. 1. Magnetization and magnetoresistance vs magnetic field at 4.2 K for Cu(50 Å)/Fe(10 Å). An easily saturable ferromagnetic component and a hard to saturate paramagnetic component are evident.

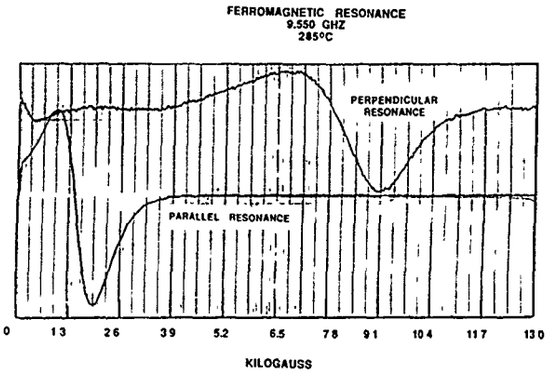

FIG. 2. 9.55 GHz FMR spectrum of Cu(50 Å)/Fe(10 Å) with applied field parallel and perpendicular to plane of film.

Fig. 2. The low value of magnetization results from the low value of the iron filling factor, ≈20%. Griscom *et al.*[4] have shown that it is proper to use the average value of the magnetization in the Kittel equations for some granular or precipitated films. Our derived values are in agreement with this conclusion, and this result is further justified below.

In a previous publication[5] one of the authors has shown that thin films of granular $Fe_{20}Cu_{80}$, made by coevaporation of the elements, with no attempt at multilayering, have larger FMR linewidths than those shown in Fig. 2. As-deposited films have linewidths of 2.5 kOe, and films annealed above 500 °C have linewidths of 4.0 kOe. The as-evaporated linewidth is attributed to a completely random distribution in the direction of the anisotropy fields[6] of the individual single-domain iron precipitates, resulting in a powder-pattern FMR lineshape with a linewidth $\Delta H=(5/3)(2K/M)$. Iron precipitates in thin films annealed at temperature higher than 500 °C have grown into multidomain particles with a linewidth[4] $\Delta H=(0.7)(4\pi M/3)$. The smaller linewidths of the granular multilayer—especially that of the parallel resonance—shows that the layer formation has restricted the spread in particle orientations, constraining it to be a less-than-random distribution. In the following section, we present some ideas on this matter, which also serve to explain why $\Delta H_\perp$ is so much larger than $\Delta H_\parallel$.

III. NETZELMANN'S CONJECTURE

The underlying multilayer structure can distort the shape of the iron precipitates by (a) inducing uniaxial distortions in what, otherwise, would be a sphere, or (b) produce a collection of pancakelike magnetic particles partially aligned along the layers. These alternatives are the two extremes, neither of which may prevail in practice. The high-sensitivity NiFe-Ag granular multilayers produced by the IBM group[1] belong to group (b).

We now assume that the sample is a collection of nearly flat islandlike particles—a discontinuous multilayer. (Assuming that the particles are spheroids aligned parallel to the layer direction does not alter our quantitative conclusions, and can be treated in the same manner.) Each particle is characterized with a demagnetization tensor $\mathbf{N}_p$, and the thin film is characterized with a tensor $\mathbf{N}_t$. Netzelmann[7] has proposed that the effective magnetostatic energy density F_N be approximated as

$$F_N=\tfrac{1}{2}(1-f)\mathbf{M}\cdot\mathbf{N}_p\cdot\mathbf{M}+\tfrac{1}{2}(f)\mathbf{M}\cdot\mathbf{N}_t\cdot\mathbf{M}, \quad (2)$$

where f is the volumetric filling factor of magnetic particles and $\mathbf{M}$ is the particle magnetization. Except for the constraint imposed by Eq. (2), each particle is assumed to precess independently during FMR. Netzelmann[7] and Yu, Harrell, and Doyle[8] have used this approach to determine particle orientation distributions from FMR spectra in magnetic tapes.

TABLE I. Values for Kittel demagnetizing factors.

Effective demagnetizing factor	Prependicular resonance	Parallel resonance
N_z	$4\pi f+4\pi(1-f)(1-2\epsilon)$	$4\pi 1-f)\epsilon$
N_x	$4\pi(1-f)\epsilon$	$4\pi f+4\pi(1-f)(1-2\epsilon)$
N_y	$4\pi(1-f)\epsilon$	$4\pi(1-f)\epsilon$

The generalized Kittel equation,[3] applicable to an ellipsoid with demagnetizing factors designated by N_x, N_y, and N_z, is

$$f/\gamma=\{[H_0+(N_y-N_z)M_0][H_0+(N_x-N_z)M_0]\}^{1/2}, \quad (3)$$

where the z axis is always in the direction of the applied field H_0, and the y and x axes are perpendicular to z. Choosing diagonal values $\mathbf{N}_p=4\pi(1-2\epsilon,\epsilon,\epsilon)$ and $\mathbf{N}_t=4\pi(1,0,0)$, appropriate to an ellipsoidal particle and a thin film, respectively, we obtain the following values for the Kittel demagnetizing factors, for parallel and perpendicular resonance, as shown in Table 1.

We now assume that the FMR linewidth is primarily caused by a flat distribution of particle ellipticity parameters ϵ, which vary between $\epsilon=0$ and $\epsilon=\epsilon_0$. Using Eq. (3), the perpendicular resonance linewidth is given by $\Delta H_\perp=4\pi M_0\epsilon_0(1-f)$, from which we obtain the value $\epsilon_0=0.12$ from the experimental value of $\Delta H_\perp$. The Netzelmann–Kittel equation yields $\Delta H_\parallel=0.65$ kOe for the value of the parallel resonance linewidth, compared to the experimental value of 0.97 kOe, and shows why the parallel resonance linewidth differs than from the perpendicular resonance linewidth. The equations also show that the appropriate magnetization to use in the Kittel formula is the average global magnetization for both flat and spherical precipitated particles.

Using nearly spherical particles with a distribution of ellipsoidal distortions, instead of pancake-shaped particles, yields the same quantitative conclusions. However, using nearly spherical particles results a larger discrepancy in the ratio of the two linewidths than using nearly flat particles. However, from FMR linewidths alone, we are hesitant to draw too many conclusions. Other[1] granular multilayer systems are found to have flat, islandlike precipitates.

IV. OTHER EXPERIMENTAL RESULTS

Mössbauer effect measurements were obtained at 80 K on the Cu(50 Å)/Fe(10 Å) multilayer studied here. The spec-

trum consisted of a hyperfine field sextet with splittings appropriate to ferromagnetic a-Fe and a broad zero-field "singlet" which we associate with the paramagnetic irons discussed in connection with Fig. 1. The paramagnetic component is strong, in agreement with magnetoresistance and magnetization results. The Mössbauer measurements indicate that the moments are in plane, as expected for either spheres or platelets with low magnetic anisotropy imbedded in a thin film. Details of another, more magnetically dilute, multilayer have been published elsewhere.[9]

The dynamic properties of this Fe/Cu granular multilayer has been investigated between 1.6 and 16 K by examining the time dependence of the thermoremanent magnetization, otherwise known as the magnetic aftereffect. Below $T^* \approx 4$ K the magnetic relaxation time becomes independent of temperature, which we interpret as evidence of quantum-mechanical tunneling of the single-domain magnetization of the Fe particles. Aharoni[10] has shown that shape anisotropy, as well as crystalline anisotropy, alters the temperature T^* at which quantum tunneling first appears. The present study, which seeks to quantify the shape anisotropy, may influence the interpretation of the quantum tunneling results. Further discussion of this remarkable effect can be found in Ref. 11.

Magnetic properties of similar granular-multilayer Fe/Cu and Dy/Cu films have been published elsewhere.[12]

The structural and magnetotransport properties have been studied in ($Ni_{81}Fe_{19}$,$Ni_{80}Co_{20}$)/Ag granular alloy films synthesized by the annealing of sputtered multilayers containing ultrathin magnetic layers. The magnetic concentration, particle size, and morphology of the precipitates can be controlled by adjusting the magnetic layer thickness during the deposition process. Magnetoresistance as large as 30% was found at 4.2 K with a rather small saturation field (<2 kOe), leading to relatively high field sensitivity. Magnetoresistance and saturation field in these alloy films essentially depend on the magnetic precipitate size, concentration, and annealing temperature. The temperature dependence of magnetization and magnetoresistance was also studied, and the correlations among the microstructure, magnetotransport, and magnetic properties are discussed.

I. INTRODUCTION

The recent observation of giant magnetoresistance (GMR) for ferromagnetic granules in a nonmagnetic metal matrix[1,2] adds a new dimension to the phenomenon of GMR in magnetic multilayers.[3] High negative MR of immiscible granular alloy systems, such as Co-Cu,[1,2] and Co-Ag,[4] have extended our fundamental understanding of GMR effects. It has been shown that the interface spin-dependent scattering plays a key role in granular systems due to the large surface-to-volume ratio of the magnetic ultrafine precipitates;[5] however, to be useful as magnetoresistive sensor devices, thin-film materials with enhanced magnetoresistance in a small magnetic field are required. Identifying a proper structure of the inhomogeneous system with these characteristics still remains a key problem.

The important requirement for preparing granular magnetic films is to control the size and spacing of the magnetic precipitates. In this article, we report the synthesis of Ni(Fe,Co)/Ag phase-separated alloy films based on the heat treatment of multilayered samples containing ultrathin NiFe or NiCo layers. Selecting a soft magnetic alloy (e.g. $Ni_{81}Fe_{19}$ or $Ni_{80}Co_{20}$) which has an intrinsically small magnetocrystalline anisotropy and which is insoluble in Ag over a wide composition range,[6] may result in enhanced MR and small saturation fields.

II. EXPERIMENTAL DETAILS

The ($Ni_{81}Fe_{19}$,$Ni_{80}Co_{20}$)/Ag multilayers with individual magnetic layers ranging from ~7 Å and Ag layers of 20 to 22 Å were prepared by dc magnetron sputtering from separate targets of $Ni_{81}Fe_{19}$ or $Ni_{80}Co_{20}$ alloy and Ag onto glass substrates at room temperature. The background pressure was $<2\times10^{-7}$ Torr. With a sputtering pressure of 7.5 mTorr of argon, the deposition rates (determined from the measured thicknesses of single films by low-angle x-ray reflectivity measurements) were 1.4 Å/s for $Ni_{81}Fe_{19}$ and 1. 6Å/s for Ag. The individual layer thicknesses of the magnetic alloys and Ag were adjusted to yield films of magnetic composition between 20 and 45 at. %. Total film thicknesses were 900–1200 Å. All the samples were examined as deposited and postheat treated under a vacuum of $<2\times10^{-6}$ Torr.

The structural characterization of the samples were performed by low- and high-angle x-ray diffraction using Cu-$K\alpha$ radiation[7] and a high-resolution Philips 200 kV (CM20) transmission electron microscope (TEM). The film compositions, as determined by electron microprobe measurements, were found to be within 4% of the nominal values. The magnetoresistance measurements were carried out using a four-terminal geometry and a high-resolution ac bridge.[8] The current was in the plane of the film with the magnetic field either in the film plane and perpendicular to the current (transverse ρ_T) or perpendicular to the plane (perpendicular $\rho_\perp$). Magnetization data between 4.2 and 300 K were obtained using a superconducting quantum-interference device (SQUID) magnetometer.

III. RESULTS AND DISCUSSIONS

The low angle x-ray reflectivity spectra reveal superlattice peaks for all the as-deposited samples down to a bilayer thickness of Λ=26 Å (with a 4 Å layer of magnetic component), indicating a well-defined composition modulation along the growth direction. The corresponding high-angle x-ray diffraction and electron diffraction for these samples show that the multilayer films have coherent interfaces and a highly textured structure with (111) orientations normal to the film plane.[9] However, after annealing the samples at 450 °C for 10 minutes, both low- and high-angle x-ray results show that the superlattice structures are washed out, indicating significant interdiffusion during the annealing stage. The NiFe particle sizes, observed from TEM images as

 0021-8979/94/75(10)/6560/3/$6.00 © 1994 American Institute of Physics

FIG. 1. TEM micrograph for the sample (NiFe 4 Å/Ag 20 Å)×30 annealed at 450 °C for 10 min. The inset is the electron diffraction pattern showing the fcc (111) textured structure.

shown in Fig. 1, have variable size up to 100 Å at this annealing temperature depending on the original thickness of the NiFe layers. The highly (111) textured structures can still be seen in the annealed samples as demonstrated by the electron diffraction in the inset of Fig. 1. As the annealing temperature is increased, the superlattice coherence is lost and, the high-angle x-ray peak intensity, which assign the (111) peak of NiFe, increases and becomes sharper, indicating the growth of NiFe particles upon the heat treatment.[9]

Magnetoresistance measurements were performed between 4.2 and 300 K in magnetic fields of up to 10 kOe. The results of the as-deposited multilayers show no apparent GMR and no evidence of antiferromagnetic coupling between the NiFe or NiCo layers across the Ag spacer, as inferred from the magnetization curves. However, the structural and magnetotransport properties are very sensitive to the heat treatment. Figure 2 shows the dependence of MR at 4.2 K on the annealing temperature T_a, for multilayers containing either ultrathin $Ni_{81}Fe_{19}$ or $Ni_{80}Co_{20}$ layers. The maximum MR is found in the samples annealed at 300 °C. In sample NiFe 4 Å/Ag 20 Å (i.e., 24 at. % NiFe), for example, an appreciable increase of $\Delta\rho$ $(=\rho_{(H=0)}-\rho_{(H=H_s)})$ up to 85% is observed upon annealing. The resistivity ρ, however, decreases by about a factor of 1.4 due to the reduced structural disorder. The net result gives an enhancement of up to 30% for the value of $\Delta\rho/\rho$. The structural studies reveal that such a behavior is correlated to a structure which is layered in the film growth direction but discontinuous in the lateral direction.[10] It is also noted that the high-temperature (>450 °C) annealing substantially decreased the MR, as can be ascribed to the extreme growth of NiFe grains or a decrease in surface-to-volume ratio. Upon substitution of $Ni_{81}Fe_{19}$ by $Ni_{80}Co_{20}$, the annealing effect is essentially similar, the relatively small magnitude of MR in $Ni_{80}Co_{20}$/Ag may be ascribed to the intrinsically small magnetization in this alloy.

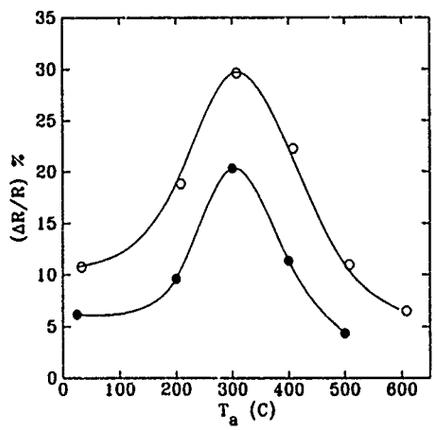

FIG. 2. Dependence of magnetoresistance, at 4.2 K, on the annealing temperature (●) (NiCo 4 Å/Ag 20 Å)×30 and (○) (NiFe 4 Å/Ag 20 Å)×30.

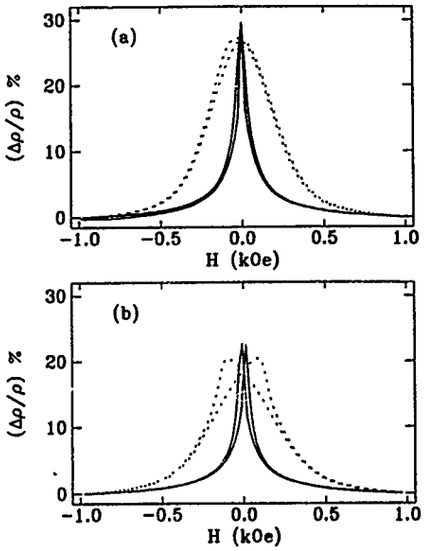

FIG. 3. GMR of the (NiFe t Å/Ag 20 Å)×30 films annealed at 300 °C, 1 h; measured at 4.2 K. Solid line: field in the film plane; dotted line: field perpendicular to the film plane; (a) t_{NiFe}=4 Å, or 24 at. % NiFe; (b) t_{NiFe}=6 Å, or 30 at. % NiFe.

The important feature of our alloy films is their small saturation fields compared with those found in other heterogeneous granular systems. Figure 3 shows typical MR curves of $Ni_{81}Fe_{19}$/Ag films annealed at 300 °C. Together with the substantial high MR magnitude, a rather small saturation field less than 2 kOe can be deduced for the sample containing a 4 Å NiFe layer (i.e., 24 at. % NiFe), as inferred from Fig. 3(a). The value is about 5–10 times smaller than those found in cosputtered Co/Cu (Refs. 1 and 2) and Co/Ag[4] granular alloy systems. Further increase of the magnetic layer thickness (namely increasing the magnetic concentration) results in a decrease of the MR as shown in Fig. 3(b). The composition dependence of MR of these films has revealed that maximum MR is near the 24 at. % magnetic content,[9] where the spin-dependent scattering, particularly at the interface of the magnetic particles and the metallic matrix, may be most effective according to the model of Zhang.[5] The saturation fields H_s, as described in a previous study,[9] are also related to the magnetic concentration. Even smaller H_s (<1 kOe) for NiFe concentrations above 35 at. % can be obtained. The MR curves, in fact, are broad for the field perpendicular to the film plane and narrow for the field in the plane of the film as can be seen from Fig. 3, implying

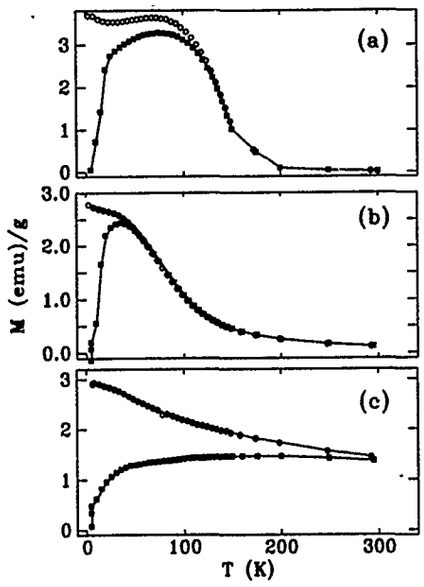

FIG. 4. Field-cooled (FC) and zero-field-cooled (ZFC) magnetization vs temperature for NiFe 4 Å/Ag 20 Å measured in an external field of 40 Oe: (a) as-deposited; (b) annealed at 300 °C, 1 h; (c) annealed at 400 °C, 1 h.

the existence of some platelik[illegible]cles. The small H_s in these films may be simply ascribed to the shape of the magnetic precipitates. We also note that the maximum MR occurs at zero applied field for 24 at. % NiFe sample [Fig. 3(a)] showing this sample to be more superparamagneticlike, while it occurs at the nonzero coercive fields for the 30 at. % NiFe sample [Fig. 3(b)] reflecting in some degree the existence of more stable single-domain particles.[11] Selecting and controlling of the structural parameters, in order to maximize MR and minimize H_s, is an important aspect for the use of granular alloy films in magnetic sensor application.

Figure 4 shows the zero-field-cooled (ZFC) and field-cooled (FC) magnetization data of $Ni_{81}Fe_{19}$ 4 Å/Ag 20 Å sample measured as a function of temperature in a small external field of 40 Oe. The as-deposited sample [Fig. 4(a)] shows a quite broad peak in the ZFC curve with the onset of the irreversibility (where the FC and ZFC curves join) occurring at a slightly higher temperature. The data reveal the existence of a large size distribution of the magnetic entities in the as-deposited sample due to the possibly imperfect layered structure, and can be interpreted in the so-called reentrant magnetic behavior representing the coexisting of both spin-glass and ferromagnetic orders.[12] The sample annealed at 300 °C [Fig. 4(b)] shows clearly a narrow ZFC peak with the peak position (defined as the blocking temperature) occurring at a fairly low temperature with the irreversibility onset closer to the peak position. This behavior reflects the possible formation of a uniform size distribution as the consequence of structural relaxation and interdiffusion after annealing. Correspondingly, MR is maximum at 4.2 K, and dramatically decreases above the blocking temperature (>50 K) where the magnetic particles exhibit superparamagnetic behavior. Heating the sample above 400 °C [Fig. 4(c)] increases the magnetic stability with increasing the particle size, as indicated by the increase of the blocking temperature and the onset of the irreversibility. The fact that both MR and magnetization can be readily saturated in a field of less than 1 kOe, may imply the formation of multidomain particles, but we have no direct evidence for this.

IV. CONCLUSIONS

We have synthesized phase-separated ($Ni_{81}Fe_{19}$, $Ni_{80}Co_{20}$)/Ag alloy films by annealing multilayered structures containing ultrathin magnetic layers. The magnetic concentration and precipitate size can be controlled by adjusting the magnetic layer thickness in the deposition stage as well as by postheat treatment. The alloy films display giant magnetoresistance with a maximum value of 30% at 4.2 K for NiFe concentration near 24 at. %, and a rather small saturation field of less than 2 kOe. Even lower saturation fields can be obtained by increasing the magnetic concentration and annealing temperature. However, in order to achieve high performance in magnetic sensor applications, further studies of granular films will be needed to explore a variety of particle shapes and size distributions.

Giant ac magnetoresistance in the soft ferromagnet $Co_{70.4}Fe_{4.6}Si_{15}B_{10}$

F. L. A. Machado, B. L. da Silva, S. M. Rezende, and C. S. Martins
Departamento de Física, Universidade Federal de Pernambuco, 50732-910 Recife, Pernambuco, Brazil

ac magnetoresistance (MR) measurements performed in thin ribbons of the amorphous soft ferromagnet $Co_{70.4}Fe_{4.6}Si_{15}B_{10}$ are reported with a longitudinal dc applied magnetic field H varying from 0 to ±15 Oe. The dependence of the MR with the frequency f of the measuring ac current was investigated for $0.4 \leq f \leq 100$ kHz. No significant frequency dependence in the resistivity ρ for $H=0$ and $H=\pm 15$ Oe was found. For intermediate values of H, $\rho(H)$ presents a peak in H which increases linearly in frequency. The MR peak in H at room temperature varies from typical values of 0.13% in the low-frequency range to a giant value of 27% at 100 kHz. Two possible sources for the frequency dependence of the magnetoresistance in amorphous alloys are discussed.

I. INTRODUCTION

Earlier magnetic studies showed that the amorphous alloy $Co_{70.4}Fe_{4.6}Si_{15}B_{10}$ is a soft ferromagnet with a magnetic permeability strongly dependent on the applied magnetic-field frequency and on its thermal history.[1] In addition this alloy shows spin-glass-like properties at high temperatures and low fields which can be understood within the random anisotropy model (RAM).[2,3] More recently we observed[4] that the magnetoresistance (MR) in this alloy presents a peak in $H=2.4$ Oe resulting from two contributions: the first one increasing with the applied magnetic field ($MR \alpha H^2$) and the second one decreasing with M^2 ($MR \alpha -M^2$). This behavior was observed for samples annealed in a magnetic field of 2 kOe. For samples annealed in $H=0$ the MR values are quite small compared to those observed in magnetic-field annealed samples. In Ref. 4, we reproduced quite well the MR magnetic-field dependence using the rotational model for induced transverse anisotropy (RMITA) and the measured magnetization. However, because of the strong frequency dependence of the MR in $Co_{70.4}Fe_{4.6}Si_{15}B_{10}$ reported in the present work, it seems to us that the RMITA may not be the correct model to account for the observed H^2 behavior. In this article we also discuss possible theoretical models for this new ac giant magnetoresistance effect.

II. TECHNIQUE AND EXPERIMENTAL RESULTS

The magnetoresistance was measured at room temperature using an ac four-probe technique. The frequency of the ac current was varied in the range $0.37 \leq f \leq 97.73$ kOe while its amplitude was kept constant at 10 mA. A pair of Helmholtz coils oriented to minimize the Earth's field generated the applied dc magnetic field. The electrical contacts in the sample were made with silver paint. The resistance of the contacts were of the order of few Ω. The samples were pieces of a ribbon of $Co_{70.4}Fe_{4.6}Si_{15}B_{10}$ taken from the same batch of the samples used in our earlier reported results. The sample was 50 μm thick, 1 mm wide, and 1.5 cm long. They were annealed for 15 min at 573 K in a magnetic field of 2 kOe applied transverse to the ribbon length but in the plane of the sample. The samples were then cooled keeping the magnetic field on. The experimental setup and the data acquisition was fully automated.

The magnetoresistance MR ($=10^2[\rho(H)-\rho(H=0)]/\rho(H=0)$) is plotted in Fig. 1 for $f=9.77$, 50.77, and 97.73 kHz [curves (a), (b) and (c), respectively]. The arrows indicate the direction the magnetic field was swept. The MR curves are quite reversible. As reported earlier,[4] the MR is positive and shows two distinct regimes which results in a peak at $H=2.4$ Oe. For small values of H, MR is dominated by a contribution which increases with the square of the applied magnetic field. For intermediate and higher H, a $-M^2$ contribution becomes dominant. The inset shows the variation of the maximum of the MR (squares) in the frequency range of the measurements. The peak in MR continuously increases with frequency with a linear dependence (solid line) for almost three decades in frequency. Strikingly, while the low-frequency MR is typical of amorphous alloys, it assumes a giant MR of 27% for $f=97.73$ kHz.

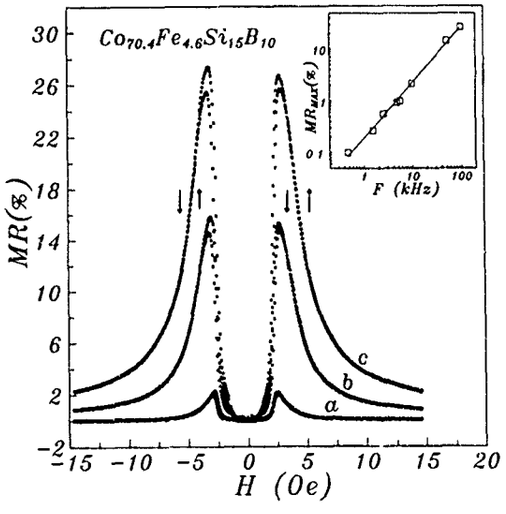

FIG. 1. Magnetoresistance MR $\{=10^2[\rho(H)-\rho(H=0)]/\rho(H=0)\}$ vs applied magnetic field H curves for three different values of measuring current frequency: (a) 9.77, (b) 50.77, and (c) 97.73 kHz. The arrows indicate the direction the magnetic field was swept. The inset shows the frequency dependence of the maximum in MR observed for $H \simeq 2.4$ Oe.

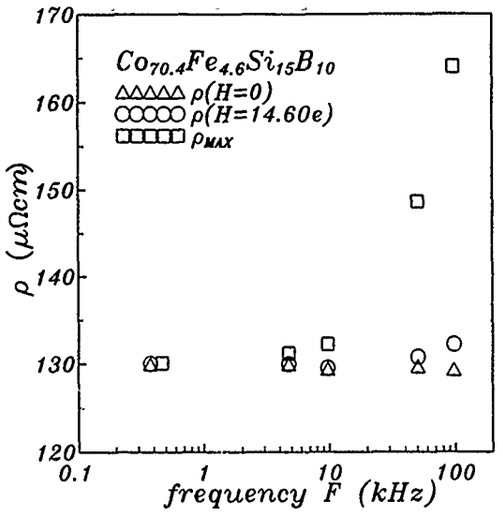

FIG. 2. Frequency dependence of the resistivity ρ for $H=0$ (triangles), $H=14.6$ Oe (circles), and for $H\simeq 2.4$ (squares) where the maximum in the resistivity is observed (ρ_{max}).

We show in Fig. 2 the resistivity ρ in $\mu\Omega$ cm versus frequency for three different field values, $H=0$ (triangles), $H=14.6$ Oe (circles), and for $H\simeq 2.4$ Oe (squares) which is the value for the peak in $\rho(H)$ ($=\rho_{max}$). Clearly the frequency dependence observed for $H=0$ and for $H=14.6$ Oe is very small compared to that of the peak.

In Fig. 3 we reproduced the room-temperature magnetization M versus applied magnetic field curve used to fit the data reported in Ref. 4. This curve was obtained for a sample with approximately the same dimensions of those used to measure MR.

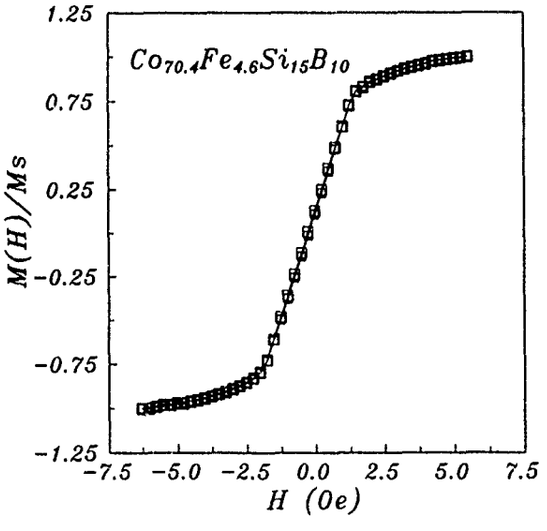

FIG. 3. Magnetization vs applied magnetic field for $Co_{70.4}Fe_{4.6}Si_{25}B_{10}$ (squares). The dimensions of the sample are about the same as those used to measure the MR. Note that the values of $M(H)$ are normalized by the magnetization measured for $H=6.27$ Oe and the coercive field is quite small (0.002 Oe). The solid line is a guide to the eyes.

III. DISCUSSIONS AND CONCLUSIONS

In an attempt to understand the frequency dependence of the magnetoresistance, we discuss a model for the transport properties of electrons in a medium with magnetic domains. This model has been extensively used by Berger[5] for dc and for fast rising pulses, but not for ac currents. The basic assumption of the model is that the domain walls experience two forces: the Lorentz force resulting from the relative motion of the electrons through the domain wall and a pinning force associated with the coercive field H_c. We extend the model for ac currents assuming that for small enough forces the domain pinning can be replaced by a restoring force proportional to the displacement x_w of the wall away from the equilibrium position,

$$\frac{2M_s}{\mu}(\beta v_e - v_w) - kx_w = M_w \ddot{x}_w, \tag{1}$$

where β is a parameter which depends on the material, M_s is the saturation magnetization, μ is the wall mobility, v_e and v_w are the electron and wall velocities, respectively, and M_w is the wall mass. For the electron, besides the Lorentz force, the equation of motion has also a force caused by the ac applied electric field E and the Drude relaxation term,

$$\frac{2M_s}{\mu}(\beta v_e - v_w) - m\frac{v_e}{\tau} - eEe^{-i\omega t} = m\ddot{x}_e, \tag{2}$$

with τ being the electron relaxation time, m the electron mass, and x_e its displacement. Assuming that M_w is negligible and solving Eqs. (1) and (2) for v_e, one gets the current density and the resistivity ($j=-nev_e=E/\rho$),

$$\frac{\rho-\rho_0}{\rho_0} = \frac{\tau}{r_i} A\left(1-\frac{\omega^2 A^2}{k^2+\omega^2 A^2}\right), \tag{3}$$

where $A\equiv 2M_s/\mu$, ρ_0 is the Drude resistivity, and we used $\beta=1$.

This model does predict a frequency dependence for MR. There is an initial decrease of MR with increasing frequency f which saturates for $\omega^2 A^2 \gg k^2$, and the MR is approximately linear in some frequency range. However, the predicted frequency-dependent MR is negative, whereas our measurements indicate a positive MR. Notice that because of the logarithmic time decay of the magnetization some models also include a restoring force in the equation of motion for the domain with a time-dependent coefficient.[6] However, this contribution does not seem to predict a linear increase of MR with ω.

Two theoretical models predict a $-M^2$ contribution to MR. The first one, which falls in the class of the model described above, is based on eddy currents due to nonuniform current in the sample.[5] Unfortunately, such a mechanism does not account for the observed frequency-dependent MR. The second model predicts a scaling of the magnetoresistance in spin-glass-like systems[7,8] with M^2. Essentially, this model shows that for this kind of magnetic phase the magnetoresistance is proportional to the Edward–Anderson order parameter

$$Q = \lim_{|t_1-t_2|\to\infty} \langle [S_i(t_1)S_i(t_2)] \rangle_{\text{avg}}$$

which is essentially given by the spin-spin correlation function at site i. The correlation function is also frequency dependent $[\sim\omega\tau/(1+\omega^2\tau^2)]$ which has a linear behavior in the limit $\omega\tau\ll 1$, where τ is the spin relaxation time. Because of the spin-glass-like properties of this material[2] associated with its frequency-dependent magnetic permeability, it is possible that the linear dependence of MR with ω is due to the random anisotropy existing in amorphous magnetic alloys.

Giant magnetoresistance has also been observed in other nonmultilayers magnetic system.[9,10] We note, however, that our system shows this property at room temperature and the saturation fields are quite low compared with granular materials. These characteristics makes amorphous $Co_{70.4}Fe_{4.6}Si_{15}B_{10}$ interesting for some technological applications.

On the resistivity minimum in amorphous metallic spin-glasses (abstract)

J. Koetzler and G. Thummes[a)]
Institut für Angewandte Physik, Universität Hamburg, D-20355 Hamburg, Germany

Though the occurrence of a low-temperature resistivity minimum is a rather general feature of magnetic metallic glasses, its origin—whether magnetic or structural—is still under debate. We have performed temperature and magnetic-field-dependent measurements of the resistivity $\rho(T,B)$ and the magnetization $M(T,B)$ on amorphous $Ni_{80-x}Fe_xSi_8B_{12}$ below and above the critical concentration for ferromagnetic order ($x_c=4$). In the ferromagnetic and reentrant phases $\rho(T\rightarrow 0)$ increases as $(-T^{1/2})$, which can be related to a quantum effect from modified electron-electron interaction in the presence of structural disorder.[1] In marked contrast, in the conventional spin glass ($x=2.4$) $\rho(T\rightarrow 0,B=0)$ exhibits a linear increase below the freezing temperature $T_f=6.2$ K. A reanalysis of literature data reveals a linear upturn of $\rho(T\rightarrow 0)$ to occur in other amorphous spin glasses, too, with a quasi-universal law: $\Delta\rho/\rho\approx -4(2)\ 1E^{-3}\ T/T_f$. This finding will be discussed in terms of elastic scattering from the spin-glass order parameter[2] and, alternatively, in terms of quantum interference on closed diffusion paths in the presence of inelastic spin-flip scattering. Recently, for the latter case, a linear T-law has been predicted to evolve from a crossover from dynamic spin scattering to the static limit at zero temperature.[3]

Dependence of the anisotropic magnetoresistance on aspect ratio in cobalt films (abstract)

Mark Tondra, B. H. Miller, and E. Dan Dahlberg
School of Physics and Astronomy, University of Minnesota, 116 Church Street S. E., Minneapolis, Minnesota 55455

High quality measurements of the anisotropic magnetoresistance, defined as the difference in the resistivities when the saturated sample magnetization is parallel and perpendicular to the current, are performing using four terminal measurements. What is occasionally not considered in these measurements is the geometry of the sample and contacts. This work reports how the anisotropic magnetoresistance (AMR), measured with four in-line point contacts attached to thin film specimens, is affected by the geometry of the films. Cobalt samples were lithographically narrowed in 2 mm steps from 10 mm×10 mm to 2 mm×10 mm. For each of the five sizes, the AMR and resistivity were measured using the four-probe-in-line technique with 3 mm from one contact to the next. The results show that the measured AMR increases by a factor of 2 from the widest to narrowest size. This width dependence of the AMR arises from spreading of the current between the voltage contacts. In order to make an accurate assessment of the AMR, the current across the entire width of the sample must be parallel to the line joining the voltage contacts. Similar work has been performed by A. Iwaide *et al.*, and published in J. Magn. Soc. Jpn. **16**, 197 (1992). The results reported in this abstract are in agreement with those in the above-mentioned paper.

Nonoscillatory behavior in the magnetoresistance of Cu/Ni superlattice (abstract)

W. Abdul-Razzaq
Physics Department, West Virginia University, Morgantown, West Virginia 26506-6315

It was reported that in many magnetic/nonmagnetic metallic multilayered systems, the interlayer-coupling oscillates between antiferromagnetic and ferromagnetic upon increasing the thickness of the nonmagnetic layer. This was evident by the oscillation of the magnetoresistance (MR) in these materials. Recently however, Harp, Parkin *et al.*[1] found that the MR and coupling strength change monotonically with increasing Cu thickness in Co/Cu multilayers deposited by MBE, contradicting results on similar samples made by sputtering in which the MR was oscillatory. In this study, we show that in the Cu/Ni superlattice made by sputtering, the MR varies monotonically with increasing Cu thickness. This nonoscillatory behavior was observed at room temperature and at 77 K and, regardless of the direction of the magnetic field in relation to the direction of the current. The resistivity at zero magnetic field as a function of temperature also changes systematically with reducing the Cu layer thickness. The nature of the magnetic state in Cu/Ni superlattice is discussed in light of the transport property measurements.

Preparation and magnetic properties of Mn_4N films by reactive facing targets sputtering

Shigeki Nakagawa and Masahiko Naoe
Dept. of Physical Electronics, Tokyo Institute of Technology, 2-12-1 O-okayama, Meguro, Tokyo 152, Japan

Ferrimagnetic Mn_4N films have been successfully prepared at low process temperatures using the facing targets sputtering apparatus. The mixture gas of Ar and N_2 with the ratio of N_2 in pressure to total gas R_{N_2} of 10% was optimal as the reactive working gas for depositing Mn_4N films, since the deposition at excessive R_{N_2} tended to cause the formation of Mn_3N_2 crystallites. In fact, they appeared in films deposited at R_{N_2} higher than 30%. The film deposited at the substrate temperature T_s of 200 °C exhibited saturation magnetization $4\pi M_s$ of about 300 G. The films prepared at T_s of 350 °C exhibited $4\pi M_s$ and an in-plane coercivity $H_{c\parallel}$ of 450 G and 300 Oe, respectively. The films annealed at 400 °C in vacuum furnace exhibited $4\pi M_s$ larger than about 510 G. However, the film annealed at temperature above 500 °C exhibited $4\pi M_s$ smaller than 80 G.

I. INTRODUCTION

Mn_4N is well known as a typical ferrimagnetic material with an effective moment of Bohr magnetons of 1–1.2μ_B per unit cell.[1–5] However, it is very difficult to synthesise bulk Mn_4N, because its process needs a gas-solid reaction at high temperatures without the inclusion of oxygen.[4] Sputtering techniques seem to be suitable for preparing Mn_4N films even on substrates at low temperatures, because the surface mobility of adatoms may be sufficiently high. In this study, Mn_4N films have been successfully deposited on substrates at low temperatures by reactive sputtering and their magnetic properties have been investigated.

II. EXPERIMENTAL PROCEDURE

The specimen manganese nitride (Mn_xN) films were prepared using a facing targets sputtering (FTS) apparatus.[6] They were deposited on Si wafers by sputtering a pair of targets of sintered Mn disks in a mixture of Ar and N_2 gases, with the total pressure during deposition set at 2 mTorr. The ratio in pressure of N_2 gas to the mixture R_{N_2} ranged from 0 to 40%. The substrate temperature T_s was varied from 40 to 400 °C. The deposition rate and thickness of Mn_xN films were about 150 Å/min and 2000 Å, respectively. Post-annealing processes were performed for 1 h in an evacuated furnace at residual gas pressure below 1.0×10^{-6} Torr at temperature T_A of 350, 400, and 500 °C.

III. RESULTS AND DISCUSSION

The nitridation degree and crystal structure in films deposited at T_s of 40 °C varied with increase of R_{N_2}. X-ray diffraction studies told that the increase of R_{N_2} in the range from 7.5% to 20% changed the preferential orientation of the α-Mn crystallites from (411) to (332) and caused an apparent lattice expansion in the crystallites. Mn_3N_2 crystallites with an excessive degree of nitridation were evident in films deposited at R_{N_2} higher than 30%. Therefore, R_{N_2} above 30% seemed to be too high for forming Mn_4N crystallites. Accordingly, it was predicted that R_{N_2} in the range between 5% and 20% was appropriate for synthesizing Mn_4N films.

Figure 1 shows the variation of x-ray diffraction patterns of films deposited at T_s of 250 °C for various R_{N_2}. Although they reveal a complicated mixture composed of α-Mn and Mn_xN crystallites, the films deposited at R_{N_2} below 10% possess Mn_4N crystallites, as clearly seen in these diffraction patterns. The increase of R_{N_2} up to 20% prevented the synthesis of Mn_4N crystallites. The deposition at R_{N_2} of about 10% seemed to be suitable for synthesizing the Mn_4N films in this reactive sputtering method.

Figure 2 shows the R_{N_2} dependence of the saturation magnetization $4\pi M_s$ for the films deposited at T_s of 250 °C.

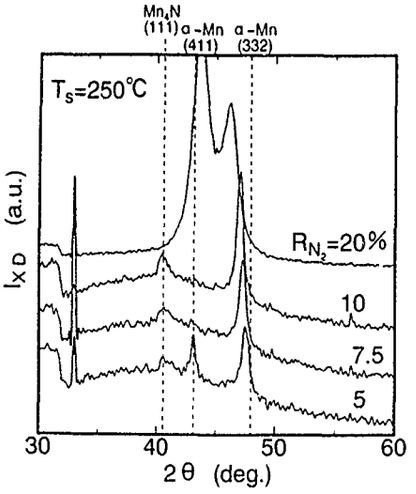

FIG. 1. Variation of x-ray diffraction patterns of the films prepared at T_s of 250 °C for various R_{N_2}.

 0021-8979/94/75(10)/6568/3/$6.00 © 1994 American Institute of Physics

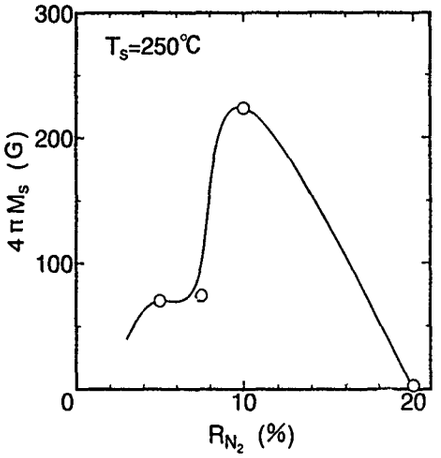

FIG. 2. R_{N_2} dependence of saturation magnetization $4\pi M_s$ for films prepared at T_s of 250 °C.

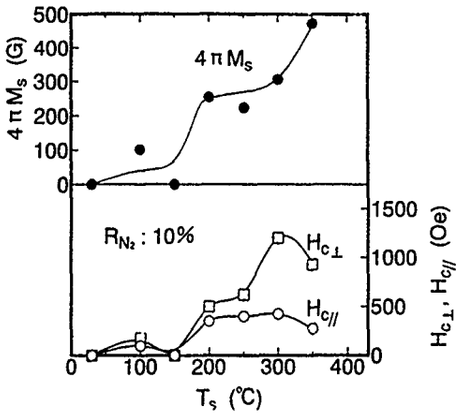

FIG. 4. T_s dependence of $4\pi M_s$, perpendicular coercivity $H_{c\perp}$ and in-plane coercivity $H_{c\parallel}$, for films deposited at R_{N_2} of 10%.

Large $4\pi M_s$ had been exhibited in the films for which the x-ray diffraction intensity $I_{X.D.}$ from Mn_4N crystallites was large, as shown in Fig. 2. It was found that films deposited at R_{N_2} of 10% have the largest amount of ferrimagnetic Mn_4N crystallites. The films deposited at T_s and R_{N_2} of 250 °C and 10%, respectively, exhibited $4\pi M_s$ of about 220 G.

Figure 3 shows the variation of x-ray diffraction patterns of films deposited at R_{N_2} of 10% for various T_s. Although the film deposited at T_s at 40 °C revealed a diffraction patterns corresponding to α-Mn crystallites, it was seen that the elevation of T_s caused the formation of Mn_4N crystallites and a decrease in $I_{X.D.}$ for α-Mn crystallites.

Figure 4 shows the T_s dependence of $4\pi M_s$, perpendicular coercivity $H_{c\perp}$, and in-plane coercivity $H_{c\parallel}$ for films deposited at R_{N_2} of 10%. It was seen that films deposited at T_s higher than 200 °C were ferrimagnetic. The elevation of T_s up to about 350 °C enhanced the formation of ferrimagnetic Mn_4N crystallites. The film deposited at T_s of 350 °C exhibited $4\pi M_s$ of about 480 G. $H_{c\perp}$ took relatively large values for films with a large amount of ferrimagnetic crystallites. It was indicated that the film with the largest $4\pi M_s$ revealed weak perpendicular magnetic anisotropy. Since the Mn_4N crystal itself owns a cubic symmetry, the perpendicular magnetic anisotropy seemed to originate from the shape anisotropy of ferrimagnetic Mn_4N grains in paramagnetic manganese nitride matrix and, in addition, stress-induced anisotropy through magnetostrictive effect. The films deposited at T_s of 350 °C exhibited $4\pi M_s$, $H_{c\perp}$, and $H_{c\parallel}$ of 450 G, 1200 Oe, and 300 Oe, respectively.

It is well known that bulk Mn_4N has been formed at a high-temperature process in a nitrogen atmosphere.[4] A study of post-annealing the as-deposited films seemed to be useful to investigate the formation process of Mn_4N crystallites. Figure 5 shows the variation of x-ray diffraction patterns of the film deposited at T_s and R_{N_2} of 40 °C and 10%, respectively, and annealed at various annealing temperatures T_A.

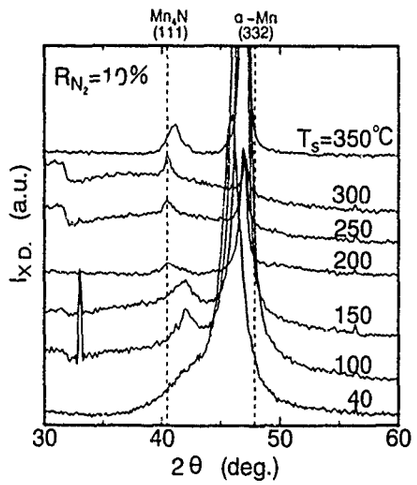

FIG. 3. Variation of x-ray diffraction patterns of the films deposited at R_{N_2} of 10% for various T_s.

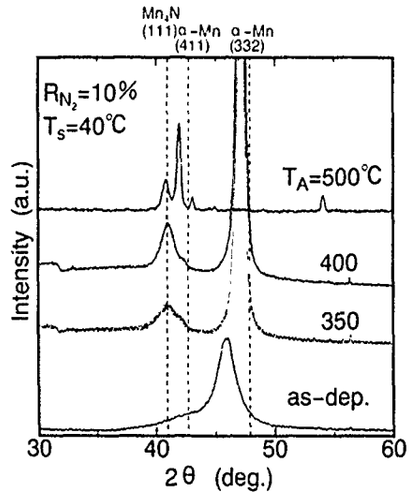

FIG. 5. Variation of x-ray diffraction patterns for films annealed at various annealing temperature T_A.

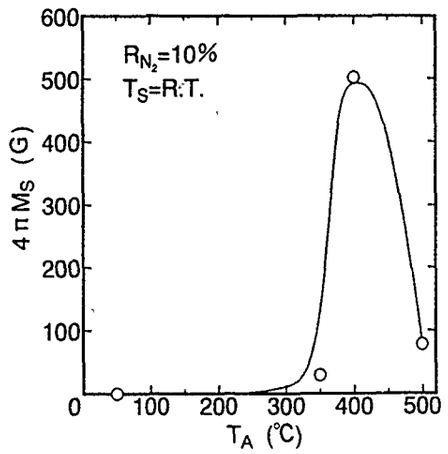

FIG. 6. Dependence of $4\pi M_s$ on annealing temperature T_A.

Although the as-deposited film did not possess Mn_4N crystallites, the film annealed at T_A higher than 300 °C was clearly found to possess those crystallites. However, the film annealed at T_A higher than 500 °C revealed a complicated diffraction pattern for 2θ between 40° and 43°. Such a complicated pattern seemed to originate from a mixture composed of several types of crystallites. The complicated structure did not show enhanced ferrimagnetism. Figure 6 shows the T_A dependence of $4\pi M_s$. The films annealed at 400 °C in vacuum exhibited $4\pi M_s$ larger than about 510 G. However, the film annealed at T_A above 500 °C exhibited smaller $4\pi M_s$ of 80 G. The nitrogen dissociation from the films and the recrystallization of other phase crystallites seemed to cause the decrease of $4\pi M_s$.

IV. CONCLUSION

The preparation of ferrimagnetic Mn_4N films has been attempted in this study using a facing targets sputtering (FTS) apparatus. R_{N_2} of 10% was appropriate for deposition of Mn_4N films at T_s higher than 200 °C. Deposition at excessive R_{N_2} tended to cause the formation of nonmagnetic Mn_3N_2 crystallites. The film prepared at T_s and R_{N_2} of 350 °C and 10%, respectively, revealed a mixed phase of Mn and Mn_4N. The film possessed $4\pi M_s$, $H_{c\parallel}$, and $H_{c\perp}$, of 450 G, 300 Oe, and 1200 Oe, respectively. The films annealed at 400 °C in vacuum exhibited $4\pi M_s$ larger than about 510 G. However, the film annealed at temperatures above 500 °C exhibited $4\pi M_s$ below 80 G. Consequently, ferrimagnetic Mn_4N films have been successfully prepared even at relatively low process temperatures using the reactive FTS apparatus.

Magnetovolume effects in strong paramagnets

E. G. Moroni

We present calculations of magnetovolume properties for different strong paramagnetic systems such as ZrV_2, $TiBe_2$, and $ZrZn_2$ in the $C15$ structure. These materials show indications of anti-Invar behavior, i.e., enhanced magnetostriction, and thermal expansion.

We report in this paper results of calculations based on the local spin density (LSD) formalism of the magnetovolume properties of several compounds in the $C15$ structure such as ZrV_2, $ZrZn_2$, and $TiBe_2$. These compounds are particularly interesting examples of weak itinerant ferromagnets as for $ZrZn_2$ or strongly exchange-enhanced systems such as $TiBe_2$ and ZrV_2. The electronic structure of these paramagnetic compounds is well known and has been studied previously mainly in connection with the superconductivity, magnetism, and electron-phonon interactions.[1,2] $TiBe_2$ is an example of strong exchange-enhanced paramagnetic system with a very large Stoner enhancement factor. This system becomes ferromagnetic when doped with a few percent of Cu,[3] while a dilute addition of Fe is sufficient to suppress the enhanced paramagnetism.[4] $ZrZn_2$ shows weak itinerant magnetism and the measured linear thermal expansion coefficient[5,6] shows a magnetic contribution also at 260 K, much above its Curie temperature of 18 K. ZrV_2 in rhombohedral phase is superconducting below about 8 K (Ref. 6) and at a temperature much higher (about 120 K) a structural transformation into the $C15$ phase occurs.

The fixed-spin-moment (FSM) procedure[8,9] has been used to determine self-consistently the total energy $E(V,M)$ at constraint magnetization M and at fixed volume V. The equilibrium properties are determined from the minimum condition of the total energy, when $P(V,M)=0$ and $H(V,M)=0$. For these compounds it is not trivial to fit all the nearly degenerate local minima of the total energy in the (V,M) space and to extract from the fitted total energy surface accurate information on pressure and magnetic field. Moreover, as is shown in Fig. 1 for $TiBe_2$, we have found that the position of the local minima of the total energy depend sensitively on the exchange-correlation potential. More stable results can be obtained by use of the computed pressure $p(V,M)$ function given by Libermann[10] and Pettifor.[11] Our calculations use the form of the Madelung potential derived in Ref. 12. Using the same technique we obtain also the spin-polarized electronic partial pressures.

The spin-polarized band structures and energies were determined self-consistently using the linear-muffin-tin-orbital (LMTO) method[12,13] and for the exchange-correlation potential we use the LSD approximation with the parametrization of Vosko *et al.*[14] For $TiBe_2$, we also tested the effects of gradient corrections[15] in describing the magnetic energy (see Fig. 1).

The computed ground-state properties for ZrV_2, $ZrZn_2$, and $TiBe_2$ in the $C15$ structure are in good agreement with experiments. For $TiBe_2$ we obtain nearly degenerate low-moment (LM) and nonmagnetic (NM) total energies, with the same lattice constant of 11.95 a.u. The measured experimental value is 12.18 a.u. The computed bulk modulus of 1.38 Mbar compares also well with the experimental one of 1.32 Mbar.[5] The calculation of the total energy for the NM state during the self-consistent procedure is unstable due to a high and structured peak of the density of states near the Fermi level. These features make it difficult to analyze the magnetic energy from total energy results. Our spin-polarized calculations show a very small magnetic moment of 0.05 μ_B/atom at the Ti site for the experimental lattice. This spontaneous magnetization result is obtained using both the Vosko potential and the gradient-corrected potential.[15] In Fig. 1(a) are shown at the fixed experimental volume the total energy behavior as a function of the total moment in the unit cell, for two different potentials. The position of the

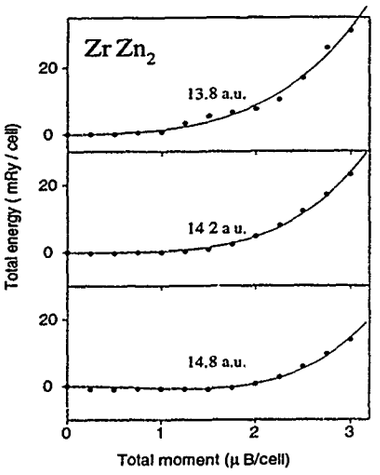

FIG. 2. Total energy vs magnetic moment for $ZrZn_2$ at $a=13.8$, 14.2, and 14.8. The reference energy E_0 is different for each curve and corresponds to the volume-dependent energy at $M=0$.

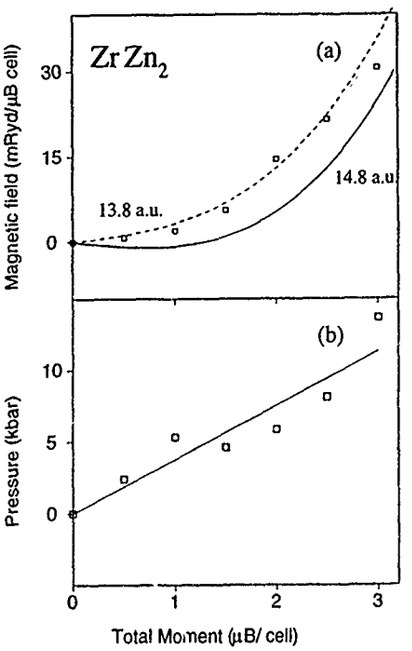

FIG. 3. (a) Magnetic field as a function of total moment for $ZrZn_2$. The broken curve is obtained from the fit procedure of $E(M)$, while the open squares are calculated via the FSM definition of $H(V,M)$. The full line estimates $H(V,M)$ at $a=14.8$ a.u., where $ZrZn_2$ is found to be magnetic. (b) Magnetization dependence of the pressure in $ZrZn_2$ for $a=13.8$ including a linear fit.

local minima of the total energy function are not the same for the two potentials. Similar results have also been obtained for iron in the fcc structure near the NM-FM instability region. However, in Fig. 1(b) is shown that the pressure behavior as a function of magnetization is almost the same also for different exchange-correlation potentials. The computed pressures differ only by a constant pressure $\Delta P = P(0)_{LSD} - P(0)_{NL} = -80$ kbar. Therefore in $TiBe_2$ the correction to the forced magnetostriction, using gradient-corrected potentials, comes essentially from the softer bulk modulus and larger lattice, rather than from a different magnetic pressure $\Delta P(M)$. More details can be found in Ref. 15. From Fig. 1(b) we can estimate (by numerical differentiation of the pressure curves) the magnetovolume coupling for $TiBe_2$. The estimated value at very low applied magnetic field is of the order of 1 kbar/μ_B. At increased field the estimated value is 5 kbar/μ_B. The numerical estimation predicts a positive relative volume expansion of $\Delta V_M/V \sim 3.4\times10^{-6}$ for a field of 1 T. This computed magnetostriction is one to two times larger with respect to the measured experimental value.[3]

For $ZrZn_2$ the energy minimum is found at 13.64 a.u. while the experimental lattice is 13.82 a.u. At the experimental lattice we observe a very low moment of the order of $0.02\mu_B$ on Zr site, in agreement with experiments that indicate a very weak ferromagnetism in this system. In Fig. 2 we show $E(M)$ results for $ZrZn_2$ at different lattices constant. To analyze the $E(M)$ curves we have performed at each lattice a Landau expansion of the energy in even powers of M, of the form, $E-E_0=\alpha M^2+\beta M^4+\ldots$, where α and β are coefficients depending on volume. Paramagnetism requires α to be positive, and when α goes to zero, the susceptibility diverges and there occurs a transition to the low-magnetic state. In the case of $ZrZn_2$ this transition occurs near $a=14.2$ a.u. The calculated results for $H(V,M)$ as a function of M for two values of the lattice constant are shown in Fig. 3(a), while in Fig. 3(b) are shown the results for $p(V,M)$. The dependence on M of $H(V,M)$ is estimated by numerical differentiation of the Landau fit of the total energy, and also by the relation $H(V,M)=[E_F^{\downarrow}(V,M)-E_F^{\uparrow}(V,M)]/2\mu_B$. As is shown in Fig. 3(a) the two different procedures give the same results, which provides a supplementary control of the accuracy of the calculations. The slope $\Delta P/M$ is not constant and can change drastically depending on the volume. The magnetovolume coupling estimated by a linear interpolation is 3.7 kbar/μ_B near the experimental volume. Using $\Delta V_M/V=\Delta P_M/B$ and with a computed estimation of the bulk modulus of 1400 kbar we obtain a positive magnetostriction at a rate of the order of 0.2% per μ_B. This can also be expressed as a relative volume expansion of 2.9×10^{-6} per T. In Ref. 5 it was found that there is a magnetic contribution to the thermal expansion. This is coupled to the magnetostriction, but the admixture of excited states makes a numerical estimate of the thermal expansion more difficult.

For ZrV_2 in the $C15$ structure the computed ground state has a minimum at 13.7 a.u. and the total moment is zero. However, in contrast to Invar systems, such as $Fe_{65}Ni_{35}$, we find that the near degeneracy between NM and low magnetic (LM) excited configurations is extended over a wide volume range (for a between 13.7 and 14.3 a.u.). The total energy $E(V,M)$ around the local minimum shows a broad rather flat region. Within this flat region the low-moment (LM) states (with $M<3\mu_B$/cell) have an energy smaller than 1 mRy per atom (or about 160 K) above the NM ground state. Models of thermal fluctuations between the LM to the NM state describe many Invar effects.[18] Here, by choosing ZrV_2, we search for an opposite situation in which the ground state is

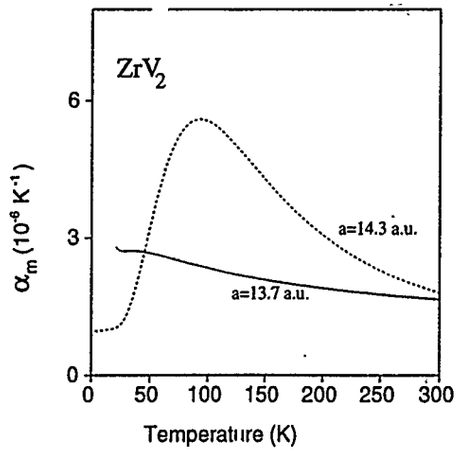

FIG. 4. Thermal behavior of the magnetic thermal expansion coefficient $\alpha_m(T)$ in ZrV_2. $\alpha_m(T)$ is computed using Eq. (2) at two different lattices.

the small volume NM state, but where small energy fluctuations to higher-volume LM states are possible. Many strongly enhanced paramagnets or very weak ferromagnets should have a LM high-volume state very near to the NM ground state, and therefore they may be good candidates for an anti-Invar behavior provided that there is also a large difference between the equilibrium volumes. We have chosen ZrV_2 as an example of such a system, since its electronic structure is well known. Combining the total energy results with a Boltzmann model we estimate the magnetic contribution to thermal expansion in ZrV_2. Therefore, similar to the model of Ref. 18, we perform a calculation in which only moment fluctuations occur. Contrary to the model for Invar behavior in Ref. 18 here $E(M)$ is so flat that several states have to be included in the sum, while for the situation in the Fe_3Ni Invar system the reduction to the two state model was possible. The thermal magnetic pressure is calculated as

$$\Delta P_m(T)=\frac{\Sigma_i \Delta P_i e^{-\Delta E_i/k_B T}}{\Sigma_i e^{-\Delta E_i/k_B T}} \tag{1}$$

with $\Delta P_i=P(M_i)-P(0)$ and $\Delta E_i=E(M_i)-E(0)$ and where the sum is over all states with varying moment but fixed volume. The result is that $\Delta P_m(T)$ increases linearly with T, indicating that the averaged volume will increase as well. By computing the change of magnetic pressure with the variation of temperature, we estimate the magnetic contribution to the thermal expansion α_m as

$$\alpha_m(T)=\frac{1}{B_T}\frac{\partial \Delta P_m(T)}{\partial T}. \tag{2}$$

The thermal behavior of $\alpha_m(T)$, calculated at the equilibrium volume and at a expanded lattice, is shown in Fig. 4. At room temperature the magnetic pressure is increased to about 1 kbar and with a bulk modulus of 1600 kbar, we obtain 0.06% of volume expansion up to room temperature (without phonon contribution).

The forced magnetostriction in ZrV_2 amounts to about 2.9×10^{-6} per T if computed at $a=13.7$ a.u., while it increases to 59.0×10^{-6} per T at $a=14.3$ a.u. Thus, when computed at the respective equilibrium lattice, we found similar forced magnetostriction, between the three studied systems. In ZrV_2 there is a large sensitivity of the forced magnetostriction on the lattice parameter and we interpret its positive value as a weak anti-Invar effect. Also in $ZrZn_2$ the conditions for the same mechanism are present, while experimentally, the situation is complicated by the FM ordering at low T.

The results suggest two ways of detecting the anti-Invar behavior; one by measuring the thermal expansion effect, and one by measuring the expected large volume expansion as a function of applied magnetic field. The latter method should be safer since it does not depend on thermal fluctuations. At increased temperatures the positive pressure due to the populations of the spin-polarized states enhances the lattice of the paramagnetic $C15$ compound. It is also possible that the competition between FM and NM states is responsible of the low-temperature structural instability of ZrV_2. The closeness between the paramagnetic ground state and the excited low-moment (LM) states has also suggested that enhanced paramagnets, like ZrV_2, may give quite unusual effect in spectroscopic measurements. In ZrV_2, calculations based on final state rule predict various signature of the magnetic state in form of unusual x-ray absorption and x-ray dichroism spectra.[16,17]

Synthesis and characterization of $Fe_{16}N_2$ in bulk form

M. Q. Huang, W. E. Wallace, S. Simizu, A. T. Pedziwiatr,[a] R. T. Obermyer, and S. G. Sankar
Carnegie Mellon Research Institute, Carnegie Mellon University, Pittsburgh, Pennsylvania 15213

Using molecular beam epitaxy and ion implantation, Japanese workers have formed $Fe_{16}N_2$ in thin Fe films. They report a large magnetic induction for this nitride, $\geq$2.8 T. In the present study, $Fe_{16}N_2$ has been prepared in bulk form by treating Fe powder with NH_3/H_2 gas mixtures at temperatures in the range 660–670 °C. The γ phase alloy, which forms under these conditions, was quenched to room temperature to form the α'-Fe-N phase and then heat treated at 120–150 °C to form the α''-Fe-N phase. The α' phase has been prepared in 80% purity, the other phase being nonmagnetic γ-Fe-N. The α'' phase has been prepared in 50% purity, the impurity phases being α-Fe and γ-Fe-N. Magnetic measurements give saturation magnetizations at room temperature of 250±10 emu/g (2.6 μ_B/Fe) for the α' phase, 285±10 emu/g (2.9 μ_B/Fe) for the α'' phase, and essentially zero for the γ phase. Mössbauer measurements confirm that nitrogen austenite is nonmagnetic. The anisotropy of $Fe_{16}N_2$ is small but detectable.

I. INTRODUCTION

It is well known that when iron is exposed at elevated temperatures to a mixture of NH_3 and H_2, it forms several nitrides. One of these Fe nitrides is nitrogen austenite, the γ-Fe-N phase. This is a material in which Fe is in a simple fcc arrangement with N distributed randomly in the octahedral sites. Upon cooling to cryogenic temperatures, the γ phase undergoes a martensitic transformation into a phase termed α' or nitrogen martensite. When nitrogen martensite, which has the stoichiometry Fe_8N, is heat treated at low temperatures (~150 °C) it undergoes a structural transformation into a phase termed α''. The α'' phase has the stoichiometry $Fe_{16}N_2$. The α'' phase is currently attracting much attention because of indications that it has a giant magnetic induction.

In a series of classic papers published in the late 1940's and early 1950's, Jack structurally characterized both the α' and α'' phases (as well as several other Fe-N phases).[1-4] He found the α' phase to be tetragonal with two atoms of Fe per unit cell and the α'' phase also to be tetragonal with one formula unit of $Fe_{16}N_2$ per unit cell. The axial ratio is ~1.1 for both phases.

$Fe_{16}N_2$ has been formed in thin Fe films by a variety of techniques, beginning with the work of Kim and Takahashi.[5] This work, and later work of a generally similar nature, indicated that nitrogenation substantially increases the Fe moment.[6] A saturation magnetic induction of 2.8–3.0 T was reported in these studies. In contrast with these findings, very recent work by Shoji *et al.*[7] on $Fe_{16}N_2$ produced through dc sputtering of Fe films showed B_{sat} no larger than that of α Fe.

In view of the discrepancy between the results of Shoji *et al.* and those of other investigators, a reexamination of the magnetic behavior of $Fe_{16}N_2$ is warranted. In the present investigation, bulk quantities of $Fe_{16}N_2$ have been prepared and studied magnetically. (The preparation method used was essentially identical with that employed by Jack.[1-4]) This is in contrast with all previous magnetic work on $Fe_{16}N_2$ which involved thin Fe films.

II. EXPERIMENTAL DETAILS

Nitrogen austenite (γ phase) with different nitrogen contents (C_N=N/100 Fe=6.4–10.7) was produced by treating Fe powder (6–9 μm) with a NH_3-H_2 gas mixture at 1 atm pressure and at temperatures in the range of 660–670 °C for 2–3 h. The alloy was then quenched to room temperature or lower by He gas and liquid N_2 or liquid He to form the martensite α' phase, followed by a low-temperature heat treatment at temperatures of 120–150 °C for 0.5–2 h in vacuum to form α''-$Fe_{16}N_2$ phase.

The phases present in Fe-N samples and their lattice parameters were determined by x-ray diffraction (XRD) using Cu radiation. Quantitative analysis of the relative amounts of each phase in the Fe-N samples was established by the direct comparison method of Cullity,[8] based on the measured intensities of XRD lines and using the calculation of the structure factor (including the multiplicity factors) and the Lorentz–Polarization factors. The nitrogen content was determined by using the equations $a=3.575+0.0080\ C_N$ for γ and $c/a=1+0.0091\ C_N$ for α', relating lattice parameters to composition. For some samples, N content was also measured by weight increase after nitriding. The magnetic properties, M, T_c, and anisotropy, were measured using standard methods. Measurements were made in the temperature range of 10–1273 K and in fields of 500 Oe to 17 kOe. Hot XRD from room temperature to 700 °C was used to detect the phase transitions. This was supplemented by TMA in a field of 500 Oe and at temperatures of 10–1273 K.

III. RESULTS AND DISCUSSION

A. Phase transformation from γ to α'-Fe-N

A number of Fe-N austenites (γ phase) with differing N content (N/100 Fe=6.4–10.7) were synthesized. The N contents were controlled by changing the ratio of NH_3/H_2. When the γ phase was quenched from high temperature to room temperature or lower, it partially transformed to α' (see Table I). The quantity transformed depends on N content and quenching temperature T_q. The crystal and magnetic properties of the quenched alloys are given in Table I. For sample 6.4, with lowest N content, almost 87% of the α' phase was

[c] M is the magnetic moment of the sample. It is lower than M for α' phase because of the presence of some nonmagnetic γ phase.
[d] T_t gives the temperature range in which the $\gamma\rightarrow\alpha'$ transformation occurs.

formed at room temperature. This sample carries a magnetic moment of 210 emu/g. For sample 10.7, with the highest N content, a near-zero magnetic moment is observed at room temperature. The XRD pattern indicates a single-γ phase (Fig. 1). On quenching to liquid-N or liquid-He temperature, the α' phase formed and the magnetic moment of the sample increased to 133 and 146 emu/g, and the relative amounts of α' phase increased to 51 and 56 at. %, respectively. The transformation temperatures from γ to α', T_t, in Table I were obtained by TMA measurements. It is to be noted that when the N content of the γ phase increases, T_t decreases.

B. The α' phase

As seen in Table I, the lattice parameters are compositionally dependent. The results obtained are in agreement with the results of others.[4,9] To determine the moment of the α' phase, one must ascertain the fraction of the sample which is in the α' phase. This is done by XRD measurements of line intensities. In principle, this is straightforward, but in practice it is complicated by line overlap of the most intense diffraction lines (see Fig. 2). The procedure employed is depicted in Fig. 3, in which the measured moment is plotted against the ratio of the intensities of the two strong lines in the XRD pattern. Magnetization increases as the intensity ratio decreases, since the amount of the nonmagnetic γ phase is decreasing. Extending the lines to $I\gamma$ (200)=0, magnetization reaches 248–262 emu/g, which can be taken as the magnetic moment of the α' phase. It seems that the α' phase with higher N content exhibits a higher moment. As seen in Fig. 3, the α' samples for the lines A, B, and C with different N contents, the corresponding magnetizations [at $I\gamma$ (200)=0] are ~248, 252, and 262 emu/g, respectively. We also used the XRD line intensities to calculate the mass fraction of α' for these samples and used these to estimate the concentration of α' phase (see Table I) as well as its moment. Both results are quite close, considering the ~5% error of estimating intensities.

C. α'' $Fe_{16}N_2$ phase

A number of samples containing the α' phases were heat treated at temperatures ranging from 120 to 150 °C for 0.5–2 h to form the α'' phase. Typical and characteristic XRD lines, (213) and (004) of α'' phase, were observed on a sample with C_N=10.0, after treating at 150 °C for 2 h (as seen in Fig. 4). The other lines, 202, 220, 400, 224, and 422, shifted from the positions of lines of original martensite α'. The lattice constants a and c are very close to that reported by Jack, a=5.718 A and c=6.290 A. The magnetic moment increases from 182 to 189 emu/g when the α' phase transforms to α''. The sample was estimated to contain 56 α'', 12% α Fe, and 31% γ. The estimated moment is ~285 emu/g for α''. As with the analysis of the moment of the α' phase, we plotted the measured moment of the α'' phase samples, M, versus the measuring XRD intensity ratio $I\gamma$ (200) [$I\gamma$(111)

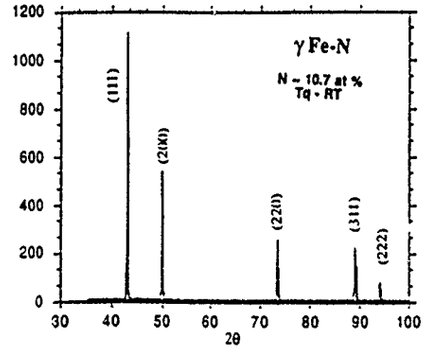

FIG. 1. XRD of sample 10.7 in Table I.

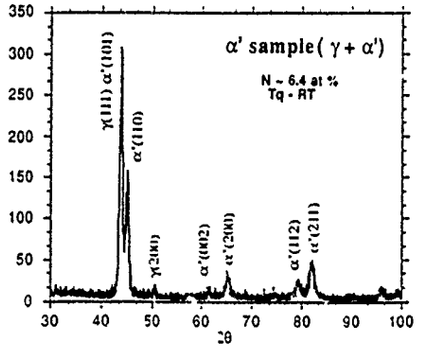

FIG. 2. XRD of sample 6.4 in Table I.

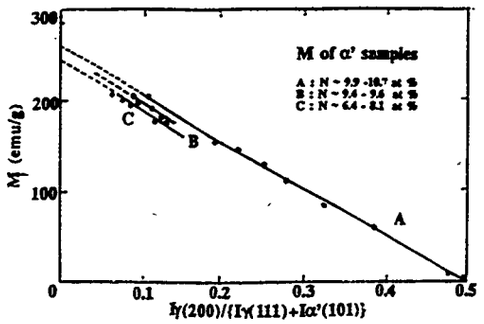

FIG. 3. M-$I\gamma(200)/[I\gamma(111)+I\alpha'(101)]$.

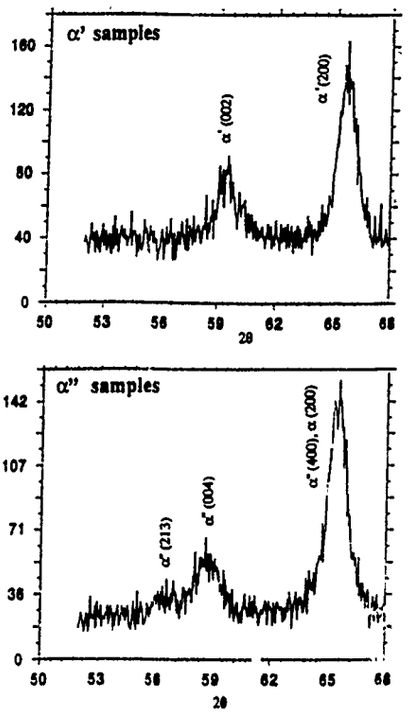

FIG. 4. (a) XRD of α' sample, (b) XRD of α'' sample.

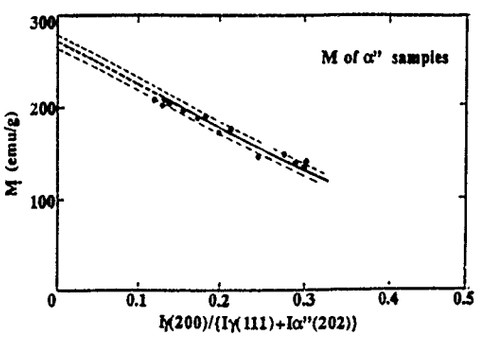

FIG. 5. M-$I\gamma(200)/[I\gamma(111)+I\alpha''(202)]$.

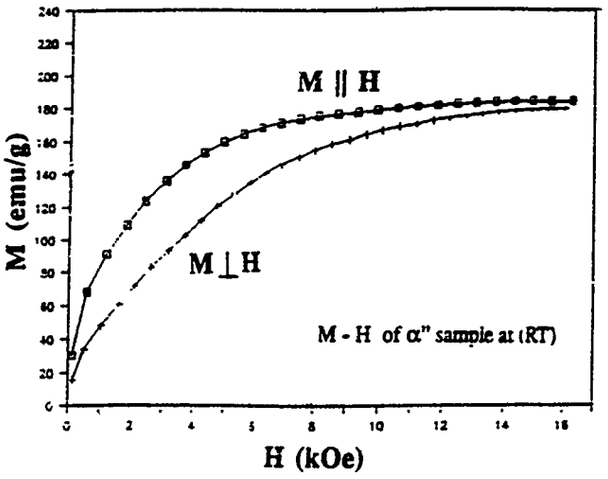

FIG. 6. M-H of α'' sample at RT.

$+I\alpha''(202)]$ in Fig. 5. When extending the plot to the intersection with the y axis, i.e., where the γ phase is absent, M reaches ~275 emu/g. The moment is contributed by the $Fe_{16}N_2$ and α-Fe phases. The maximum N content in the α' phase is 10.7, which is less than that of the α'' phase, 12.5. Hence, during the formation of α'', Fe is rejected in the form of α-Fe. Based on the known N concentration, one can estimate the amount of α-Fe formed. Knowing this, one can establish the moment of the α'' phase to be 280 ± 10 emu/g.

As reported by Drabecki,[10] the α'' phase shows a weak uniaxial anisotropy with $K_0=78.10^4$ J/M^3, as measured magnetically. We examined the anisotropy by observing the difference of XRD of an α'' sample random and aligned in a magnetic field of 17 kOe. The XRD intensities did show a slight change after alignment when a 17 kOe field is applied. The field dependencies of magnetization for aligned powders are shown in Fig. 6 for fields applied parallel and perpendicular to the aligning field. These confirm that there is a measurable magnetic anisotropy.

ACKNOWLEDGMENTS

Magnetic properties of FeRhP: Influence of metallic clusters on ferromagnetism

M. Guillot, M. Artigas,[a] M. Bacman,[b] D. Fruchart,[b] D. Boursier,[c] and R. Fruchart[c]
Service National des Champs Intenses, C.N.R.S. B.P. 166 X, 38042 Grenoble Cédex, France

Synthesis of compounds belonging to the FeRhP system reveal the existence of three main structures: hexagonal H_3-Fe_2P type, orthorhombic O_{10}-NdCoB type, and hexagonal H_{12}-FePdP type described as polytypes resulting from different packings of a pseudorhombohedral FeRhP subcell. High magnetic field magnetic measurements were carried out in the 4.2–300 K temperature range in fields up to 200 kOe. Very different magnetic properties were observed for the three phases. To explain the low saturation magnetization of both O_{10} and H_{12} phases compared to that of the H_3 phase, a structural magnetic framework that leads to the formation of diamagnetic clusters within the ferromagnetic matrix is proposed.

I. INTRODUCTION

Several phosphides of the first-row transition metals, for example, Fe_3P, Fe_2P, MnP, MnAs are ferromagnetic.[1] Fe_2P has attracted attention due to its peculiar magnetic properties (a first-order transition at 214 K and giant short-range magnetic order up to temperatures three times higher than T_c), but saturation moments and Curie temperatures reported in the literature vary widely.[2–4] These conflicting results reflect the extreme sensitivity of the magnetic properties to both chemical and physical parameters, e.g., low substitutions of Mn and Cr or nonstoichiometry, structural defects, sensibility to pressure and magnetic field. In this work, we report high magnetic field magnetization and magnetic susceptibility measurements made on ternary iron phosphides of compositions FeRhP and $Fe_{1.33}Rh_{0.66}P$.

First, the hexagonal structure of Fe_2P (space group $P\bar{6}2m$ with three formulae/unit cell) will be briefly described. Along the c axis, phosphorus atoms form, alternately, in tetrahedra and square-based pyramids generating channels of triangular section.[5] Because the occupation of both tetrahedral and pyramidal sites cannot happen simultaneously inside the same channel, two kinds of channels must occur: in the first one, only the tetrahedral sites are occupied; in the second one, only Fe atoms are surrounded by five P atoms (pyramids). Channels of different types share common pyramidal square bases to form channel pairs. This pairing results in pseudorhombohedral subunits which consist of two filled sites (square-based pyramid and tetrahedron) and two empty sites (inset Fig. 1).

The preparation of the different polytypes of composition FeRhP was a delicate task.[6] For a long time it was suggested that this compound did not exist. The difficulties resulted from the successive and unusual structural transformations required to accommodate the formation of clusters. Furthermore it should be noted that in $Co_{0.8}Ni_{0.2}P$, similar clusters of cobalt and nickel produce diamagnetic properties.[7]

II. EXPERIMENTAL PROCEDURE

Rhodium-iron-phosphides cannot be prepared by the diffusion of powdered rhodium in FeP at temperatures of about 1200 K as in the case for the other ternary phosphides.[6] FeRhP and the parent Fe $(Fe_xRh_{1-x})P$ solid solutions must be stabilized under various structural forms through a drastic control of the thermal treatment. Three main structures were identified from the magnetic susceptibility temperature dependence and analysis of powder x-ray patterns.[8,9] The first form discovered was assigned the hexagonal Fe_2P-type structure;[7] since it is unstable, it must be stabilized by a water quenching from 1320 K to room temperature; it is designed the H_3 polytype. On the other hand, a slow cooling of the H_3 phase from 1320 K to room temperature leads to the CoNbB-type orthorhombic structure (O_{10} polytype). Finally, a third structural type (H_{12} polytype) was stabilized by annealing of the H_3 phase near 500 K with patterns apparently similar to H_3 Fe_2P type: absence of superstructural lines indicates a low-ordering range (LOR) for this phase, designed H_{12}. After a long annealing of 72 days at 670 K, the superstructural lines which appear lead to an hexagonal structure of the FePdP type.[10] All of the polytype phases can be considered as 3D networks of the rhombohedral subunit previously described: the subscript of letter H or O repre-

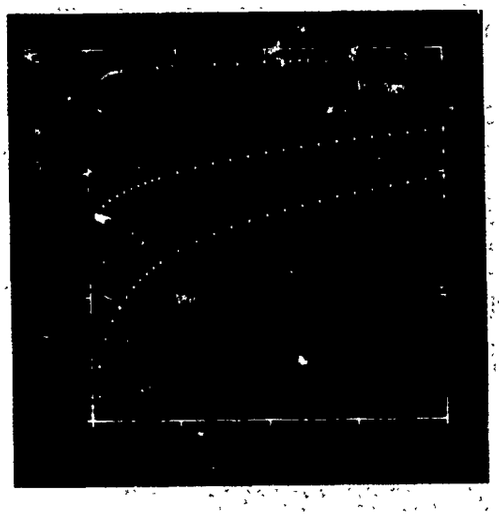

FIG. 2. Magnetization curves for a powder sample of FeRhP in O_{10} (CoNbB type) phase at different temperatures.

sents the number of rhombohedra. The phases H_{12} and O_{10} result from the cooperative displacements of c/2 of some chains of phosphorus atoms along the c axis. Whereas in the H_3 structure both iron and rhodium atoms are distributed over the tetrahedral and pyramidal sites with a nearly complete degree of disorder, in the two other phases the translations of the chains of P atoms result in strong variations of these characterized distributions. In FePdP an overconcentration of rhodium around some particular phosphorus atoms was observed.[7,9] In order to determine the influence of these metallic clusters on the ferromagnetism of he FeRhP system, magnetic properties of the three polymorphic phases will be reported.

Measurements of the magnetization over the temperature range 4.2–400 K were carried out using extraction technique in dc magnetic fields up to 200 kOe produced by a water-cooled Bitter magnet (magnetometer is described in Ref. 11). On the other hand, the temperature dependence of the initial magnetic susceptibility were determined in the 300–1300 K temperature range using a homemade Faraday-type device.

III. RESULTS AND DISCUSSION

Some typical magnetic isotherm curves reported in Figs. 1 and 2 reveal significant differences between the three polytypes of the two studied phosphides. First, a large discrepancy between the magnetic moments is observed (nearly a factor of 2 between the H_3 and H_{12} phases). Second, whereas for both H_3 and O_{10} phases the general shape of the $M(H)$ curves is in accordance with a rapid saturation, for the H_{12} polytype only 90% of saturation is reached at 50 kOe. Within our experimental accuracy ($\mp 1\%$), neither hysteresis on the $M(H)$ curves nor changes on the results were observed after cooling from 300 to 4.2 K under 200 kOe. This behavior confirms the good quality of the samples which were initially checked by x-ray and neutron diffractions.[9]

For all of the samples studied, the experimental curves are well described by a law of approach to saturation which contains a b/H^2 term only[12] in a high-field domain (100–200 kOe). The saturation moment (M^{sat}) in Bohr magneton μ_B per mole, at 4.2 K, was determined using a least-squares procedure. The results are in Table I with the corresponding values of m^{ferro}, μ_B/iron atom. For the H_3 and O_{10} polytypes, m^{ferro} decreases with the rhodium content but in the H_{12} form, m^{ferro} is practically independent of the Rh content (Table I). The first-order anisotropy constant K is determined from the coefficient b ($b=4K^2/15M_{sat}^2$ in the hexagonal case), it is obtained: $K\sim 1.7\times 10^7$ erg cm^{-3} and $K\sim 2.5\times 10^7$ erg cm^{-3} for $Fe_{1.333}Rh_{0.666}P$ and FeRhP respectively in the H_{12} phase. In the H_3 phase, K is found to be $\sim 0.7\times 10^7$ erg cm^{-3} and is independent of Rh content. This last value constrasts strongly with the average value of 2.5×10^7 erg cm^3 proposed for Fe_2P.[2]

TABLE I. Magnetic Properties of the metallic H_3, O_{10}, and H_{12} polytypes of iron-rhodium phosphides.

FeRhP	H_3	O_{10}	H_{12}
$M^{sat}(\mu_B mole^{-1})$	2.02	1.46	1.09
T_c(K)	355	235	120
C (uem)	1.42	1.26	1.14
$n_{eff}(\mu_B)$	3.37	3.18	3.02
$m^{ferro}(\mu_B)$	2.02	1.46	1.09
$m^{para}(\mu_B)$	2.50	2.35	2.18
$Fe_{1.333}Rh_{0.666}P$	H_3	O_{10}	H_{12}
$M^{sat}(\mu_B mole^{-1})$	2.11	1.64	1.38
T_c(K)	360	290	230
C (uem)	1.77	1.53	1.44
$n_{eff}(\mu_B)$	3.26	3.04	2.95
$m^{ferro}(\mu_B)$	1.58	1.24	1.04
$m^{para}(\mu_B)$	2.41	2.20	2.12

For all samples, the reciprocal magnetic susceptibilities follow a Curie law (see figure in Ref. 8). The experimental values of both Curie constants (C) and paramagnetic Curie temperature (T_c) are summarized in Table I where the values of n_{eff}, effective number of Bohr magnetons/Fe atom, deduced from C are also reported. As the classic plot of H/M vs M^2 provides values of T_c that are in very good agreement with the preceding determinations, we conclude that the paramagnetic and ferromagnetic Curie temperatures coincide. The values of m^{para}, magnetic moment in the paramagnetic state, given in Table I were deduced from the relation $n_{eff}^2=m^{para}(m^{para}+2)$.[13] It should be noted that the ratio m^{para}/m^{ferro} is always much larger than 1 as expected by a localized electron model; this result can be interpreted on the basis of a collective electron model of ferromagnetism.[13] In addition, a strong decrease of m^{para} is observed when the structure turns from H_3 to H_{12}.

To explain the very different magnetic behaviors observed for the three phases, we shall analyze the H_{12} case. All of the atoms occupy planes perpendicular to the [001] direction at $z=0$ and $z=1/2$, respectively. The structure consits of 12 pseudorhombohedral subunits which form two types of blocks. The first contains three subunits and is projected as hexagons in the (001) plane; projection in this plane of the second type, which contains six of the rhombohedral subcells, leads to the "star-shaped" arrangement (Fig. 3).[9] In the unit cell described by the association of two "hexagon"

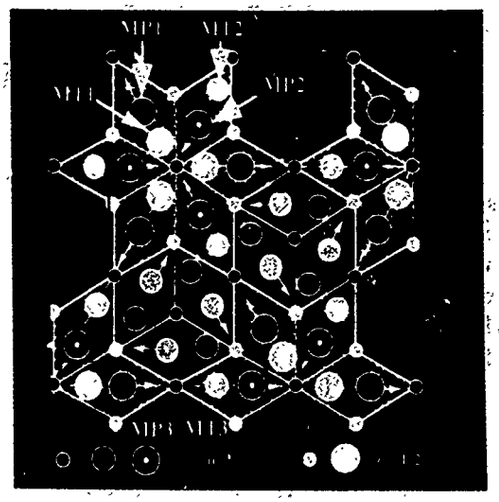

FIG. 3. FeRhP structure in the H_{12} form: projection on the (001) plane; the iron content for the six metallic sites is equal to: 0 for MT_1 and MP_1, 54% for MP_2, 41% for MP_3, 91% for MT_2, and 82% for MT_3, respectively (arrows on the pyramidal sites suggest the axial symmetry).

and one "star-shaped" blocks, the metallic atoms are distributed over three tetrahedra (noted MT) and three pyramids (MP): on four sites ($MT2$, $MT3$, $MP2$, and $MP3$), a statistical disorder of the Fe and Rh atoms is observed (occupations are given in the caption of Fig. 3). In contrast $MT1$ and $MP1$ which belong to the "star-shaped" block are occupied only by rhodium atoms. It is important to emphasize the local overstochiometry of rhodium around the P (0,0,0) atom when the the structure changes from H_3 to H_{12}.

For the completely disordered H_3 phase, the magnetization of the pseudorhombohedral unit (formula FeRhP) is equal to

$$m(\text{phase } H_3) \simeq (3/6)(m_T + m_P), \tag{1}$$

m_T and m_P represent the Fe atom magnetic moment in tetrahedral and pyramidal positions, respectively. In the H_{12} phase, the saturation magnetization is given by

$$m(\text{phase } H_{12}) = 0.2275 m_{T2} + 0.135 m_{P2} + 0.205 m_{P3} + 0.41 m_{T3}. \tag{2}$$

Since no values of m_T and m_P are available to explain the saturation of the H_3 form, we estimate that $m_T \simeq 1\mu_B$ and $m_P \simeq 3\mu_B$ based on the order of magnitude proposed for Fe_2P. In the H_{12} phase, the $MP2$ site is located in the region where the overstochiometry of rhodium occurs; on the other hand, this site contains only 54% Fe atoms. These two points lead to the conclusion that the Fe atoms of this site are nonmagnetic, and occurs as diamagnetic clusters. According to this hypothesis, m_{P2} is taken equal to zero; furthermore assuming always that $m_T = m_{T2} = m_{T3} \simeq 1\mu_B$ and $m_P = m_{P3} \simeq 3\mu_B$, we can roughly estimate that the saturation of the H_{12} phase is equal to $1.25\mu_B$. Although the compound contains a very large amount of iron, the presence of diamagnetic clusters can be explained by a gain of stability created by a complete filling of the Fe d^{10} levels due to valence electrons transferts from neighboring rhodium and phosphorus atoms in the region of high rhodium content to form $(Fe_{1.62}Rh_{7.38}P)$ group s. This hypothesis suggests more localized bondings in the clusters. It appears, therefore, that very simple structural chemical framework can explain critical behavior of the magnetic properties which are strongly influenced by this metal clustering. Similar arrangement occurs in the O_{10} phase although the distribution of the iron atoms is more complex.[9] This existence of diamagnetic clusters was previously suggested to interpret the diamagnetic properties of the system Ni_2P-Co_2P.[7]

In this paper quantitative data on the intrinsic properties of the FeRhP system are reported. Through the interpretation of these results and those of earlier studies, we have determined that diamagnetic clusters occur in the H_{12} and O_{10} phases. It is clear that further experiments on local properties using Mössbauer effect and neutron diffraction are needed to obtain more detailed information on diamagnetic clustering in both O_{10} and H_{12} polytypes.

Magnetism in metastable bcc and fcc iron-copper alloys

P. A. Serena and N. García
Departamento de Física de la Materia Condensada, Universidad Autónoma de Madrid, Cantoblanco, E-28049 Madrid, Spain

We present linearized augmented plane-wave calculations for FeCu fcc and bcc metastable phases using the local density approximation. Curves for the density of states (without including the spin-polarization effects) at several Fe concentrations are given, noticing that the density of states at the Fermi level for determinated fcc alloys suffers significant large increases in relation to the fcc Fe. This fact provides an explanation to the magnetic character found in some fcc FeCu alloys. The magnetization is calculated at different compositions by applying the Stoner criteria, assuming a simple behavior for the magnetic exchange integral, and including the effect of randomness in a simple way. We find that the magnetic moment per Fe atom is similar to that of bcc Fe for some fcc FeCu alloys.

In the last few years it has been possible to prepare metastable phases of fcc and bcc Fe-Cu alloys by mechanical alloying[1] and sputtering.[2,3] These techniques have provided new perspectives of understanding mechanisms for producing magnetism as well as the growth of new magnetic materials. In particular, Chien *et al.*[2] have shown that the fcc phase can be grown by sputtering if the amount of Fe is smaller than 75%, where the fcc phase starts to coexist with bcc phase. Also, recent magnetic measurements[4] have shown that the metastable fcc phase of $Fe_{52}Cu_{48}$ has a larger magnetic moment than the segregated fcc-Cu and bcc-Fe phase. However, the magnetic properties of these new metastable alloyed phases are far from being explained and represent a field in which an intensive work remains to be done.

In order to understand the magnetic behavior of these FeCu alloys we have performed all electron linearized augmented plane-wave (LAPW) calculations of band structures and density of states (DOS) for Fe_xCu_{100-x} ordered alloys in both bcc and fcc phases and for some specific Fe concentrations x. The calculations were carried out by using the Soler–Williams[5] implementation of the APW method in its linearized version.[6] The computations were performed within the framework of the local density approximation[7] (LDA) and therefore they do not include the spin polarization, so that not exchange splittings are obtained. However, the LD densities of states at the Fermi level of the unpolarized systems can be approximately correlated to the exchange splittings and magnetic moments through the Stoner theory.[8,9]

Due to the mandatory use of supercells in LAPW calculations, the representation of bcc and fcc Fe_xCu_{100-x} ordered alloys involves serious difficulties when intermediate fractions x are considered, since there are a huge number of nonequivalent atomic positions, turning a detailed description into a unaffordable task. Thus, we have restricted ourselves to the study of five concentrations ($x=0$, 25, 50, 75, 100) for which there are simple ordered representations involving few atoms. In this way, the study of bcc and fcc phases has been carried out with unit cells containing four atoms, reducing as much as possible the calculation resources. We use the same muffin-tin radius for both Fe and Cu species, taking $R_{mt}=2.30$ a.u., and a plane-wave energy cutoff of $T_{\max}=10.0$ Ry has been considered in all the cases. The exchange-correlation functional was described within the LDA by using the Hedin and Lundqvist[10] parametrization. Here, we must point out that due to the absence of spin-polarization effects, there is no way of of determining directly the magnetic properties (magnetic moment and exchange splitting) as in the local-spin-density[11] (LSD) approximation. Sampling grids ranging from 56 to 126 special points[12] in the irreducible wedge of the Brillouin zone are used for the study of bcc and fcc structures.

In order to test the validity of the parameters we have chosen for describing the FeCu alloys, we have started our investigations with pure bcc Fe, obtaining a cohesive energy of 5.8 eV per atom and a density of states at the Fermi level of DOS $(E_F)=3.4$ states/eV per atom. Notice that we have used the experimental lattice constant, and no minimization of the total energy versus the unit cell volume was performed. Both quantities are in agreement with previous results of Moruzzi *et al.*[13] After determining the DOS, we have included the polarization of the electrons using a scheme based on the Stoner model[8] by shifting rigidly the two half bands (up and down) a relative magnetic exchange energy of 2.2 eV, previously computed[13] within the LSD approximation. Once the rigid shift is applied, we have calculated the transferred charge from the down to the up bands, obtaining a magnetic moment of $2.25\mu_B$ per atom which agrees well with the $2.15\mu_B$ LSD result.[13] Hence, this confirms that our calculated band structure describes the crucial features of the system. Now, we proceed to apply the same computational scheme to our set of periodic representants of these Fe_xCu_{100-x} alloys. All the calculations for the fcc phase compounds were done assuming that the lattice constant a is identical to that of fcc Cu ($a=6.82$ a.u.), whereas for bcc phase compounds we took the bcc Fe lattice constant ($a=5.42$ a.u.), being these values very similar to those found experimentally,[2] although the effect of small variations of the unit cell volume also will be discussed below.

In Fig. 1 we show the density of states (DOS) for the Fe_xCu_{100-x} alloys in bcc and fcc phases obtained from the present nonpolarized LAPW calculation. Looking at the bcc series, we can notice that when bcc Fe samples are doped with Cu, the d peak close to the Fermi level is diminishing and the bottom of the band suffers strong modifications due to the appearance of Cu deeper levels. The situation in the fcc case is rather more complicated. When the fcc Cu sample

 0021-8979/94/75(10)/6580/3/$6.00 © 1994 American Institute of Physics

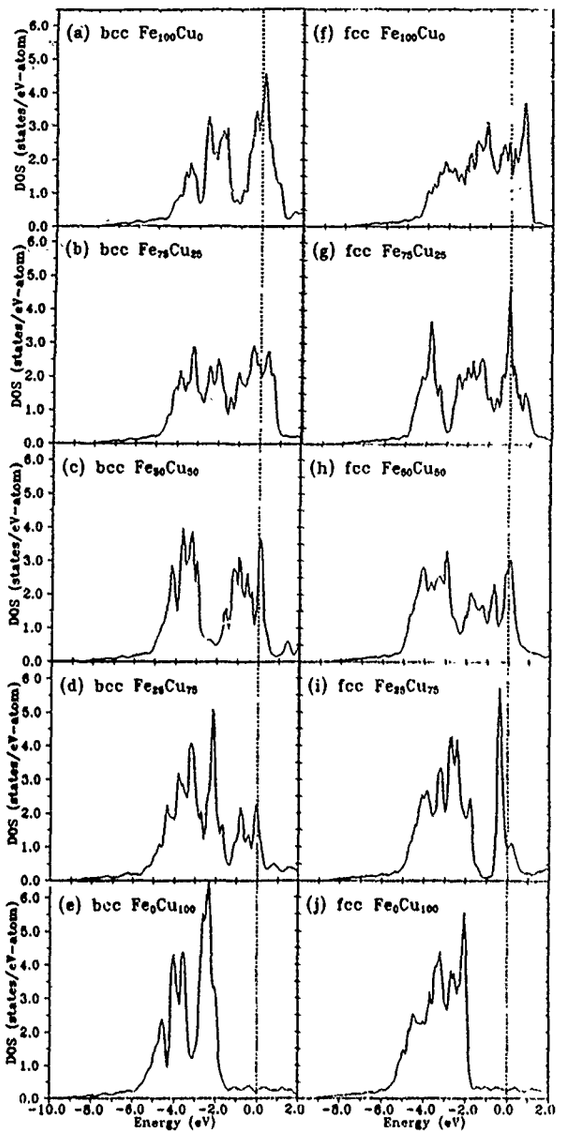

FIG. 1. Density of states (DOS) for bcc (a)–(e) and fcc (f)–(j) Fe_xCu_{100-x} alloys with Fe fractions $x=0$. 25, 50, 75, and 100.

is doped with Fe a strong peak corresponding to Fe states is developed near the Fermi level. The more surprising characteristic we can see is that for the compounds $Fe_{50}Cu_{50}$ and $Fe_{75}Cu_{25}$ the DOS at E_F presents a value higher than that found in fcc Fe. Furthermore, in the case of $Fe_{75}Cu_{25}$ the DOS at E_F is even larger than the value found for the pure bcc Fe. We have checked the influence of possible lattice constant contractions expansions for the case $x=75$, since for such Fe content a change of 4% in the sample volume has been reported.[2] For the bcc $Fe_{75}Cu_{25}$ we have increased the volume per atom in a 4% noticing an increase of a 3% in the DOS at E_F. For the fcc $Fe_{75}Cu_{25}$ phase a similar change in the volume per atom lead to an increase of 1.6% in the DOS at the E_F. These results represent only a minor variation in the DOS and they do not imply any change in the magnetic behavior we will discuss below.

Figure 2 shows the density of states at the Fermi level

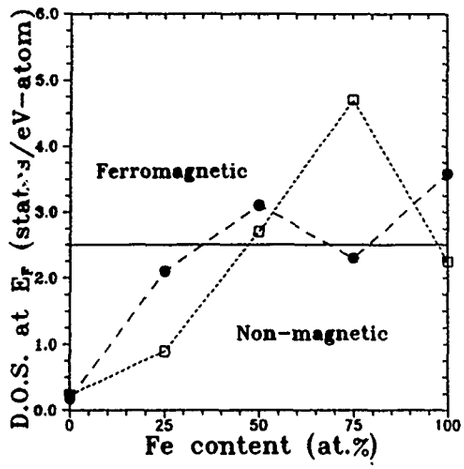

FIG. 2. DOS at the Fermi level E_F for bcc (black circles) and fcc (open squares) Fe_xCu_{100-x} metastable phases. Lines connecting points are guides for the eye. The horizontal line represents the DOS (E_F) frontier value between ferromagnetic and nonmagnetic behaviors corresponding to a molecular exchange constant of $\lambda=6000$.

for the fcc and bcc structures. Once this value is computed we have applied the Stoner model,[8] using a molecular exchange constant $\lambda=6000$ (Ref. 14) in order to take into account the magnetic interactions in these systems containing iron. The Stoner criteria has been graphically displayed on Fig. 2 by defining a frontier line (associated to such molecular exchange constant) for the DOS (E_F) value, which permits to distinguish magnetic from nonmagnetic systems. Above this value the behavior is ferromagnetic whereas below the behavior is nonmagnetic. We notice that with this reasonable choice of λ the pure bcc Fe presents ferromagnetic properties whereas the pure fcc Fe structure corresponds to a paramagnetic system. A striking fact is that the DOS for bcc $Fe_{75}Cu_{25}$ is approximately equal to the DOS at E_F for fcc Fe, which is nonmagnetic, and therefore this could explain the diminishing of the magnetic moment in segregated phases with respect to fcc phases[4] by assuming that a fraction of the Cu atoms enter into the bcc Fe structure, giving raise to a decrease of the magnetic moment. From these results, and after applying the Stoner criteria, we conclude that metastable alloys $Fe_{50}Cu_{50}$ and $Fe_{75}Cu_{25}$ present a well-defined ferromagnetic character despite the fcc Fe structure is not ferromagnetic.

In order to calculate the magnetic moment associated to each configuration we have assumed a magnetic exchange splitting of 2.2 eV for Fe and that such a value decreases to 1.5 eV in the limit of one isolated Fe atom in a Cu matrix,[15] being these values obtained from previous LSD results. In this way we can estimate the magnetic moment for our magnetic ordered representants. For instance, the calculated magnetization for fcc $Fe_{50}Cu_{50}$ is 117 emu/g and only differs in a 7% with respect to the experimental measurement[4] on the real alloy, which is a good result taking into account our previous hypothesis for λ or the exchange splitting. Therefore, once we have delimited the magnetic properties of these ordered configurations, we assume that the magnetization of

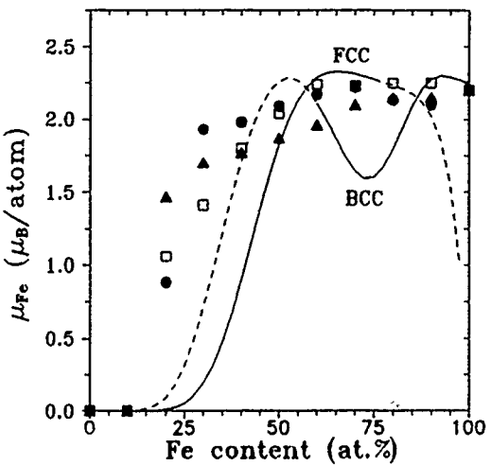

FIG. 3. Magnetic moment per Fe atom for bcc and fcc Fe_xCu_{100-x} metastable alloys. Dashed lines represent nonobserved experimentally phases. Experimental results are also shown (triangles from Ref. 2, black dots from Ref. 16, and squares from Ref. 17).

other fractional configurations (different from those here presented) can be calculated by a simple interpolation scheme. However, these calculated values do not take into account directly the alloy random character. We can incorporate the effect of randomness into the alloy composition by assuming that the lattice positions are to be occupied following a Poisson distribution which is dependent on the iron content of the alloy. This means that for a given average concentration x, it is possible to find small regions of different stochiometric composition with a probability determined by the corresponding Poisson distribution, and, furthermore, the magnetization of these small regions can be evaluated by the interpolation scheme from the values obtained for the ordered samples. Figure 3 summarizes the results for the magnetic moment of the Fe_xCu_{100-x} alloys. Our main result is that the magnetic moment for Fe atom is almost independent of the Cu richness for a wide range of Cu content, in good agreement with experimental data[2,16,17] up to 50% of Cu content.

In conclusion, we have shown that the fcc phase is magnetic for some configurations ($Fe_{75}Cu_{25}$ and $Fe_{50}Cu_{50}$) and why the magnetic moment per Fe atom is almost constant for a wide interval of Fe content in FeCu alloys.[2,16,17] Although our results are based on a combination of LDA, Stoner criteria, the choice of a low number of ordered representants for the description of the alloy composition, and the mixing of the magnetic moments through a Poisson distribution, we believe that the basic ideas needed for the description of magnetism in these systems rely on the high density of states noticed for some specific cases. Furthermore, preliminary studies based on LSD calculations[18] seem to confirm the present results.

The degree of alignment of the magnetic moments of Fe^{3+} ions in ultrafine maghemite particles has been studied in samples with induced magnetic texture. The textured samples were prepared by freezing ferrofluids, containing 7.5 nm maghemite particles, in a magnetic field. Mössbauer spectroscopy studies of the textured samples in large magnetic fields demonstrate that the lack of full alignment is not an effect of large magnetic anisotropy, as suggested recently, but that the effect is rather due to canting of individual spins.

I. INTRODUCTION

The lack of full aligment of the spins in ultrafine maghemite particles in large applied fields was demonstrated by Coey[1] more than 20 years ago. He found, by using Mössbauer spectroscopy, that even a magnetic field of 5 T was insufficient to align all spins in 6 nm γ-Fe_2O_3 particles. The spin structure of the particles was suggested to be noncollinear due to competing antiferromagnetic exchange interactions, most likely at the surfaces of the particles.[1] The observations by Coey also explain why the saturation magnetization of small magnetic particle systems is smaller than that of the bulk material. The phenomenon of canting of spins in nominally ferrimagnetic particles has later been observed in other oxides[2–4] as well as for thin oxide layers on metallic iron.[5]

The suggestion[1] that spin canting is a surface phenomenon has been supported by several later studies, e.g., by ^{57}Fe or ^{57}Co surface enrichment of maghemite particles.[6–8] However, recent Mössbauer studies of maghemite particles, with and without surface enrichment with ^{57}Fe, have indicated[9] that spin canting is not a surface effect, but rather a finite-size effect that is uniform throughout the whole volume of the particles. Also, lately, Pankhurst and Pollard[10] have shown that the observation of nonzero $\Delta m=0$ Mössbauer line intensities may be explained by the response of a randomly oriented ferrimagnetic powder to a large magnetic field when the individual particles are assumed to have a large uniaxial anisotropy, i.e., they suggest that the so-called spin canting effect is due to the lack of full alignment of all the spins in the particles. Hence, the lack of full alignment of spins is a matter of continuing dispute, despite the long history of the discussion and the great importance of maghemite particles in, for example, magnetic recording media and ferrofluids.

We have devised a simple experiment in order to clarify whether the incomplete spin alignment in ultrafine maghemite particles is an effect of specific spins being canted relative to the field direction or, as suggested by Pankhurst and Pollard,[10] that it stems from the inability of the applied field to make the magnetization vector overcome the magnetic anisotropy of the particles. The idea of our experiment is that if full alignment of the magnetic moments is hindered by the volume anisotropy of the particles, then the degree of alignment will depend on the angular distribution of the anisotropy directions with respect to the applied field. A non-random distribution of easy axes (magnetic texture) can be obtained by freezing a ferrofluid in an applied magnetic field. The degree of texture is a function of the magnetic moment of the particles, the intensity of the applied magnetic field, the magnetic anisotropy, and the freezing temperature of the ferrofluid.[11,12] Here, we will show, results of studies of magnetically textured samples of 7.5 nm γ-Fe_2O_3 particles. Recently, we performed similar experiments on 9.0 nm maghemite particles.[13] The advantage of studying 7.5 nm maghemite particles is, as will be shown, that the so-called spin canting effect is more prominent in the smaller particles.

II. EXPERIMENT

Magnetite particles were prepared by coprecipitation of Fe(II) and Fe(III) from an aqueous solution. Leaving the prepared ferrofluid in air resulted in oxidation of the magnetite (Fe_3O_4) into maghemite (γ-Fe_2O_3).

Magnetization measurements were carried out by using a vibrating-sample magnetometer. Mössbauer spectroscopy studies were performed by using a conventional constant acceleration spectrometer with a ^{57}Co source in rhodium. Magnetic fields between zero and 4.35 T could be applied parallel or perpendicular to the γ-ray direction. Transmission electron microscopy was performed using a Philips EM301 electron microscope.

Energy dispersive x-ray diffraction spectra were obtained by measuring the energy spectrum of scattered white x-ray radiation. From the line broadening of the diffraction peaks an estimate of the mean crystallite size could be deduced.

III. RESULTS AND DISCUSSION

Figure 1 shows the magnetization versus applied magnetic field at room temperature. The solid line is a fit, following the method of Chantrell *et al.*,[14] to the magnetization curve, assuming a lognormal distribution of particle size.

 0021-8979/94/75(10)/6583/3/$6.00 © 1994 American Institute of Physics

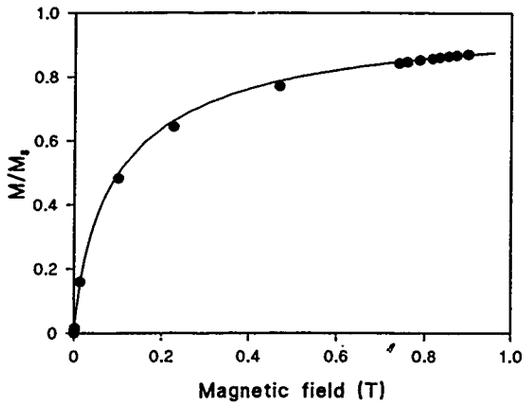

FIG. 1. The magnetization, at room temperature, as a function of applied magnetic field. The full curve is the best fit obtained using the method of Chantrell *et al.*[14]

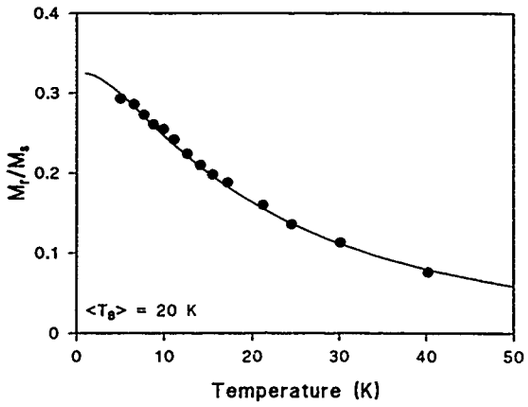

FIG. 2. The temperature dependence of the remanent magnetization. The circles are the experimental data and the solid lines are the best fits, using Eq. (1), for different chosen $\langle T_B \rangle$ values. The distribution of T_B has been assumed to be lognormal (see the text).

From electron micrographs, Mössbauer spectroscopy, x-ray diffraction, and magnetization measurements, the volume-weighted mean particle diameter was found estimated to be $\bar{D}=7.5\pm1.0$ nm.

From the decay of remanence the mean superparamagnetic blocking temperature, $\langle T_B \rangle$, can be extracted by fitting with the following expression:

$$\overline{M_r}(T)=\frac{M_r}{M_s}=\overline{M_r}(0)\int_{T/\langle T_B\rangle}^{\infty} f(T_r)dT_r, \tag{1}$$

where $\overline{M_r}$ is the reduced remanence, $M_r(0)$ is the reduced remanence at 0 K, $T_r=T_B/\langle T_B \rangle$ is the reduced blocking temperature, and $f(T_r)$ is the normalized distribution of blocking temperatures. Assuming the effective magnetic anisotropy constant, K_{eff}, to be size independent, $f(T_r)$ will follow a lognormal distribution. The best fit of Eq. (1) to the $\overline{M_r}(T)$ curve (see Fig. 2) was found for $\langle T_B \rangle \approx 20$ K. From

$$\tau_m=\tau_0 \exp(K_{\text{eff}}V/k_BT_B), \tag{2}$$

where $V=\pi/6\bar{D}$, and τ_m and τ_0 are the measuring time (100 s) and the minimum relaxation time (10^{-10}–10^{-12} s),[15–17] respectively, K_{eff} is deduced to be $(3–4)\times10^4$ J m^{-3}.

Mössbauer spectra of the ferrofluid, frozen in a magnetic field of 4.35 T applied parallel or perpendicular to the sample plane, are shown in Fig. 3. The spectra were obtained at 5 K in a remanence field of 0.06 T perpendicular to the sample plane. The spectra are typical for ultrafine maghemite particles,[18] the spectra are asymmetric with lines 1, 2, and 3 more intense than lines 4, 5, and 6, respectively, and with an inward broadening of each of the absorption lines. As evident from Fig. 3, the spectra have different absorption intensities in the line pair 2 and 5 (the spectra have been normalized to the same maximum absorption intensity in line 1). The relative intensity of the absorption lines 2 and 5 depends on the direction of the magnetic hyperfine field, acting at the absorbing Mössbauer nuclei, relative to the direction of the gamma rays. When the hyperfine field is parallel to the γ-ray direction, the intensity of lines 2 and 5 will be zero, while a spin orientation perpendicular to the γ-ray direction will result in the relative line intensities 3:4:1:1:4:3. The different intensities of lines 2 and 5 for the two sample preparation fields thus reveal different average orientations of the magnetic moments, i.e., it demonstrates the induced texture of the samples. The lower part of Fig. 3 shows the difference spectrum.

Increasing the magnitude of the magnetic field applied during the measurements results in a change of the relative areas of lines 2 and 5. Already for fields below 1 T, a saturation is found in the orientation of the magnetic moments in the direction of the applied field. Mössbauer spectra of 7.5 and 9.0 nm samples, when measured in a magnetic field of 4.35 T applied parallel with the γ-ray direction, are shown in Fig. 4. The line intensities of lines 2 and 5 were found to be independent of the direction of the induced texture. The intensities of lines 2 and 5 have decreased considerably, but

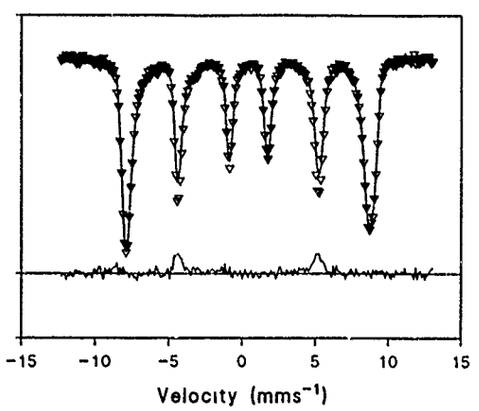

FIG. 3. Mössbauer spectra of samples with frozen-in magnetic texture. The freezing field was 4.35 T. The spectrum of the sample frozen in a field perpendicular to the sample plane is given by a solid line, while the triangles denote the sample frozen with the field applied parallel to the sample plane. The Mössbauer spectra were obtained at 5 K in a field of 0.06 T along the γ-ray direction. The spectra have been normalized to the same maximum absorption in line 1. The lower part of the figure shows the difference spectrum.

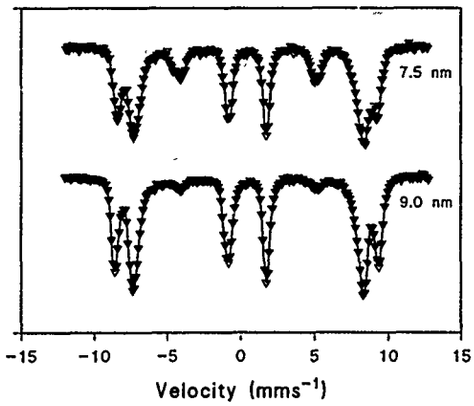

FIG. 4. Mössbauer spectra of 7.5 nm (the upper spectrum) and 9.0 nm maghemite[13] particles in a magnetic field of 4.35 T parallel to the γ-ray direction. The spectra were obtained at 5 and 15 K, respectively.

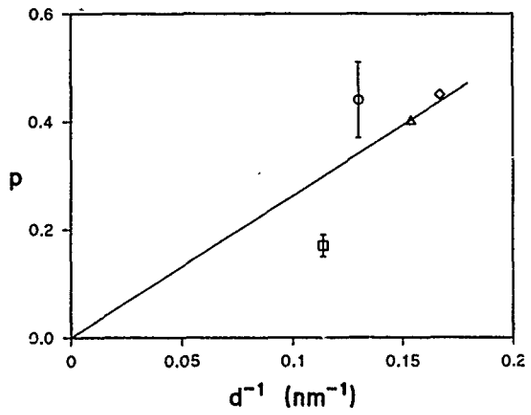

FIG. 5. The fraction of canted spins, p, versus the inverse of the particle diameter of maghemite particles (◇,[1] △,[4] □,[13] and ○, present study) as found, by Mössbauer spectroscopy, at about 5 K and in an applied field of 4–5 T.

they have not achieved the value of zero as they should if all spins were aligned by the field. This observation is similar to that made by Coey.[1] If the model of Pankhurst and Pollard (the PP model) was correct, one should expect that the degree of spin alignment in the 4.35 T field should differ for the 7.5 and the 9.0 nm samples. The fact that relatively low fields, applied during the measurements, are able to align the particle magnetic moment, but with some spins retaining an angle relative to the applied field, is consistent with the concept of spin canting.

Furthermore, the magnetic anisotropies of the studied maghemite particles are much smaller than would be necessary to account for the lack of full alignment by the model of Pankhurst and Pollard.[10] We find $K_{\text{eff}}=(3-4)\times10^4$ J m^{-3}, while in the PP model an effective magnetic anisotropy constant about an order of magnitude larger is needed to explain the observed incomplete alignment.

The degree of spin canting depends on the particle size. As shown in Fig. 4, the intensity of lines 2 and 5 is largest for the 7.5 nm particles. When assuming the area ratio of line pairs (2,5) and (1,6) in the Mössbauer spectra to be $\frac{2}{3}$ for canted spins and zero (in an applied field of 4–5 T) for noncanted spins, the fraction, p, of the spins being canted may be found. In Fig. 5, p is plotted for different samples as a function of the inverse particle diameter. It is clear that the degree of spin canting increases with decreasing particle size. This is expected, both when assuming the spin canting to be a surface effect and when assuming it to be a finite size effect uniform throughout the particle. If the spin canting is due to spin canting of a certain surface layer with thickness t, then the plot of p vs d^{-1} should, in a first-order approximation, follow a straight line. From the straight-line fit in Fig. 5, $t\approx0.9$ nm is deduced. However, the data suggest that other parameters than the particle size influence the degree of spin canting in ultrafine maghemite particles.

When fitting the Mössbauer spectrum of the 7.5 nm particles in Fig. 4 with single lines, the deduced magnetic hyperfine field derived from the positions of lines 2 and 5 is found to be about 1 T smaller than that deduced from lines 1 and 6. This observation cannot be accounted for by the PP model, because the incomplete alignment is ascribed to the incomplete alignment of all spins, whereas the observation can be understood in the model of spin canting, because the canting of the spins must originate from the surroundings of the spins being different from that of the average spin (on either the A site or the B site). A similar observation has been made for the 9.0 nm maghemite particles.[13]

A magnetic and Mössbauer spectroscopy study of nonoriented and magnetically oriented samples of $Nd_6Fe_{13}Sn$ was performed. At 4.2 K a metamagnetic transition takes place in a field of 7.1 T. Strong evidence for antiferromagnetic spin arrangements in the iron magnetic sublattice and antiferromagnetism of the Nd moments with only a small contribution to the net magnetization in fields up to 14 T was found.

The preparation and some of the magnetic properties of the new ternary compounds $RE_6Fe_{13}M$ where RE=Pr, Nd, Sm and M=Ge, In, Pb, Tl, Sn, Bi, Sb were recently reported.[1,2] They crystallize in the tetragonal $Nd_6Fe_{13}Si$-type structure[3] with five nonequivalent iron sites $4a$, $4d$, $16k$, $16l_1$, and $16l_2$ and two nonequivalent rare-earth sites $8f$ and $16l$. In the case of the Nd-containing compositions the magnetic critical temperatures lie between 330 and 550 K,[1] in dependence on the type of the element M. A ferrimagnetic type of ordering with the iron moments oriented antiparallel to the rare-earth moments was proposed in Ref. 1. A more detailed magnetic and Mössbauer study of $Nd_6Fe_{13}Ge$ and $Pr_6Fe_{13}Ge$ (Ref. 2) was interpreted in terms of slightly uncompensated antiferromagnetic ordering of the Fe spins which has to result in a magnetization of $1.6\mu_B$/f.u. and an antiferromagnetic order of the rare-earth moments with no contribution to the net magnetization. In order to get a better insight in the peculiarities of the spin structure in the $RE_6Fe_{13}M$ compositional series we chose the compound $Nd_6Fe_{13}Sn$ and we combined magnetometric measurements in fields up to 14 T with a Mössbauer study on both nonoriented and magnetically oriented samples.

The $Nd_6Fe_{13}Sn$ samples were prepared by arc melting of the pure constituent elements. The crystal structure of $Nd_6Fe_{13}Sn$ was confirmed to be of the tetragonal $Nd_6Fe_{13}Si$ type[3] with the space group $I4/mcm$.[1] The magnetic measurements were carried out using a vibrating sample magnetometer (VSM) in fields up to 14 T at temperatures between 4.2 K and room temperature (RT). The ^{57}Fe Mössbauer spectra were taken using a conventional Mössbauer spectrometer equipped with a ^{57}Co (Rh) source at temperatures between 4.2 K and RT. Some spectra were obtained in the presence of a magnetic field up to 8 T parallel to the direction of the gamma rays. For both the magnetic and Mössbauer measurements oriented samples were also used. The particles of $Nd_6Fe_{13}Sn$ were aligned at RT in a magnetic field of about 2.8 T. The field-oriented Mössbauer absorbers were prepared by embedding the powder in epoxy resin before applying a field perpendicular to the plane of the absorber.

The magnetization curves of an oriented $Nd_6Fe_{13}Sn$ sample measured in the first quadrant at 4.2 K and RT with a magnetic field oriented perpendicular or parallel to the direction of the orientation field are shown in Figs. 1 and 2. A sharp transition at about 7.1 T (B_{cr1}) was observed at 4.2 K for the measurement in a field perpendicular to the orientation field at a magnetization value of $14\mu_B$/f.u. At $24.3\mu_B$/f.u. a less sharp transition in a field of 11.3 T also takes place. For the measurement in the parallel field the magnetization increases stronger in the range 0–10 T but in a rather continuous manner, but again with a transition in the field of 11.3 T. The magnetization curve of an unaligned powder was very similar to the one of the oriented powder for the measurement in perpendicular field.

The drastic increase of the magnetization above B_{cr1} at 4.2 K reminds one of similar findings in the case of unaligned $RE_6Fe_{11}Al_3$ powder samples[1] considered as typical for metamagnetic transitions or a more general first-order magnetization process (FOMP). As can be seen from Fig. 2, the difference between the magnetization curve in perpendicular and parallel fields is strongly reduced at RT. The hysteretic character of the magnetization found at 4.2 K practically vanishes at RT. It is also worth mentioning that the value of the magnetization reached at 4.2 K in our maximum field of 14 T was $29.1\mu_B$/f.u. The Mössbauer spectra taken at

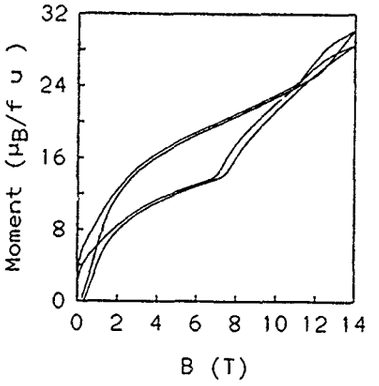

FIG. 1. Magnetization curves of a field-oriented $Nd_6Fe_{13}Sn$ sample at 4.2 K; measuring field applied parallel to (upper curve) and perpendicular (lower curve) to the orienting field.

4:2 and 77 K and RT shown in Fig. 3 were basically fitted to four Lorentzian sextets with intensity ratio 1:4:4:4 corresponding to the population of the unequivalent four iron sites under the assumption that the Sn atoms occupy all the available $4a$ sites. The as-variable taken linewidths varied at 4.2 K between 0.32 and 0.35 mm s^{-1}. An extra sextet with a relative intensity lying between 6% and 9% and a hyperfine field of 29 T at 4.2 K was necessary in order to substantially improve the fit. A Mössbauer spectrum taken at 320 K eliminated the suspicion of the presence of some amount of Nd_2Fe_{17} with T_C=329 K as a second phase. The origin of the fifth sextet still has to be determined.

The magnetic ordering temperature, the one at which the narrowing sextets collapsed giving rise to paramagnetic doublets, reached about 410 K in very good agreement with T_N=420 K obtained recently in a magnetic study of $Nd_6Fe_{13}Sn$.[4] The values of the hyperfine (HF) field at 4.2 and 77 K and RT are given in Table I. The assignment of the HF values to the different Fe sites is based as proposed in Ref. 2 on the nearest-neighbor environment of the Fe atoms, i.e., the number of Fe and RE neighbors and distances to them. Our room-temperature HF values are similar to the ones found recently by Hu *et al.*[2] for $Pr_6Fe_{13}Ge$ and $Nd_6Fe_{13}Ge$. The average HF values of 31 and 30.6 T at 4.2 and 77 K, respectively, are very similar to the average hyperfine fields of 31.2 T at 4.2 K and 29.7 T at 77 K found for the intermetallic compound Y_2Fe_{17}.[3] Taking 15 T/μ_B for the iron hyperfine field constant one obtains an average iron moment of 2.06μ_B at 4.2 K and 1.64μ_B at RT.

The 4.2 K Mössbauer spectrum of a sample prepared from a powder previously oriented in a magnetic field at RT offered strong evidence for the preferential orientation of the Fe moments close to or in the plane of the absorber. Such behavior was confirmed by taking RT Mössbauer spectra of the oriented absorber under the variable angles of 90°, 60°, 45°, and 35.3° with respect to the direction of gamma rays. From the ratios between the intensities of the third and second lines of the Mössbauer fitting sextets one derives an average angle of about 30° between the direction of the Fe spins and the plane of the absorber. Because one cannot expect a perfect orientation of the particles which already may contain several crystallites it seems reasonable to assume that

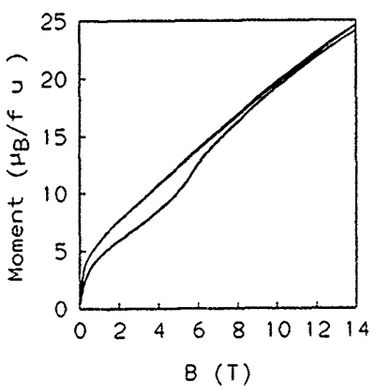

FIG. 2. The same as in Fig. 1 but at RT.

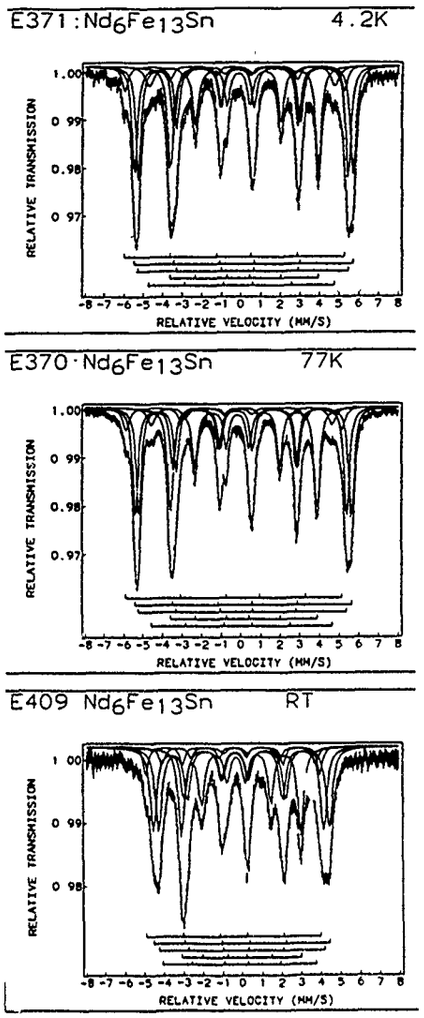

FIG. 3. Best fits to the Mossbauer spectra of $Nd_6Fe_{13}Sn$ taken at 4.2, 77, and 295 K.

Fe moments are probably oriented close to or in plane of the absorber. A parallel ferromagnetic orientation of the Fe moments has to provide at 4.2 K a contribution to the total moment of 26.8μ_B/f.u. It is usual to take for the Nd moment in the rare-earth intermetallics with iron the free-ion value of 3.2μ_B, giving rise for the parallel alignment to a contribution of 19.2μ_B/f.u. In the ferromagnetic alignment of both Fe and Nd moments one should therefore expect 46μ_B/f.u. at 4.2 K, i.e., much more than the 29.1μ_B/f.u. we got from the mag-

TABLE I. Hyperfine field values at 4.2, 77, and 295 K for the four crystallographically nonequivalent Fe sites in the crystal lattice of $Nd_6Fe_{13}Sn$.

Crystallographic site	Hyperfine field (I) 4.2 K	77 K	RT
$4d$	36.6	35	29.5
$16k$	34.7	34.4	27.8
$16l_1$	33.3	33.1	26
$16l_2$	23.5	23.4	19

netic measurement in 14 T at this temperature. The tendency of the Fe spins to lie in a plane perpendicular to the direction of the orientation field at room temperature and also after cooling the oriented Mössbauer absorber down to 4.2 K speaks for a type of antiferromagnetic, maybe noncolinear, spin arrangement of the Fe magnetic sublattices. In fact a ferromagnetic arrangement even with a small total magnetic moment would give rise to a Mössbauer absorber prepared under field orientation to another pattern of intensities with the tendency of the disappearance of the lines 2 and 5, which was obviously not the case. The Mössbauer spectra of an unoriented absorber taken in fields of 2, 4, and 8 T at RT also offer evidence for an antiferromagnetic spin arrangement as a ground state. In fields up to 4 T the lines of some Mössbauer subspectra shift as if the field direction would be opposite to the direction of the hyperfine field, whereas for other subspectra the shifts correspond to hyperfine fields parallel to the direction of the applied magnetic field. However, the Mössbauer spectrum taken in a field of 8 T all the lineshifts can be attributed to Fe moments oriented preferentially in the direction of the applied field, which has to be opposite to the intrinsic hyperfine field. It is worth mentioning that the field of 8 T is larger than the critical field B_{cr1} of 7.1 T in which (at 4.2 K) the more drastic increase of the magnetization already mentioned above starts (Fig. 1). For this reason we can tentatively assume that at B_{cr1} a kind of metamagnetic transition involving the Fe magnetic sublattices of $Nd_6Fe_{13}Sn$ takes place. An interesting point is that the relative change of the average Fe hyperfine field between 4.2 K and RT coincides practically with the relative variation of the magnetization in the same temperature range. That could mean in agreement with Hu *et al.*[2] that at least up to our maximum field of 14 T the Nd contribution to the total magnetization is relatively small, and the Nd magnetic sublattice is basically antiferromagnetic with a strong negative coupling, the overall exchange coupling to the Fe magnetic sublattice being probably rather weak.

In conclusion it seems that the $RE_6Fe_{13}M$ intermetallics are characterized by not very strong antiferromagnetic interactions inside the Fe magnetic sublattice, whereas in the RE sublattice the antiferromagnetic exchange is much more stronger. Magnetic measurements in very high fields on both polycrystalline and single-crystal samples and magnetic scattering studies would be very useful indeed in order to better understand the complex spin structure of these compounds.

The noncollinear hexagonal antiferromagnet UPdSn exhibits two magnetic phase transitions, at 35.5 and 23 K. The first transition is from a hexagonal paramagnetic state to a noncollinear antiferromagnetic state with a doubled unit cell (phase I). The second 23-K transition is to a monoclinic magnetic structure (phase II). Ever since these transitions were discovered, the question has been whether the moments simply rotate at 23 K, or whether the y and z components of the moment order at 35.5 K while the x component orders out of incipient fluctuations at the lower 23-K transition. While previous powder studies were rather inconclusive on this point, in this study new single-crystal neutron-diffraction results are presented that show the second picture to be correct. In addition, the structural distortions that accompany the change in symmetry are discussed and show that there is phase-II type magnetic short-range order between 23 and 35.5 K.

The ternary intermetallic compound UPdSn is one member of the set of 1:1:1 UTX (where T=transition metal, X=p-electron metal) compounds that has been studied for some time now[1–3] with a view to understanding the role of f-d hybridization in uranium magnetism, and in particular the huge magnetocrystalline anisotropies that are observed. A picture is emerging in which the f electrons hybridize in directions or planes containing nearest-neighbor U–U links, with the ordered magnetic moments perpendicular to these directions or planes. However, UPdSn does not fit the general pattern and exhibits more localized behavior, as manifested in its low electronic specific heat (γ_{el}=5 J mol^{-1} K^{-2})[4] and its relatively large ordered moment (2.05 μ_B at low temperature).[5] The Pd and Sn atoms are ordered chemically in the GaGeLi structure and the uranium ions exhibit a complicated noncollinear magnetic structure with a Néel temperature of 37 K.[5] The original powder-diffraction work[5] on the magnetic structure assumed two magnetic phase transitions, the lower being at 25 K, with a monoclinic noncollinear magnetic structure (phase II, see Fig. 1) below 25 K, an orthorhombic noncollinear magnetic structure (phase I, in which θ=0 and γ=90°) between 25 and 37 K and a paramagnetic hexagonal phase above 37 K. Magnetically driven structural distortions with these symmetries have recently been observed and characterized,[6] confirming the original magnetic structure determination. However, there have always been two different ways of regarding the 25-K transition; in a moment-rotation picture, well-defined local moments would start to rotate away from the b-c plane at 25 K, but there would be no anomalies in the temperature variation of the total uranium moment. Alternatively, the y and z components of the moment could order at 37 K, while the x component ordered at the lower temperature of 25 K. In between, μ_x would only be short-range ordered or fluctuating. In this case, there would be a discontinuity in the variation of the total moment with temperature, so the two pictures should be distinguishable by experiment. In fact a careful temperature-dependent study has already been done on a powder sample,[7] but the results were rather inconclusive. If viewed in spherical-polar coordinates, the order parameters all seem to vary smoothly with no evidence of the 25-K transition. On the other hand, if viewed in Cartesian coordinates, it seems that μ_y orders at 37 K or so while μ_x orders at 25 K, thereby favoring the idea that μ_x condenses at the lower temperature.

Since that study single crystals have been grown and, in the course of a study of the magnetic phase diagram[8] of UPdSn, it was shown that the 010 reflection, whose intensity is proportional to μ_x^2, does vary much more sharply with

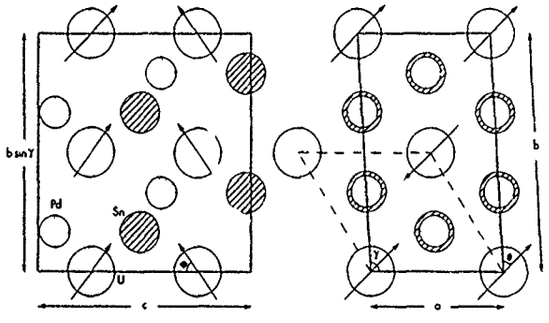

FIG. 1. The crystallographic and magnetic structures at low temperature of UPdSn, with magnetic space group P_c112_1. The figure on the right shows the monoclinic basal plane. The primitive crystallographic unit cell (which corresponds to the parent hexagonal cell) is shown by the dashed lines, while the magnetic unit cell is shown by the solid lines. The figure on the left shows the projection onto a plane perpendicular to the a axis. Neither the atom sizes nor the lattice constants are drawn to scale and the deviation from 90° of the monoclinic angle γ has been grossly exaggerated. However, the atom coordinates within the cell are drawn to scale.

temperature than in the powder. In this article, we report new temperature-dependent single-crystal data taken on the 010, 011, 012, 100, and 120 reflections. These give definitive evidence that μ_x does indeed condense at the lower temperature of 23 K and that it is short-range ordered or fluctuating between 23 and 35.5 K.

The crystal of UPdSn is the same 1 mm-diam 5-mm-long sample used in previous studies of the magnetic phase diagram[8] and magnetic form factor.[9] It was grown by the tri-arc Czochralski method and for the present experiments was glued into a 1-cm-diam cylindrical aluminum block. The cylinder axis of the crystal was approximately 18° away from the $[110]_{\text{hexagonal}}$ $(=[100]_{\text{orthorhombic}})$ axis which was aligned along the axis of the aluminum block. This was installed in a closed-cycle helium refrigerator, which was mounted on the BT-4 triple-axis spectrometer at the NIST Research Reactor. A pyrolytic graphite monochromator and filter were used with an incident neutron wavelength $\gamma=2.35$ Å and the analyzer was removed. For most of the data presented here, the collimation was 40′/40′/40′, but both coarser (40′/40′/open) and tighter (60′/20′/20′ and 20′/20′/10′) collimations were used in the specific instances noted in some of the figures. Two different crystal orientations were used; (a) with the [100] orthorhombic axis vertical, giving access to the 010, 011, and 012 reflections of one particular domain pair, and (b) the [001] axis giving access to the 010, 120, and 100 reflections of the same domain pair. As the cylinder axis of the sample is close to vertical in the first geometry, corrections for self-absorption are a minimum in this case and will be similar for the 010, 011, and 012 reflections. In contrast, with the [001] axis vertical such corrections will be much larger and more variable from reflection-to-reflection. We have, therefore, only used the 010, 011, and 011 reflections to determine the model parameters μ, θ, and ϕ in the magnetic structure of UPdSn.

The temperature variations of the peak intensities of all reflections measured are shown in Fig. 2. The peak widths were also measured at a limited sample of these temperatures for each reflection and, except for the case of the 100 reflection, were found to be temperature independent. There is evidence in these scans of two transitions and we extract transition temperatures of 23 and 35.5 K. These values are in reasonable agreement with previous results.

In the case of the 100 reflection, full peak scans were also made in order to measure the integrated intensities and the results are shown in Fig. 3. These results are very different from the peak intensities in Fig. 2(e) and the reason is that the peak width increases dramatically below 23 K. The inset to Fig. 3 shows peak widths of rocking curves measured with very high angular resolution. This broadening is due to the structural transformation, i.e., orthorhombic to monoclinic, that accompanies the magnetic transition from phase I to phase II.[6] The monoclinic angle γ has previously been determined to be 90.35°, by means of high-resolution neutron powder diffraction.[6] No splitting between the two monoclinic domains was observed, but the angular distribution is broad and flat-topped with a width of approximately 0.8° full width at half-maximum (FWHM). This is qualitatively consistent with having both monoclinic domains and

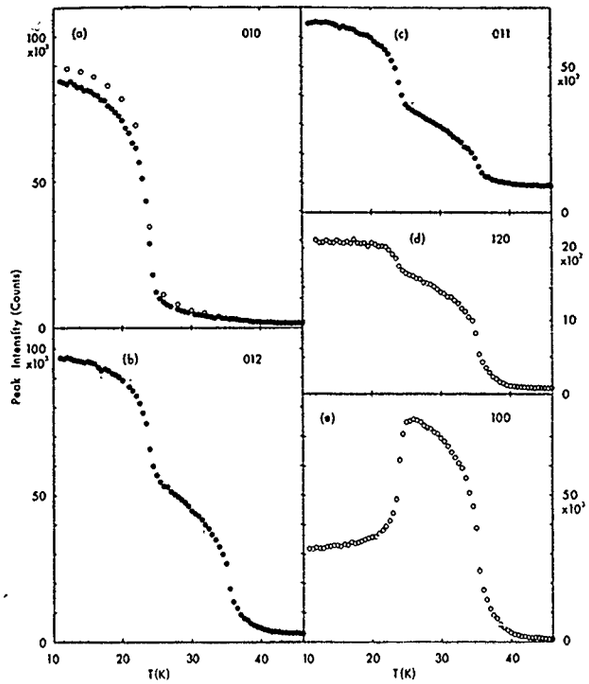

FIG. 2. The variation in peak intensity with temperature for the following magnetic Bragg reflections: (a) 010, (b) 012, (c) 011, (d) 120, and (e) 100. All data are for the magnetic domain (or pair of domains in the low-temperature monoclinic phase) and 40′/40′/40′ collimation was used in all cases. The solid circles represent data taken with the [100] orthorhombic axis vertical, while the open circles represent data taken with the [001] axis vertical. The data were counted for 5 min per point except for the solid circles in (a) which were counted for 3 min per point. These single crystal data are directly comparable with the powder results in Fig. 4 of Ref. 7.

the consequent angular spread of 0.7° between them, but with a large population of domains in each orientation and a continuous distribution of orientations to accommodate the strains that are induced by the transformation.

We therefore believe that, apart from the 100 reflection, the peak intensities are proportional to the integrated intensity that one would measure in a rocking-curve measurement. The intensity of the 010 reflection shown in Fig. 2(a) is much as reported previously, for this single crystal.[8] There is also clear evidence of two transitions in Figs. 1(b)–(d). Indeed it is almost inconceivable that simple moment rotation could give rise to the step rise at approximately 23 K. In order to demonstrate this point definitively, the intensities of the 010, 011, and 012 reflections were fitted to the model of the magnetic structure shown in Fig. 1. The high-temperature background, derived from data points with temperatures greater than 42 K, was subtracted from the data and the intensities were corrected for the difference in counting time, the $1/\sin\theta$ Lorentz factor as is appropriate for integrated intensities of rocking curves[10] and the U^{3+} magnetic form factor.[9] The model parameters μ, θ, and ϕ were then treated as adjustable variables and the results are shown as the solid circles in Fig. 4. The rise in total moment at 23 K is clear evidence that the moments are not simply rotating. An extra component seems to be condensing at this temperature. The open circles in Fig. 4 represent simply the component of the

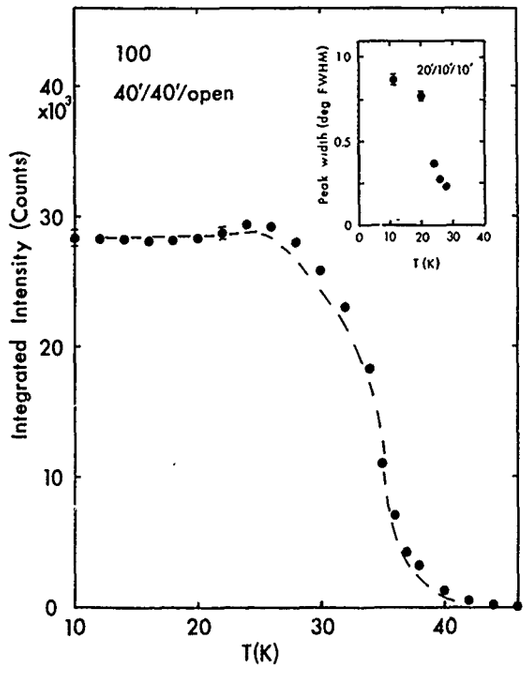

FIG. 3. The variation in integrated intensity for rocking curves through the 100 magnetic reflection, as a function of temperature. The solid circles are the raw data and the dashed line is calculated from the model parameters displayed in Fig. 4, which were in turn derived from the peak intensities of the 010, 011, and 012 reflections as displayed in Fig. 2. The inset shows the variation in peak width with temperature for the same 100 reflection measured with 20′/10′/10′ collimation.

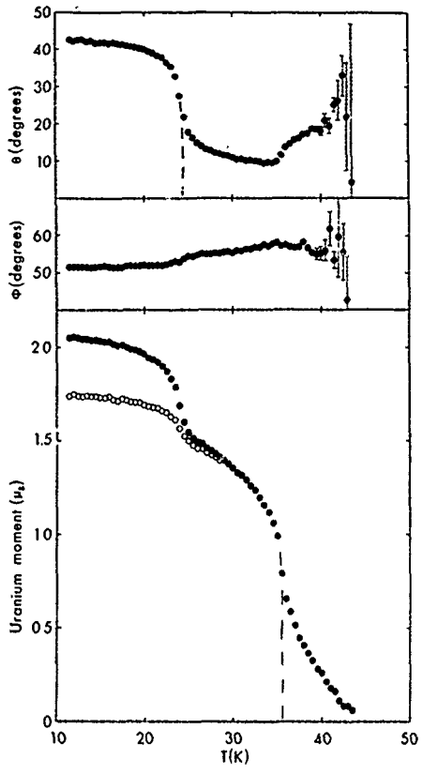

FIG. 4. The variation of model parameters μ, θ, and ϕ, with temperature as extracted from the 010, 011, and 012 peak intensities from Fig. 2. These single-crystal data are directly comparable with the powder results in Fig. 3 of Ref. 7. The dashed lines are guides to the eye and have no theoretical significance.

moment in the b-c plane and this is fairly well behaved at 23 K. The small glitch there may be evidence of coupling between moments in the b-c plane and those perpendicular (μ_x) to it, but the basic picture for this material is that the in-plane moments condense at 35.5 K with μ_x condensing at the lower transition. Now, the integrated intensity of the 100 reflection is simply proportional to μ_y^2 and we can, therefore, calculate the intensity of the 100 reflection at all temperatures from the values of μ_y. Suitably scaled to the lowest-temperature-measured integrated intensity, these results are shown as the dashed line in Fig. 3. The agreement between these results, which were derived from the peak intensities of the 010, 011, and 012 reflections are in very good agreement with our direct measurements of integrated intensities for the 100 reflection.

In summary, the main result of this article is shown in the lowest panel of Fig. 4, which shows definitively that the 23-K transition in UPdSn is best thought of as due to condensation of a long-range ordered μ_x out of short-range magnetic order in this coordinate between 23 and 35.5 K. In UPdSn, we are not dealing with simple rotation of local moments. In addition, we have observed a large orientational broadening in the single crystal, which is consistent with the monoclinic structural distortion previously observed by powder diffraction.

We are grateful to M. F. Collins, who originally suggested to us that the 25-K transition might be better thought of as due to the x-component ordering at a lower temperature than the components in the b-c plane. This work was supported in part by the division of Basic Energy Sciences of the U.S. Department of Energy.

Although many binary heavy rare-earth alloy systems have been studied extensively, there has been little work reported on the Dy-Lu system. The properties of single-crystal Dy_xLu_{1-x} films grown by molecular beam epitaxy are reported. SQUID magnetometer and neutron diffraction measurements on samples with $x=0.4$, 0.5, and 0.6 show that the samples order helimagnetically with Néel temperatures of $T_N=90$, 105, and 120 K, respectively. The helical turn angle was mapped as a function of temperature for each of the three alloys. Magnetic x-ray scattering, the first in an alloy, was observed at the $(002)^{\pm}$ positions at 15 and 60 K in the $x=0.4$ sample using resonant exchange scattering of synchrotron radiation at the Dy L_{III} edge.

Due to the similarity of their chemical properties, the heavy rare earths and yttrium are almost completely mutually soluble. In binary alloys, the concentration may be varied continuously to change such properties as the ordering temperature and lattice spacings.[1] Ordering temperatures and wave vectors for the heavy rare-earth binary alloys with each other and with Y have been shown to follow universal curves.[2] While many rare-earth alloys have been studied in the past, little work has been reported on the Dy-Lu alloy system. This system is of interest as part of our ongoing work on Dy/Lu superlattice structures.[3]

We have studied three c-axis samples grown by molecular beam epitaxy (MBE) at the University of Illinois Epicenter. The $Dy_{0.4}Lu_{0.6}$, $Dy_{0.5}Lu_{0.5}$, and $Dy_{0.6}Lu_{0.4}$ alloy films are 2300, 2400, and 20 540 Å thick, respectively. The films were grown on Y and Nb buffer layers upon a sapphire substrate and with Lu cap layers. Sample quality was verified by x-ray diffraction. The 2300- and 2400-Å films have in-plane mosaics of 0.3° and 0.4°, respectively. The thick (2.05-μm) film has an in-plane mosaic of 0.1°. The c-axis coherence lengths of the films were 760 Å for the $Dy_{0.4}Lu_{0.6}$ film, 600 Å for the $Dy_{0.5}Lu_{0.5}$ film, and 1330 Å for the thickest film ($Dy_{0.6}Lu_{0.4}$).

In bulk Dy, the moments initially order at $T_N=179$ K in a c-axis helimagnetic structure; the moments are confined to the basal plane, and their direction rotates through a turn angle $\omega(T)$ in going from layer to layer along the c axis. The initial turn angle ω_i is 43° just below T_N, decreasing to 26.5° at $T_C=89$ K. Below T_C, bulk Dy is ferromagnetic. Bulk Lu is weakly paramagnetic. We will contrast the properties of Dy-Lu alloys with bulk Dy.

The magnetic moment was measured as a function of temperature using a SQUID magnetometer in zero-field cooled (ZFC) and field-cooled (FC) configurations. Cusps in the field-cooled susceptibility indicate that the Néel temperatures occur at 90, 105, and 120 K for the $Dy_{0.4}Lu_{0.6}$, $Dy_{0.5}Lu_{0.5}$, and $Dy_{0.6}Lu_{0.4}$ films, respectively (see Fig. 1). The Néel temperatures of the alloys follow the 2/3 power of the effective spin parameter (de Gennes factor)

$$x=c(\lambda-1)^2J(J+1), \tag{1}$$

where c is the concentration of the rare earth with angular momentum J, and λ is the Landé factor. Néel temperatures of many other rare earth–rare earth, rare earth–yttrium, and rare earth–lutetium binary alloys have been shown to follow this universal curve[4] (see inset, Fig. 2). Consistent with previous results,[5] which show a sharp suppression of T_C in heavy rare earths diluted with Y and Lu, no ferromagnetic transition was observed at temperatures above 10 K in any of the three Dy-Lu alloy samples.

The Néel temperatures were confirmed by neutron diffraction, and the films were shown to order helimagnetically (see Fig. 2). The magnetic coherence length along the c axes of the films is approximately the same as the structural c-axis coherence length at low temperatures. The intensity and position of the magnetic satellites were determined as a function of temperature for the three films. The separation Q of

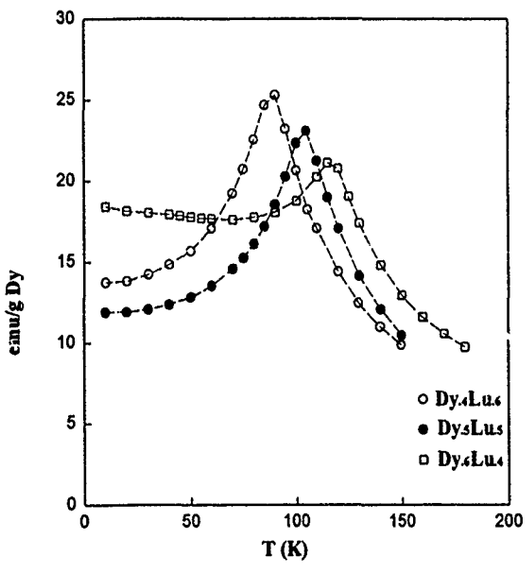

FIG. 1. Field-cooled SQUID magnetization data in a 5-kOe field. Cusps in the susceptibility indicate Néel temperatures of 90, 105, and 120 K for the $Dy_{0.4}Lu_{0.6}$, $Dy_{0.5}Lu_{0.5}$, and $Dy_{0.6}Lu_{0.4}$ alloys, respectively.

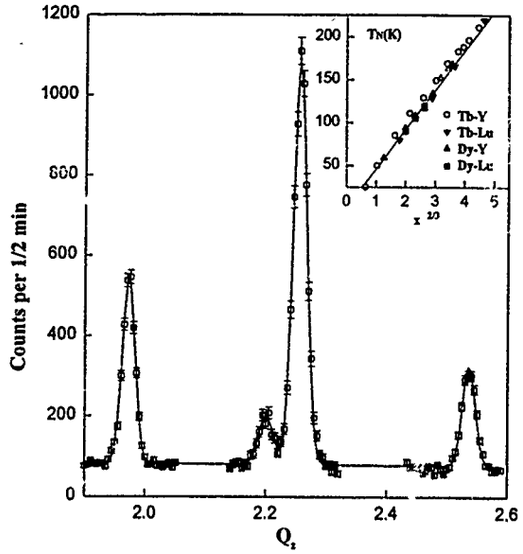

FIG. 2. Neutron scan along the c^*hcp axis of sample $Dy_{0.5}Lu_{0.5}$ at 30 K. The structural (002) Bragg peak at $Q_Z=2.26$ Å^{-1} has magnetic satellites at 1.97 and 2.54 Å^{-1}, indicating helimagnetic order. The structural peak at 2.20 Å^{-1} is from the (002) Y buffer layer. *Inset*. Néel temperature as a function of the 2/3-power of the de Gennes factor for selected alloys. Tb-Y, Tb-Lu, and Dy-Y data are from from Ref. 5. The data are seen to follow the curve given by $T_N=46x^{2/3}$.

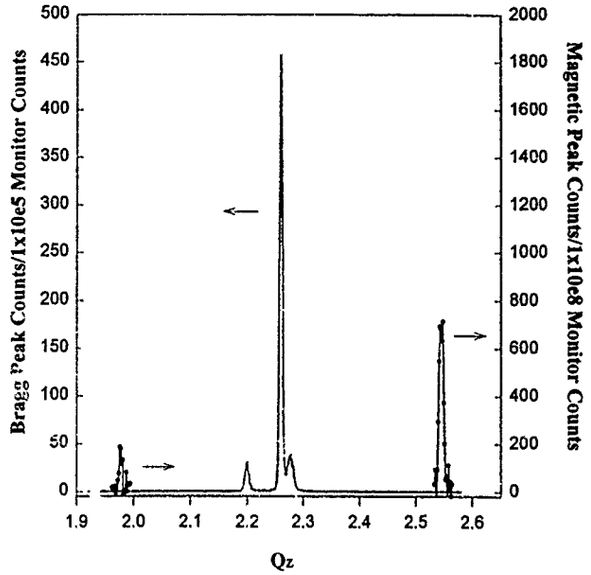

FIG. 4. Synchrotron xray diffraction data showing the Dy (002) Bragg peak ($Q_Z=2.26$ Å^{-1}) and x-ray resonant enhanced magnetic satellites ($Q_Z=1.974$ and 2.541 Å^{-1}) of sample $Dy_{0.4}Lu_{0.6}$ at 15 K. The structural peaks at 2.20 and 2.27 Å^{-1} are due to the Y buffer layer and Lu cap layer, respectively. Note the different scales for the nuclear and magnetic scattering.

the magnetic satellites from the central (002) Bragg peak determines the turn angle per atomic layer. The turn angles $\omega=Qc/2$, where c is the lattice constant, for the $Dy_{0.4}Lu_{0.6}$ and $Dy_{0.5}Lu_{0.5}$ films varied with temperature from 47° at T_N to 45° at low temperature (see Fig. 3). The turn angle for the thicker film varied over a wider range; from 47.5° at the Néel temperature to 43.5° at low temperature. Previous work has shown similar results; Child[5] *et al.* have found that the turn angle initially decreased linearly with temperature from T_N in heavy rare earth–yttrium alloys, then remained constant at low temperatures. As the concentration of Y was increased, $\omega(T)$ varied over a smaller range, and at high Y concentrations approached 50° per layer at all temperatures below T_N. The Tb-Lu[5] and Dy-Lu systems have qualitatively similar behavior to the rare earth–yttrium systems, although the limiting turn angle appears closer to 48°.

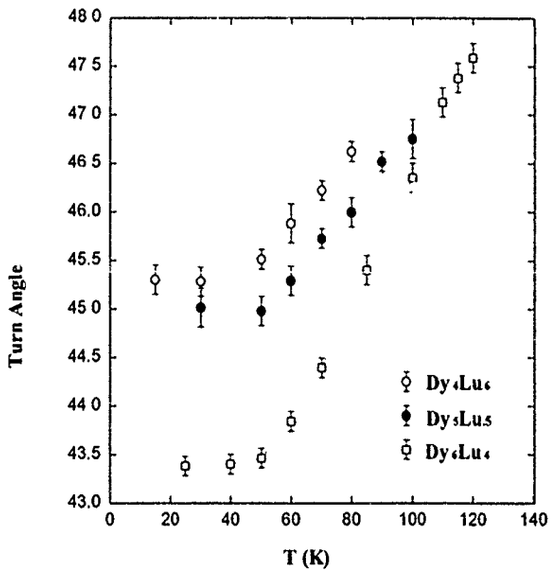

FIG. 3. Helimagnetic c-axis turn angle per atomic layer for each of the three alloys as a function of temperature. Lines through data points serve to guide the eye.

Synchrotron x-ray magnetic scattering, the first in an alloy, was observed from the $(002)^{\pm}$ magnetic satellites using resonant exchange scattering enhancement (XRES) at the Dy L_{III} edge.[6] The $Dy_{0.4}Lu_{0.6}$ alloy was studied at the National Synchrotron Light Source at Brookhaven National Laboratory. The first-order harmonic was used to study the helimagnetic structure of the alloy at low temperature. A polarimeter was used to separate magnetic from charge scattering by exploiting the fact that the polarization of magnetically scattered radiation is rotated 90° relative to the incident polarization. Here, we label the major polarization component of the incident radiation (97%) σ and the orthogonal polarization π. Radiation scattered from the sample is diffracted a second time from the polarimeter analyzer crystal at a Bragg angle (θ) of 44.8° in order to select out a single polarization component.

The Dy $(002)^{\pm}$ magnetic satellites of the (002) Bragg peak were seen when scattering from the incident σ polarization into the detector π configuration. At 15 K, magnetic satellites are located at $Q(002)^{+}=2.541$ Å^{-1} and $Q(002)^{-}=1.974$ Å^{-1} (Fig. 4), corresponding to a turn angle of 45.2° per atomic layer. At 60 K, the integrated intensity of the magnetic peaks has decreased by a factor of 0.7 from the 15 K data, and the turn angle is 45.7° per atomic layer. These results are consistent with the earlier neutron diffraction data

taken at NIST. At 120 K no magnetic satellites were visible. The satellites were not observed in the analyzer σ-σ scattering configuration at any temperature.

We have studied the magnetic ordering of Dy_xLu_{1-x} alloys using a variety of techniques. The Néel temperatures of the three alloys (x=0.4, 0.5, and 0.6) and suppression of the Dy ferromagnetic transition are consistent with the behavior of other rare-earth alloy systems. A helimagnetic structure was confirmed by neutron diffraction, and the turn angle $\omega(T)$ was shown to have a qualitatively similar temperature dependence to Tb-Y, Tb-Lu, and Dy-Y alloys.[5] Magnetic x-ray scattering was observed at the $(002)^{\pm}$ positions at 15 and 60 K in the x=0.4 sample using resonant exchange scattering of synchrotron radiation at the Dy L_{III} edge.

Magnetic ordering and electric polarizability of Zn-doped $La_2CuO_{4+\delta}$ single crystals

G. Cao, J. W. O'Reilly, J. E. Crow, and L. R. Testardi
National High Magnetic Field Laboratory and Center for Materials Research and Technology, Florida State University, Tallahassee, Florida 32306

Magnetization, magnetic susceptibility, and low-frequency dielectric constant of $La_2Cu_{1-x}Zn_xO_{4+\delta}$ ($x=0$, and 0.07) single crystals were measured. Results obtained in this work show that Zn doping eliminates spins from CuO planes, thus, reducing the correlation length, ξ_{2D}. However, unlike Sr doping, magnetic dilution due to Zn doping is a very local effect, thus suppresses T_N relatively slowly and shows little impact on metamagnetic behavior. Our data marks a difference from some results previously reported which claimed a stronger effect on Zn doping on the magnetic properties. It is interesting that Zn doping shows a large influence on the dielectric properties, and resulting in a significant change in the dielectric constant K_c. Most remarkably, the simultaneous polarization and magnetization ordering, described in this study, suggests a coupling of magnetic ordering and electric polarizability in the oxides.

One of the fundamental features found in the high T_c cuprates is the dramatic disappearance of the insulating antiferromagnetic (AF) long-range order and the appearance of the superconducting state upon the introduction of mobile vacancy. The properties of the AF insulating state for La_2CuO_4 can be understood in terms of a two-dimensional (2D) $S=1/2$ Heisenberg model, and the origin of the magnetism is commonly attributed to the copper $3d^9$ configuration. However, the nature of the superconducting state remains a puzzle. A considerable attention has been focused on pairing models originating from a variety of approaches applied to the t-J, 2D Hubbard, and other related models. These models generally rely on some type of magnetic interactions to drive the charge carrier pairing responsible for the superconductivity. Thus it is critical to establish a more complete understanding of the unusual magnetic behavior displayed by La_2CuO_4 and the change of their magnetic response with change in carrier density and impurities. The dielectric constant, on the other hand, can also provide important insights. It has been observed that the near-conducting phases of $YBa_2Cu_3O_{7-\delta}$,[1] $PrBa_2Cu_3O_{7-\delta}$,[2] and related materials[3–5] have shown the occurrence of enhanced low-frequency dielectric response approaching values reported for ferroelectrics. Recently, we have reported[6] dielectric measurements of $La_2CuO_{4+\delta}$ which, again, show large dielectric constants and, in addition, a further enhancement of the electric polarizability in the vicinity of the magnetic ordering. Since such dielectric behavior is often the signature of ferroelectricity or incipient ferroelectricity in many perovskite oxides, such as $BaBi_{1-x}Pb_xO_3$, it has been tempting to suggest the possibility of a common origin of ferroelectricity and high T_c superconductivity in oxides.[7–9] Bussmann-Holder *et al.*,[10] in particular, have drawn attention to this point and described a lattice dynamical model for displacive-type (or soft mode) ferroelectrics which might be applied to high T_c superconductors.

With these considerations in mind, we have recently focused our attention to Zn-doped $La_2CuO_{4+\delta}$ as an extension of our study of magnetic and dielectric properties in La_2CuO_{4+x}. It is well known that substituting small amounts of Zn for Cu strongly inhibits superconductivity in both $La_{2-x}Sr_xCuO_{4+\delta}$ and $YBa_2Cu_3O_{7-\delta}$. Zn ($3d^{10}$) is a unique dopant in that it has almost the same ionic radius as Cu ($3d^9$) ($r_{Cu^{2+}}=0.73$ A and $r_{Zn}=0.75$ A) and the same ionic valence (+2). With a filled d^{10} shell, however, Zn is nonmagnetic. Therefore, it would be expected that Zn substitution at Cu site removes a spin from the 2D antiferromagnetic lattice with little effect on the semiconducting properties of the material except a disruption of the Cu-O hybridization in conductive samples. However, our results appear to indicate that Zn doping not only suppresses T_N but also dramatically changes the dielectric properties of the system, and, thus, suggests a possible correlation between magnetic and dielectric properties.

The magnetization was measured using a Quantum Design magnetometer (SQUID). Measurements of the impedance with E field parallel to the c axis were made at temperatures between 100 and 400 K with frequency varying from 10 kHz to 1 MHz using an HP model 4284A precision LCR meter. To make electrical contacts the two surfaces normal to the field direction were covered with silver paint. As discussed in Ref. 11, at low frequencies, contact effects, which is negligible at low temperatures, becomes significant at higher temperatures due to the decreasing resistances of the sample and contact. To ensure the true dielectric constant, we restricted our measurements to the frequency range where the dissipation factor was below 6.

Figure 1 shows $\chi(T)$ (defined as M/H) as a function of temperature T for $La_2Cu_{1-x}Zn_xO_{4+\delta}$ with $x=0$, and 0.07. The data were obtained under a magnetic field $H$of 0.5 T parallel to the c axis. The Néel temperature T_N decreases as Zn is doped. This is expected in that Zn doping eliminates spins from the 2D lattice, thus reducing ξ_{2D}, the 2D spin–spin correlation length and consequently suppressing magnetic ordering. It is worth noting that T_N for the doped sample with $x\approx 0.07$ is at $T=200$ K, and much higher than those ($T_N<150$ K even for $x=0.04$) on polycrystalline samples reported previously,[12–14] some investigators even claimed that 5.5% Zn would drive T_N to zero.[13] Apparently, the depression of T_N by Zn observed in this work is much

slower. In fact, our data are supported by results of muon-spin-rotation measurements (μSR),[15] which clearly show that AF long-range order exists up to significantly larger value of $x(\sim0.11)$, and T_N for 7% Zn is of 180 K. The value of T_N presented here is also consistent with results published earlier by other investigators, where Néel temperatures of several Zn-doped La_2CuO_4 samples up to 8% Zn concentration was reported.[16] The discrepancy for the value of T_N is likely due to quality of samples. In addition, it is remarkable that the peak for the 7% doped sample remains as sharp as the undoped one. This is, again, in variance from results on polycrystalline samples reported earlier where the width of the peak in the $\chi(T)$ increases upon Zn doping and, thus, the peak becomes less well defined.[12,14] It is believed that within the mean-field theory the sharpness of the peak is the total 3D susceptibility is entirely controlled by the rapid variation with T of $\chi_{2D}(\sim\xi_{2D}^2/\kappa_B T$ at low temperatures), the staggered susceptibility of the CuO_2 planes. The variation of χ_{2D} thus depends on the rapid or slow variation of ξ_{2D} with T. The broadened peak observed in those measurements was accordingly attributed to the rapid reduction of the correlation length ξ_{2D}.[14] The sharp peak for the doped sample displayed in the Fig. 1 suggests that the effect of the peak broadening is not intrinsic and validity of this view point is thus in question.

In Fig. 2 the magnetization M as a function of the magnetic field H parallel to the c axis was measured for the same Zn-doped sample at temperatures below and near the Néel temperature $T_N\approx200$ K. For $T<T_N$, a sharp metamagnetic transition with $H_c\approx4$ and 5 T is seen at $T=120$ and 160 K, respectively, whereas a nearly straight line at $T=195$ K, as expected, is found. The behavior seen here is obviously similar to that found in the parent compound $La_2CuO_{4+\delta}$ reported earlier except for $H_c(T)$ is corresponding to lower temperatures, suggesting little impact of Zn doping on the metamagnetism. This metamagnetic response can be well described by a Dzyaloshinskii–Moriya (DM) antisymmetric term.[17] This term is allowed by certain broken crystal symmetries due to the slight rotation of the CuO_6 octahedra around the Cu sites, and can produce a canting of the spins away from the plane of staggered magnetization, thus a ferromagnetic moment pointing in the direction perpendicular to planes appear. For $T<T_N$ and $H<H_c$ the canting alternates its direction between planes. At $H=H_c$, the canting in all planes abruptly aligns with the finite external field which is the cause of the jump in Fig. 2. In earlier reported data,[12,14] the magnetization was largely broadened and less well defined due to, at least, partially unoriented polycrystalline samples.

It becomes apparent that Zn doping has much weaker effect on both the depression of the Néel temperature and metamagnetic behavior than Sr doping, which introduces mobile holes. Our data on Sr-doped single crystals of $La_2CuO_{4+\delta}$ (not shown) confirms that roughly 2% Sr doping drives T_N to zero, which is in agreement with results already published. It has been thought that this difference is primarily a consequence of the different locations of the two types of vacancies. Zn doping, as stated above, removes the spin on the Cu site, thus reducing ξ_{2D}, but, even for x as high as 0.07, does not suppress T_N as dramatically as some other dopants. It resembles the situation of magnetic dilution. In contrast, Sr doping introduces the excess hole which resides on the oxygen site. The mobile hole couples with neighboring Cu spins effectively removing these spins from the system or frustrates the local AF order. It has been found that the hole introduced by Sr is only weakly localized before the insulator-metal transition ($x\sim0.05$),[9] whereas the Zn nonmagnetic site is completely localized. Thus the finite mobility of the hole associated with Sr effectively or globally suppresses magnetic ordering, whereas the Zn doping inhibits magnetic ordering only by locally diluting the spin lattice.

Figure 3 shows the temperature dependence of the relative dielectric constant in the c axis, K_c, of $La_2CuO_{4+\delta}$ for three measurement frequencies. Note that values ~1500 at room temperature are obtained, again showing the large elec-

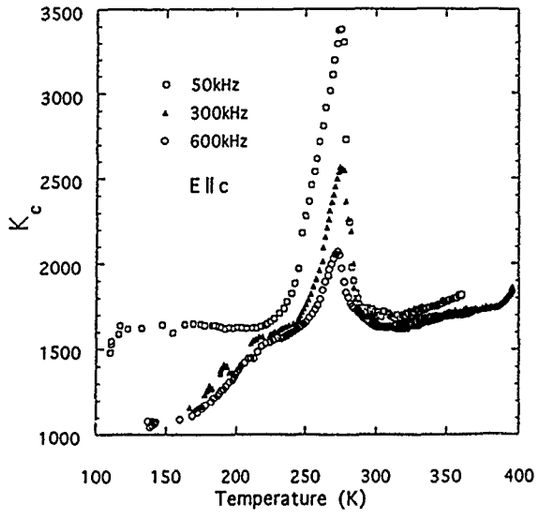

FIG. 3. Dielectric constant in the c-axis direction, K_c vs temperature for $x=0$ at three measurement frequencies.

tric polarizability of the insulating parent oxide phase. One notable difference for La_2CuO_4 compared to $YBa_2Cu_3O_{7-\delta}$ and $PrBa_2Cu_3O_{7-\delta}$, however, is the substantially smaller frequency dependence of the former's high dielectric constant in the vicinity of 300 K.

The major feature of the dielectric response is the large enhancement in K_c occurring near 270 K, Néel temperature T_N. We thus infer that the transition state for magnetic ordering is accompanied by a large additional electrical polarizability. No evidence of a shift in the temperature of the peak in K_c (i.e., thermal activation) with frequency can be discerned.

Shown in Fig. 4 is the relative dielectric constant K_c of $La_2Cu_{1-x}Zn_xO_{4+\delta}$ ($x\approx0.07$) as a function of temperature for the six measurement frequencies. The values $K_c\sim5000$ obtained in the temperature range $190\leqslant T\leqslant250$ K is larger than those (~1500) at room temperature for the parent compound. Additionally, unlike La_2CuO_4, the peak of the enhancement becomes not only largely broadened but also strongly frequency dependent in the temperature range $160\leqslant T\leqslant300$ K. The behavior found here may suggest the possible thermal activation in the system which is not evident in the parent compound. However, there is a striking common feature of the dielectric response for both undoped and doped samples, i.e., the large enhancement in K_c tends to occur near the Néel temperature T_N. Yet, the peak of the enhancement for the doped sample is frequency dependent, but the peak appears to occur around $T=200$ K, where the Néel temperature T_N is as the static limit is approached. Indeed, this point becomes more perceived in inset of Fig. 4, a plot of peak temperature, T_{peak}, as a function of frequency, where extrapolation to 0 Hz gives $T_{peak}=200$ K.

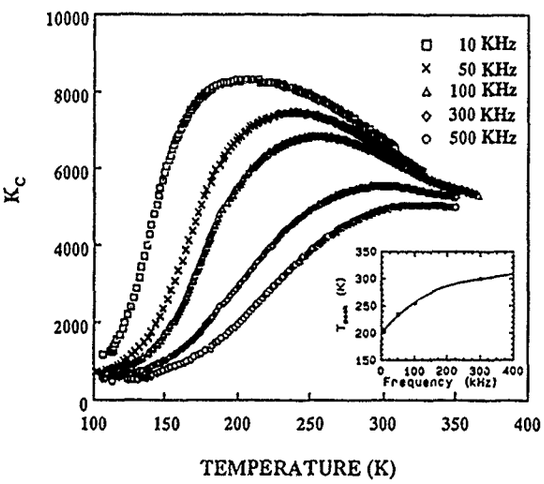

FIG. 4. Dielectric constant in the c-axis direction, K_c vs temperature for $x\approx0.07$ at five measurement frequencies. Inset: the peak temperature T_{peak} vs frequency for $x\approx0.07$.

The unusual phenomena we have observed in this study seem to imply a correlation between the antiferromagnetic ordering and the electrical polarizability in the oxides. However, no quantitative model for the strong microscopic magnetoelectric coupling indicated by these data have been published. Structural instability models of (anti)ferroelectricity driven by O atom displacements or rotations would lead to behavior similar to that observed. Although (anti)ferroelectric antiferromagnets are known to exist, the authors are unaware of a case of simultaneous polarization and magnetic ordering.

Neutron diffraction techniques have been used to investigate the magnetic ordering of the Tb ions in polycrystalline $Pb_2Sr_2TbCu_3O_8$. Significant magnetic correlations are found to develop below ~10 K, and these correlations are two dimensional in nature, representative of the strongly anisotropic magnetic interactions in these layered materials. The correlation length increases with decreasing temperature, and long-range order is observed to develop at $T_N \approx 5.5$ K. However, the sawtooth Bragg profile for the scattering demonstrates that the long-range order is two dimensional, rather than three dimensional, with a spin configuration where nearest-neighbor spins are antiparallel. The scattering profile can be explained quantitatively by assuming long-range order within the *ab* plane, with no significant correlations along the *c* axis to the lowest temperatures measured (1.36 K). Our results suggest that the system is well described by a two-dimensional Ising model. The only other (pure) system where a crossover to three-dimensional behavior is *not* observed is $DyBa_2Cu_4O_8$.

One of the most remarkable properties of the Cu and $\mathcal{RE}$ ($\mathcal{RE}$=rare-earth elements) magnetism of the high T_c oxides is that they are two dimensional (2D) in nature. The 2D behavior of the Cu magnetism originates from the strong Cu-O bonding within the layers, which yields highly anisotropic exchange interactions between the Cu ions. On the other hand, the $\mathcal{RE}$ atoms form an orthorhombic sublattice where the nearest-neighbor distance along the *c* axis is much greater than that within the *ab* plane, which again leads to highly anisotropic magnetic interactions between the $\mathcal{RE}$ ions and generates the 2D magnetism. Such 2D behavior of the $\mathcal{RE}$ ions has been observed in the $\mathcal{RE}Ba_2Cu_3O_7$[1,2] ($\mathcal{RE}$1237), $\mathcal{RE}Ba_2Cu_4O_8$[3] ($\mathcal{RE}$1248), and $\mathcal{RE}_2Ba_4Cu_7O_{15}$[4] ($\mathcal{RE}$4715) systems. Among them, a rod of scattering characteristic of 2D behavior has been observed[2] in single crystals of Er1237 and Dy1237, and their order parameters are found to obey the Onsager[5] solution for the $S=\frac{1}{2}$, 2D Ising antiferromagnet. Moreover, for the Dy ions in the Dy1248 a geometric cancellation of the already weak interactions occurs along the *c* axis, which renders the system two-dimensionally ordered even at temperatures well below the Néel temperature.[3]

In this article we report another system which exhibits 2D magnetic order, as observed by neutron diffraction experiments. In this material we observe significant 2D magnetic correlations of the Tb spins in the $Pb_2Sr_2TbCu_3O_8$ (Tb22138) compound below $T \sim 10$ K. Long-range order is observed to develop at $T_N \approx 5.5$ K, but even at $T = 1.36$ K the magnetic correlations are still mainly two dimensional, with nearest-neighbor spins within the *ab* plane being aligned antiparallel.

The $\mathcal{RE}$22138 systems are even more anisotropic in their physical properties than those of the $\mathcal{RE}$1237 system,[6,7] as there are more intervening layers of atoms stacked along the *c* axis. The rare-earth atoms in the $\mathcal{RE}$22138 system form an orthorhombic unit cell where the distance between the nearest neighbors along the *c* axis is more than four times that in the *ab* plane. It is clear that the crystallographic anisotropy naturally leads to highly anisotropic magnetic interactions. The rare-earth unit cell is related to the nuclear unit cell of the compound by rotation of the *a* and *b* axes of the nuclear unit cell by ~45° and reducing their lengths by $\sqrt{2}$. We employ the notation of (abc) and $(a'b'c')$ to represent the axes of the nuclear and rare-earth unit cells, respectively. We note that by using this system of notation, the *ab* plane and $a'b'$ plane are essentially the same planes.

Powder samples of $Pb_2Sr_2TbCu_3O_8$ were prepared by the standard solid-state reaction techniques, and the details of the sample preparation technique can be found elsewhere.[8] Both x-ray and neutron diffraction were used to characterize the sample. The x-ray diffraction pattern is well described by the orthorhombic Y22138 structure,[6] which is only slightly deviated from tetragonal symmetry, with room-temperature lattice parameters $a = 5.452(7)$ Å, $b = 5.459(9)$ Å, and $c = 15.66(2)$ Å for the chemical unit cell of the compound. The nearest-neighbor distances of the Tb ions are, therefore, $a' \approx b' = 3.856$ Å within the $a'b'$ plane and $c' = 15.66$ Å along the c' axis, respectively.

Neutron diffraction measurements were performed at the Research Reactor at the U.S. National Institute of Standards and Technology. The data were collected using the BT-9 triple-axis spectrometer which was operated in double-axis mode. A pyrolytic graphite PG(002) crystal was used as the monochromator to extract neutrons of energy 14.8 meV ($\lambda = 2.351$ Å). A PG filter was also placed after the monochromator position to suppress higher-order wavelength contaminations. The angular collimations used were 40′ before the monochromator, and 48′-48′ before and after the sample, respectively. The sample was mounted in a cylindrical aluminum can filled with helium exchange gas to facilitate thermal conduction at low temperatures. A pumped ^{4}He cryostat was used to cool the sample, and the lowest temperature

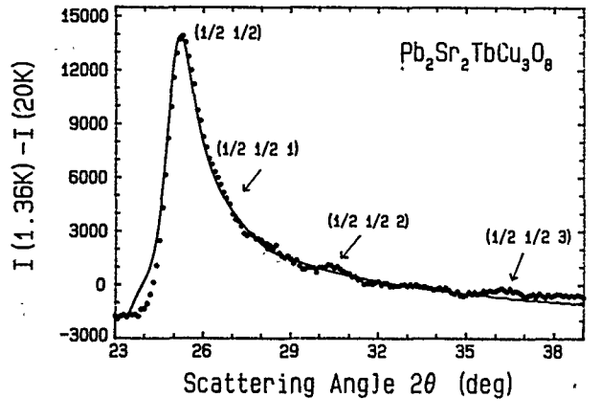

FIG. 1. Magnetic intensities observed in $Pb_2Sr_2TbCu_3O_8$ at $T=1.36$ K, which is well below the ordering temperature. The pronounced asymmetry of the observed peak is a classic profile of the two-dimensionally ordered system. The magnetic peaks may be indexed as the $(\frac{1}{2}\frac{1}{2})$ rod of scattering based on the Tb unit cell. Small 3D-like Bragg peaks, with positions that may be indexed as the $\{\frac{1}{2}\frac{1}{2}1\}$, $\{\frac{1}{2}\frac{1}{2}2\}$, and $\{\frac{1}{2}\frac{1}{2}3\}$ reflections, are also revealed. The solid line is a fit to the 2D theoretical profile.

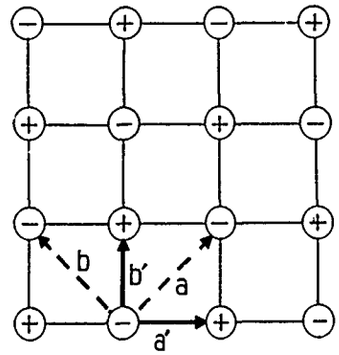

FIG. 2. The 2D spin configurations of the Tb ions within the $a'b'$ plane. The nearest-neighbor spins are aligned antiparallel, and the plus and minus signs then represent spins that are in opposite directions. a' and b' indicate the axes of the Tb unit cell, and a and b indicate the axes of the nuclear unit cell of the compound.

obtained was 1.36 K. For each temperature change, sufficient time was given to allow the sample to reach thermal equilibrium.

Three powder diffraction sets of data were collected over the range of scattering angles from $2\theta=5°$ to 65°: One at a temperature well below, one just above, and the other well above the Néel temperature. The subtraction technique[9] was used to isolate the magnetic signal from the nuclear one, where the diffraction pattern taken at a temperature well above the ordering temperature was subtracted from the one taken at low temperature.

The magnetic diffraction pattern obtained at $T=1.36$ K is shown in Fig. 1, where the diffraction pattern taken at $T=20$ K serves as the nonmagnetic "background" has been subtracted from the data. The sawtooth Bragg profile of the observed peak is a classic profile of a two-dimensionally ordered system.[3,10] The scattering pattern is dominated by a single 2D-like peak, even though we were well below the Néel temperature ($T_N\approx5.5$ K, see below). The solid curve in the figure is a least-squares fit to the theoretical 2D scattering profile convoluted with the Gaussian instrumental resolution function, assuming long-range order within the $a'b'$ plane and no correlations along the c'-axis direction. Based on the Tb unit cell, the observed asymmetrical peak corresponds to the $(\frac{1}{2}\frac{1}{2})$ rod of scattering. This is the same type of scattering that has been observed[3] in Dy1248. The magnetic correlations along the c'-axis direction are much weaker than those within the $a'b'$ plane. However, the observed intensities shown in Fig. 1 also suggest some 3D ordering character, where small 3D peaks at $2\theta=26.23°$, 30.09°, and 36.23°, which would correspond to the $\{\frac{1}{2}\frac{1}{2}1\}$, $\{\frac{1}{2}\frac{1}{2}2\}$, and $\{\frac{1}{2}\frac{1}{2}3\}$ Bragg reflections, respectively, are evident. This may indicate that a small fraction of the samples is ordered three dimensionally at low temperatures.

The presence of the $(\frac{1}{2}\frac{1}{2})$ rod of scattering demonstrates that the 2D magnetic unit cell of the Tb ions is doubled in size compared to the nuclear one along both the a' and b' axes. The nearest-neighbor spins of the Tb ions are therefore aligned antiparallel. The 2D spin configuration for the Tb moments in the $a'b'$ plane is shown in Fig. 2, where the a and b axes of the nuclear unit cell of the compound are also indicated. In addition, the weak $(\frac{1}{2}\frac{1}{2}l)$ type of reflections, with l=integer, revealed in Fig. 1 indicate that the Tb spins have the tendency to align parallel along the c' axis. These data suggest that 3D order may set in at lower temperatures. Further work at lower temperatures is planned to clarify this point.

The low-temperature ordered moment was obtained by comparing the magnetic to nuclear intensities. For the case of 2D magnetic ordering, we need to integrate the magnetic scattering over the angular range corresponding to the first Brillouin zone. Comparing the magnetic intensity with the {001} nuclear intensity establishes that the saturated moment for each Tb ion is $\langle\mu_Z\rangle=7.43\pm0.02\ \mu_B$, assuming the spin direction is along the c'-axis direction. This choice of the c'-axis direction is consistent with the moment direction usually found in these materials.

The temperature dependence of the intensity at the 2D $(\frac{1}{2}\frac{1}{2})$ peak position is shown in Fig. 3. The magnetic Bragg intensity is proportional to the square of the ordered moment, which is the order parameter of the phase transition. Assuming that the magnetic peak profile remains the same for the temperature range studied, a measurement of the temperature dependence of the peak intensity then measures the square of the order parameter. The sharp drop in intensity shown in Fig. 3 is typical for a 2D magnetic phase transition, while the rounding in the vicinity of the ordering temperature is typical for the (critical) scattering observed in a powder. The Néel temperature is estimated to be $T_N\approx5.5$ K.

Above the ordering temperature magnetic scattering was also observed, and the shape of this scattering also demonstrates the 2D magnetic character of the system. Figure 4 shows the $(\frac{1}{2}\frac{1}{2})$ rod of scattering observed at $T=6$ K, which is just above the ordering temperature. The intensity on the lower angle side of the peak does not show as sharp an increase because of the finite correlation range above the ordering temperature. The solid curve is a fit to the theoreti-

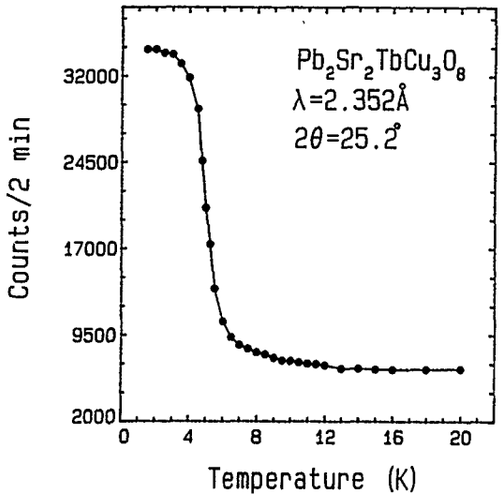

FIG. 3. Temperature dependence of the $(\frac{1}{2}\frac{1}{2})$ peak intensity, showing the variation of the square of the staggered magnetization with temperature. The sharp drop in intensity is typical for a 2D order parameter. The ordering temperature is determined to be $T_N \approx 5.5$ K. The solid curve is a guide to the eye only.

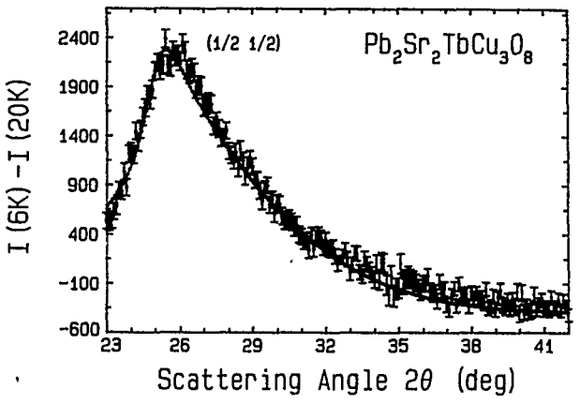

FIG. 4. The $(\frac{1}{2}\frac{1}{2})$ rod of scattering observed at $T=6$ K, which is just above the ordering temperature. The observation of this scattering directly demonstrates the 2D energetics of the system. The solid line is a fit to the 2D theoretical profile with a correlation length of $\xi=550$ Å within the $a'b'$ plane and no correlations along the c'-axis direction.

cal 2D profile, assuming a finite correlation length within the $a'b'$ plane and no correlations along the c'-axis direction. The 2D Bragg rod gives an excellent fit to the observed data. We, hence, conclude that there are strong magnetic correlations within the $a'b'$ plane while those along the c'-axis direction are weak, and the fundamental energetics is 2D in nature. The intrinsic linewidth of this peak is related to the inverse 2D correlation length, and the correlation length that we obtained from the fit at $T=6$ K is $\xi=550$ Å. Further work is in progress on the temperature dependence of the 2D magnetic correlation length in this system.

The intermetallic compound Mn_3Sn has the hexagonal DO_{19} crystal structure with six Mn and two Sn atoms per unit cell. The triangular antiferromagnetic order that develops below T_N=420 K becomes modulated below 270 K in what is generally described as a helical modulation. However, magnetic excitation spectra show the presence of an energy gap of about 4 meV for both the triangular and the modulated phases, and this can occur for a helical modulation only if the period is commensurate with the lattice. This prompted us to re-examine the structure of the modulated phase by neutron diffraction. We find two distinct moment modulations, both propagating along the c axis and both of which are commensurate below 120 K with periods of $11c_0$ and $14c_0$. Above 120 K, both modulation wave vectors increase with temperature and become incommensurate. The satellite reflections exhibit quite different intensities and temperature dependencies, and this suggests coexistent modulated phases. For the predominant $11c_0$ (22 layer) phase, we observe a third harmonic with about 20% of the amplitude of the first harmonic and with no fifth harmonic to 1% in amplitude. This shows that the modulation in Mn_3Sn is definitely not that of a uniform helix. The observed intensity distributions are compared with configurational models in which multilayer blocks of the triangular order align along the easy sixfold axes in the basal plane and rotate by 60° per block in proceeding along the c axis.

E. Gratz
Institut für Experimentalphysik, TU Wien, A-1040 Wien, Austria

RCu_2 compounds (R=rare earth) with orthorhombic crystal structures exhibit a rich variety of magnetic structures at low temperatures, originating from a subtle interplay between RKKY-type exchange and crystal field anisotropy. Though most of the magnetic properties of $NdCu_2$ are well understood,[1] there are controversial proposals for the magnetic phases, as deduced from different experiments.[1,2] Therefore we have investigated the magnetic structure of $NdCu_2$ by neutron diffraction as a function of temperature between 1.4 and 8 K in the zero external field. The diffraction patterns of a powdered sample were obtained on the multidetector DN5 at the SILOE reactor of CEN-G. Only two different magnetic phases were observed, in agreement with Ref. 1. For temperatures between 5.2 K and T_N=6.5 K, the magnetic structure can be described by a sinusoidal oscillating component along b with wave vector τ_2=(0.62, 0.042, 0). Accordingly, the structure is incommensurate with the lattice. Below 4.0 K the structure remains an oscillating component along b. However, the wave vector becomes commensurate with the lattice and is given by τ_1=(0.60, 0, 0). Additionally, a progressive squaring up from the appearance of the third harmonic 3τ in the range from 4.0 K down to 1.4 K is observed. At 1.4 K the amplitudes of the fundamental and the third harmonic are $2.4\mu_B$ and $0.9\mu_B$, respectively. Around 4.4 K, the spectra seem to be determined by a superposition of the high- and low-temperature phases. The low-temperature structure of $NdCu_2$ is comparable with that for $TmCu_2$, observed earlier in Ref. 3. Though in that work a different interpretation was chosen, the wave vector of the fundamental oscillation can be described by (0.625, 0, 0), while the amplitudes for the fundamental and third harmonic are given by $8.0\mu_B$ and $2.6\mu_B$, respectively.

Easy-axis transition in $SmMn_2Ge_2$ (abstract)

R. B. van Dover, E. M. Gyorgy, R. J. Cava, J. E. Krajewski, W. F. Peck, Jr., and R. J. Felder
AT&T Bell Labs, Murray Hill, New Jersey 07974

$SmMn_2Ge_2$ is a layered ferromagnet with unusual magnetic and electrical properties. In some regards it is a natural analog to artifically layered thin film materials, and its study can provide valuable insights. $SmMn_2Ge_2$ is ferromagnetic from 0 to 90 K, with easy axes parallel to the (110) directions (FM1 state). Between 90 and 150 K it is antiferromagnetic, and from 150 K to T_c (340 K) it is again ferromagnetic, with an easy axis parallel to the (001) direction (FM2 state). We have used a continuous recording torque magnetometer to monitor the energy surface of $SmMn_2Ge_2$ as a function of temperature. We have found that the moments are parallel to (110) in the AFM state, and that the anisotropy constant varies continuously, i.e., that $K \rightarrow 0$ at the easy-axis transition, which is found to be at essentially the same temperature as the zero-field AFM/FM2 transition. The FM1/AFM and AFM/FM2 transition temperatures can be varied over a wide range by substitution on the various sites. Substitution of Y or Gd on the Sm site increases $T_{AFM/FM2}$ strongly, and is found to increase the temperature of the easy axis transition, but not by precisely the same factor. Substitution of a small amount of Cr on the Mn site decreases $T_{AFM/FM2}$ but appears to have no effect on the easy-axis transition. M-H curves and M-T curves taken in a vibrating sample magnetometer and in a SQUID magnetometer provide corroborating evidence for these conclusions.

Neutron diffraction study of the magnetic ordering of $BaCuO_{2+x}$ (abstract)

Neutron diffraction experiments have been performed in order to study the magnetic ordering of $BaCuO_{2+x}$. In these measurements unpolarized neutrons and polarized neutrons with full polarization analysis have been utilized. From these measurements it has been determined that $BaCuO_{2+x}$ orders antiferromagnetically below $T_N = 15.0 \pm 0.5$ K with a magnetic propagating vector $\kappa = [1\ 1\ 1]$. This structure is commonly referred to as a $[\pi\pi\pi]$ or a G structure. The Cu atoms in the Cu_6 ring clusters, located at the $(\frac{1}{4}, \frac{1}{4}, \frac{1}{4})$ positions, order ferromagnetically within these clusters while the clusters themselves order antiferromagnetically. The ordered magnetic moment of each of these Cu atoms is $0.89 \pm 0.05\ \mu_B$ at $T = 4.2$ K. No evidence of long-range magnetic ordering of the Cu atoms in the Cu_{18} clusters, located at the (0, 0, 0) and $(\frac{1}{2}, \frac{1}{2}, \frac{1}{2})$ positions, was found down to a temperature $T = 2.5$ K. The work at Oak Ridge National Laboratory (ORNL) was sponsored by the Division of Materials Sciences, U.S. Department of Energy (DOE). ORNL is managed for the U.S. DOE by Martin Marietta Energy Systems, Inc., under Contract No. DE-AC05-84OR21400. Ames Laboratory is operated for the U.S. DOE under Contract No. W-7405-Eng-82. The work at Ames was supported by the Director for Energy Research, Office of Basic Energy Sciences.

Magnetic properties of metallic Co- and Fe-based granular alloys

Gang Xiao and Jian-Qing Wang
Department of Physics, Brown University, Providence, Rhode Island 02912

We have studied the magnetic properties of Co-Ag and Fe-Ag granular alloys made using vapor-quenching techniques and thermal annealing. Magnetic coercivity (H_c) and remanence can be controlled over a large range by varying annealing temperature and particle volume fraction. A large H_c on the order of 2 kG has been obtained in the Co-Ag system. We have investigated magnetic anisotropy, the effect of particle size, and coalescence in these nanostructured materials.

Magnetic granular solids have received considerable attention in the past few years.[1–10] In these composite materials, ultrafine magnetic particles of a few nanometers in size are embedded in a metallic or insulating matrix by certain synthesis processes. Because of their microstructure and the tunability in materials and geometrical parameters, these materials possess different and sometimes enhanced properties when compared with their bulk counterparts. In particular, a giant magnetic coercivity (H_c) has been achieved in Fe-SiO_2 granular films,[1] with H_c enhanced by as much as three orders of magnitude over the bulk value. The large H_c and magnetization of the material make it suitable for application in magnetic recording. It has also been discovered that metallic granular alloys, such as Co-Cu, Co-Ag, and Fe-Ag, exhibit giant magnetoresistance effects (GMR),[6–10] with a magnitude rivaling the best multilayers with GMR. These developments in granular solids call for more systematic studies of their magnetic properties. The understanding of the novel GMR effect also requires the exploration of the underlying magnetic state which strongly correlates with the behavior of GMR. In this work, we present a study on two transition metal granular solids, Co-Ag and Fe-Ag, both of which have been shown to have GMR effect.[8–10] The main focus here is how the thermal treatment and volume fraction of the magnetic particles affect the magnetic properties.

We have fabricated Co-Ag and Fe-Ag granular films by taking advantage of the immiscibility between Co (or Fe) and Ag in alloy formation. High vacuum sputtering from a cold-pressed composite target yields a phase-separated film with magnetic particles precipitating from the Ag matrix. The particle size of an as-sputtered sample is very small, on the order of 1–2 nm. We have also fabricated samples using codeposition technique and obtained similar physical properties. Thermal annealing is an effective means to enlarge the particle size. We have prepared a series of samples with different thermal annealing as well as varying volume fraction. Phase separation has been confirmed by using a combination of analysis, i.e., transmission electron microscopy (TEM), x-ray diffraction, and magnetic susceptibility measurement. Detailed results will be presented elsewhere.[11] Analysis of phase separation for the Co-Ag system can also be found in Ref. 12.

We used a superconducting quantum interference device (SQUID) magnetometer to measure the magnetic hysteresis curve of our samples. Since we are interested in the ground state properties, most of our measurements were carried out at low temperatures. The saturated magnetization of the magnetic component (Fe or Co) is approximately equal to that of the bulk. In addition to magnetic measurements, we have also performed magnetoresistance and Hall effect measurements. Both Fe-Ag and Co-Ag show GMR effect and extraordinary Hall effect.[8–10] The Hall resistivity can be described by $\rho_{xy}=\rho^0_{xy}+R_sM$. In this relation, ρ^0_{xy} is due to the ordinary Hall effect and is linear in magnetic field. The second term, due to the extraordinary Hall effect,[13] results from the left–right asymmetry in electron scattering in magnetic systems. Because of its linear relationship with M, the field dependence of ρ_{xy} after removing ρ^0_{xy} shows a one-to-one correspondence with the magnetic hysteresis curve. Therefore, when the sample plane is perpendicular to the external magnetic field, we can consistently obtain remanent magnetization and coercivity from either Hall effect or magnetization measurements. It is noted that it is more efficient and economical to measure the Hall effect than the magnetization using a SQUID magnetometer.

Figure 1 shows the magnetization curves at $T=5$ K for two representative as-prepared samples, $Co_{20}Ag_{80}$ and $Fe_{20}Ag_{80}$, with H perpendicular and parallel to the sample plane (both samples are specified by volume fractions of their components). The initial susceptibility measurement indicates that the superparamagnetic transition temperature is about 20–30 K. Therefore, at 5 K, the magnetic moment vectors of the particles are fixed in random directions. As shown in Fig. 1, the $Co_{20}Ag_{80}$ sample has a much larger H_c than the $Fe_{20}Ag_{80}$ sample. Most interestingly, the easy axis tends to be out of plane for Co-Ag, whereas it is in plane for Fe-Ag.

The anisotropy in Co-Ag is most likely caused by the crystalline and shape anisotropies of the Co particles. The maximum H_c which could result from crystalline or strain anisotropy is about 2900 (fcc) or 600 G respectively.[14] The large perpendicular H_c value of about 2 kG seen in Fig. 1 can be accounted for by magnetocrystalline anisotropy. The perpendicular H_c in Co-Ag is larger than the parallel H_c. To account for the observed perpendicular H_c in Co-Ag, it is reasonable to conjecture that the Co particles are slightly enlongated along the growth direction. Another possible source of anisotropy is from the interface between the magnetic particles and the surrounding Ag matrix. Because of the

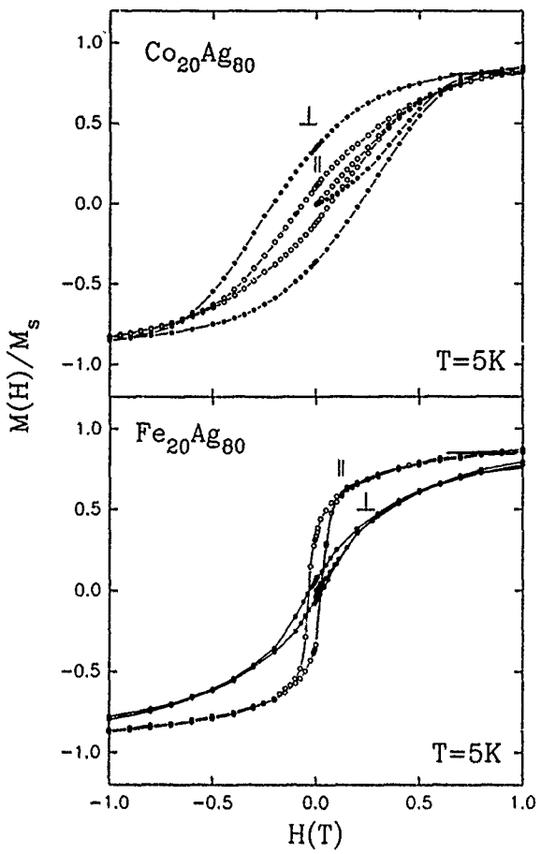

FIG. 1. Magnetic hysteresis curves in perpendicular and parallel field configurations for $Co_{20}Ag_{80}$ (upper panel) and $Fe_{20}Ag_{80}$ (lower panel) at $T=5$ K.

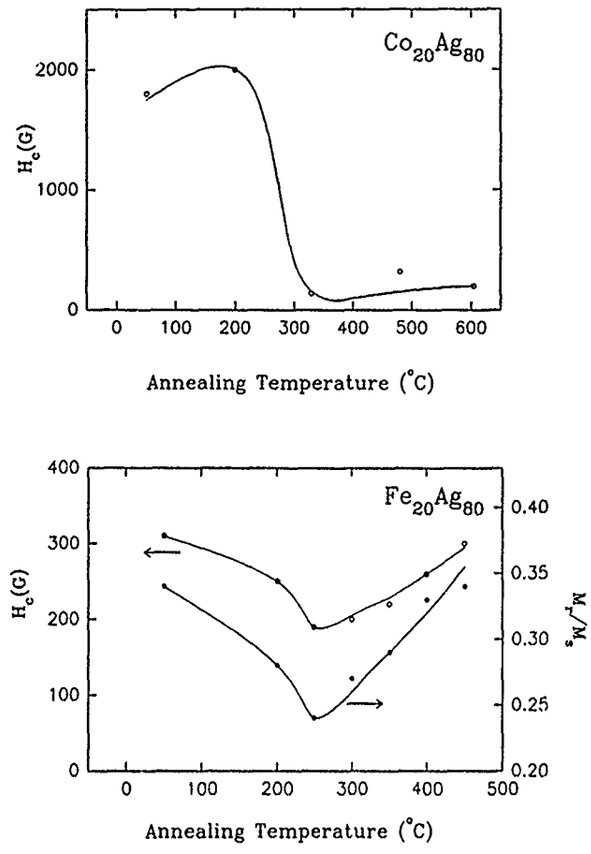

FIG. 2. Coercivity H_c vs annealing temperature T_A for $Co_{20}Ag_{80}$ (upper panel) and $Fe_{20}Ag_{80}$ (lower panel). Also shown in the lower panel is the remanence M_r/M_s for $Fe_{20}Ag_{80}$. $T=5$ K.

small size of the particles, interfacial effect could play an important role. Nevertheless, without the proposed growth texture, it is difficult to imagine how the interface anisotropy could cause the observed perpendicular anisotropy under the influence of the large demagnetization field of the thin film.

The H_c for the Fe-Ag system is of the magnitude of 300 G. While it is considerably larger than that of a polycrystalline Fe film (a few tens of G), it is much below the limit of crystalline (540 G) and strain (600 G) anisotropy for single-domain particles.[14] The shape anisotropy in Fe can provide a maximum H_c of 10.7 kG,[14] although experimentally such a large H_c in single-domain Fe particles has never been discovered. In Fe-SiO_2 granular films, a maximum H_c value of about 3 kG has been observed,[1] where the Fe particle size is about 50 Å. We have obtained the particle sizes in our $Fe_{20}Ag_{80}$ samples using both TEM and analysis of superparamagnetic behavior.[11] The $Fe_{20}Ag_{80}$ sample used for Fig. 1 has an average particle size of 29 Å. Thermal annealing at 300 °C enlarges the particle size to 51 Å, but the H_c was found to decrease to about 200 G. The comparison between Fe-Ag and Fe-SiO_2 granular systems shows convincingly that particle-matrix interface could be one of the important factors in the magnetic anisotropy of Fe-based systems.

Among the magnetic parameters of a ferromagnetic solid, the ground state magnetization is basically an intrinsic parameter, whereas H_c and remanence M_r/M_s are primarily extrinsic parameters. They are sensitive to disorder, stress, and particle morphology. Thermal treatment is an effective means to induce phase separation, to enlarge particle size, and to reduce crystalline disorder and stress in granular materials. In Fig. 2, we present the results of annealing on H_c for $Co_{20}Ag_{80}$ and $Fe_{20}Ag_{80}$. Also included in Fig. 2 is an annealing temperature (T_A) dependence of M_r/M_s for $Fe_{20}Ag_{80}$. Thermal annealing was done in high vacuum (1×10^{-7} Torr) at a chosen T_A for 15 min, followed by natural cooling. From the TEM micrograph, it was found that the Co particle size increases from about 20 to 130 Å as T_A reaches 605 °C. X-ray diffraction revealed that the Co particles have fcc structure and are [111] textured.[8]

As shown in Fig. 2, H_c for $Co_{20}Ag_{80}$ drops by a large amount once T_A exceeds 250 °C. This variation of H_c has been verified more than once. Such a drop in H_c is desirable because it tends to reduce the saturation field and hysteresis in GMR effect, which was indeed observed.[8] There are a few possible causes for this drop. First of all, it is not due to the enlarged particle size which may induce multidomain formation and reduce H_c. Within our T_A range, the Co particle size is always below the critical single-domain particle size.[14] Most likely, as the particle size grows, the original growth texture diminishes, which reduces the particle shape anisotropy. Another possible cause is that annealing makes phase separation more complete and tends to reduce crystalline disorder and stress. Both effects will reduce pinning force for magnetization, and, therefore, lower H_c.

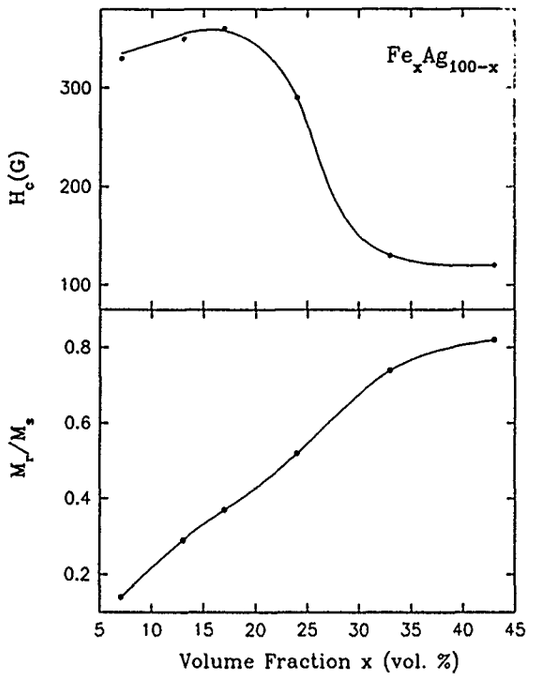

FIG. 3. Coercivity H_c (upper panel) and remanence M_r/M_s (lower panel) for Fe_xAg_{100-x} alloys as functions of volume fraction x. $T=5$ K.

The variation of H_c with T_A for $Fe_{20}Ag_{80}$ resembles the behavior in $Co_{20}Ag_{80}$, in that we see a similar drop in H_c near 250 °C. However, beyond 250 °C, H_c increases as Fe particles become larger. The remanence has a similar dip near 250 °C. Particle size analysis shows that the Fe particle size steadily increases from 21 Å in the as-sputtered sample to 71 Å at the maximum T_A of 400 °C. All are considered as single-domain particles.[14]

The above results reveal that thermal annealing has the universal effect of increasing particle size, however, its role on H_c is not straightforward, but is material dependent in metallic granular solids. At present, the cause for these diverse observations is not clear. However, it is important to remember that there are many sources at play for H_c, almost all are affected to varying degrees by thermal annealing.

Earlier studies have shown that thermal annealing substantially *enhances* H_c of various Fe-[2,4] and Co-based[3,4] granular solids. This is in sharp contrast with the behaviors of our Fe-Ag and Co-Ag systems, where moderate annealing depresses H_c. The difference is due to the fact that the earlier studies were performed at room temperature, whereas ours are at low temperature. At $T=300$ K, thermal relaxation reduces H_c severely for moderately annealed samples where the magnetic particles are small in size. In fact, any superparamagnetic sample has zero hysteresis. For samples annealed at high temperatures, and therefore, having large particle size, thermal agitation is less important, and H_c appears higher. In order to eliminate the effect of thermal relaxation, measurements need to be done at low temperatures.

Next we turn our attention to the effect of particle volume fraction (x) on magnetic properties. Here, x was determined from the composition and the bulk density of each component. Figure 3 shows H_c and M_r/M_s as functions of x for the Fe_xAg_{100-x} as-sputtered system. In the low x region ($x<0.2$), H_c remains relatively constant. Starting at $x\sim0.2$, H_c gradually decreases, approaching the bulk value of polycrystalline Fe. M_r/M_s, on the other hand, increases smoothly with x in the whole x range studied. The evolution of H_c and M_r/M_s with x is the result of the transition from an assembly of almost independent particles to a network of connected particles. As x increases, there is an increasing coalescence of magnetic particles. In fact, above the percolation threshold x_c, cluster network of infinite extension is formed. Beyond this limit, the granular solid becomes increasingly bulk-like, and bulk polycrystalline Fe film is characterized by low H_c and large remanence.

For a random three-dimensional system, the percolation threshold x_c is near 0.2. In our granular material, H_c starts to decrease at almost the same x. We have also measured the GMR effect ($\Delta\rho/\rho$) as a function x.[10] $\Delta\rho/\rho$ exhibits a peak at $x=0.2$, coinciding with the peak of H_c. This is because both GMR and H_c are sensitive to multidomain or cluster formation in a granular solid.

In summary, ground state magnetic properties have been measured for Co-Ag and Fe-Ag granular alloys which exhibit GMR. The Co-Ag films have a perpendicular magnetic anisotropy, whereas the easy axis of the magnetization of the Fe-Ag films is in-plane. The large H_c and perpendicular anisotropy in Co-Ag are attributed to the crystalline anisotropy and the enlongation of Co particles in the growth direction. Thermal annealing affects H_c profoundly in both systems. This cannot be explained by the monotonical increase of magnetic particle size. Other mechanisms such as phase separation, effect of disorder, and evolution of particle shape need to be considered. It is also found that coalescence of particles reduces H_c.

We are grateful to Dr. C. L. Chien for providing some Co-Ag samples. We also thank Dr. P. Xiong for helpful discussion and technical assistance. This work was supported by National Science Foundation Grant No. DMR-9258306. G. X. wishes to thank the A. P. Sloan Foundation for a fellowship.

Magnetic and ferromagnetic resonance studies in Co-Cu composite films

R. Krishnan, H. Lassri, M. Seddat, and M. Tessier
Laboratoire de Magnétisme et Matériaux Magnétiques, C.N.R.S. 92195 Meudon, France

Sivaraman Guruswamy and Satyam Sahay
Department of Metallurgical Engineering, University of Utah, Salt Lake City, Utah 84112

$Co_{1-x}Cu_x$ composite films with $0 \leqslant x \leqslant 83$ have been sputter deposited on to water-cooled glass substrates. Transmission electron microscopy and scanning tunneling microscopy studies reveal clusters whose average size is 250 Å. Magnetization when corrected to the Co volume is independent of Cu concentration and is equal to that of bulk Co. The in-plane saturation field is about 200 Oe at $x=0$, starts increasing for $x=40$, and shows a peak value of 1.2 kOe for $x=60$. Coercivity shows a similar behavior. Out-of-plane perpendicular anisotropy develops with the increase in Cu concentration. The ferromagnetic resonance studies show that (i) the linewidth increases for $x>75$ and (ii) perpendicular anisotropy, probably induced by stress, also increases with x. Annealing up to 300 °C does not produce any noticeable changes but when annealed at 400 °C the perpendicular anisotropy decreases indicating some stress relief.

INTRODUCTION

Granular solids, consisting of metallic particles embedded in a matrix of another metal or oxide material have been studied in the past because of their interesting physical properties.[1,2] Recently great interest has indeed been aroused in such materials following the exciting work by Berkowitz *et al.*[3] and Xiao *et al.*,[4] who observed large magnetoresistance (MR) in composite films of Co-Cu and Co-Ag. The origin of this effect is far from being well understood. Several papers which are basically devoted to the study of MR effects are appearing on these materials. Considerable effort is being devoted to the materials research of these kinds of films in order to optimize the properties for applications as sensors. We have chosen the Co-Cu system for this study and focused our attention on magnetic properties such as magnetization and anisotropy using ferromagnetic resonance (FMR) techniques. We have also carried out some structural studies using transmission electron microscopy (TEM) and scanning tunneling microscopy (STM).

EXPERIMENTAL DETAILS

The Co-Cu composite (we prefer this terminology to alloy) films were deposited on water-cooled glass substrates by rf sputtering using a 75-mm-diam disk of Co and Cu chips as target. Most of the samples were prepared under standard conditions, namely, with a rf power of 80 W, argon pressure p_{Ar} of 6 mTorr and a film thickness of 1400±200 Å, monitored by quartz oscillators. Some samples were prepared with rf power of 80 and 100 W, p_{Ar} in the range $3-23\times10^{-3}$ Torr, and film thickness ranging from 300 to 2600 Å.

The composition of the samples was determined by electron probe microanalysis and the film thickness with a profilometer. Some selected samples were studied by TEM using a JEOL 200 CX microscope and also by STM.

Magnetization and $M-H$ loops were measured with a vibrating sample magnetometer. FMR was observed at 9.8 GHz with the dc applied field both in the film plane (H_{para}) and perpendicular (H_{perp}) to it.

RESULTS AND DISCUSSIONS

The planar TEM picture corresponding to the sample with Cu=46 at. % shown in Fig. 1, has a magnification of 308 571×. One can observe clusters varying in size from about 160 to 450 Å. The average cluster size averaged over 30 clusters that are reasonably clear is about 250 Å. The clusters are separated by grain boundaries. The cluster size varies from location to location even within this micrograph. This appears to be consistent with STM studies to be described below.

Surface roughness studied by STM of several samples showed no significant differences with the film thickness or Cu content. Figure 2 shows the surface roughness of the sample with Cu=66 at. % as a typical case. The top surface appears to be wavy with the average maximum height of about 50 Å. The size of such zones is in the range 300–450 Å although one could see regions of smaller ones. Such shapes and sizes would lead to demagnetization factors which are not easy to calculate as discussed later.

The $M-H$ loops along the film normal were typical of hard axis ones with no remanence. The in-plane $M-H$ loops are rectangular and their shapes change with increasing Cu

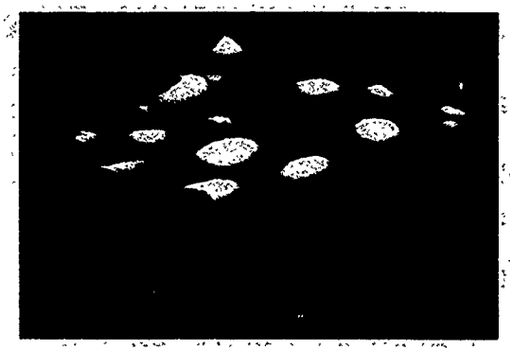

FIG. 2. STM surface image of the sample with Cu=66%. x axis 50 nm/div, z axis 15 nm/div.

content due to the appearance of perpendicular anisotropy (H_p). We will discuss the presence of H_p when describing the FMR results. No uniaxial anisotropy in the film plane could be detected. Figures 3(a) and 3(b) show two typical results for $x=20$ and 60, respectively. Figure 3(b) is typical of a loop with the presence of H_p and consequently this leads to an increase in the saturation field H_s. Figure 4 shows the Cu content dependence of H_s. It seen that it is low and around 200 Oe for $x \leqslant 40$ but shows a sudden jump for $x>40$ to reach a peak value of about 1.2 kOe for $x=60$. The Cu content dependence of the in-plane coercivity H_c is also very interesting and somewhat analogous to that of H_s as shown in Fig. 4. H_c first increases sharply for $x>30$ and after showing a broad peak it decrease again. The peak value of H_c is about 100 Oe. The magnetization, when expressed in terms of the total sample volume Co+Cu shows a linear decrease as x increases. But since Co and Cu do not form an alloy the magnetization should be expressed in terms of the actual Co volume. In this case the magnetization of all the samples equals that of bulk Co. A similar conclusion was also reached by Kneller[5] on evaporated Co-Cu films. This shows that the Co moment is conserved because the Co atoms tend to cluster together. The magnetization of the samples was independent of the deposition parameters and the film thickness in the range 300–2500 Å, but not so for the FMR properties as will be discussed later.

The FMR resonance linewidth ΔH, as is well known, is a sensitive tool to check the quality of the films. We made a systematic study of ΔH as a function of the deposition parameters (rf power and p_{Ar}) and film thickness. Changing the rf power from 80 to 100 W did not sensibly affect the FMR

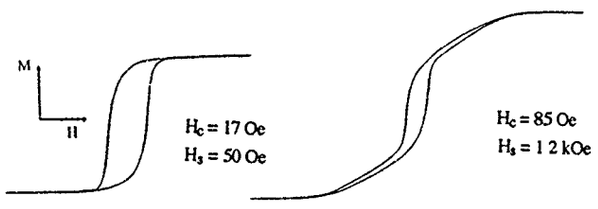

FIG. 3 The in-plane $M-H$ loops for the samples for (a) Cu=20 and (b) 60 at. %, respectively.

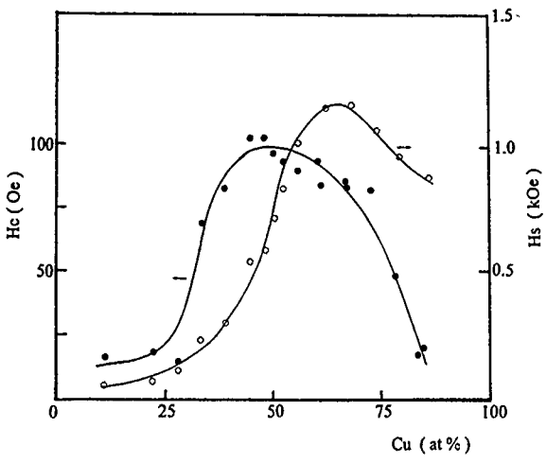

FIG. 4. The Cu content dependence of the saturation field H_s and the in-plane coercivity H_c.

properties. ΔH_{para} was generally higher than ΔH_{perp} in all the samples. This could arise from an inhomogeneous demagnetization field in the film plane due to the interspersing of Co and Cu clusters. For a given composition both ΔH_{para} and ΔH_{perp} remain almost independent of p_{Ar} in the range 6–23 mTorr but show a rapid increase by a factor of 7 for $p_{Ar}=3.5$ mTorr. This is due to inhomogeneous line broadening and it can be inferred that very low p_{Ar} leads to inhomogeneity. This cannot be due to Ar inclusion which is known to occur only for high Ar pressures. Therefore we attribute this to the inhomogeniety caused by the high kinetic energy of the adatoms resulting from lesser collisions due to a large mean free path at the fairly low Ar pressure. This leads to more mixing of Co and Cu and the resonance fields are perturbed by the presence of nonmagnetic inclusion of Cu. Also at low argon pressures, plasma instability occurs. Finally the study of the thickness dependence of ΔH_{perp} showed that it decreases from 90 to 70 Oe when the film thickness is increased from 300 to 1400 Å and then decreases only slightly for 2600-Å-thick sample. So the following standard conditions of preparation were adopted; $p_{Ar}=6$ mTorr, rf power=80 W, and film thickness=1400±200 Å. The properties of the samples with different Cu content are discussed below.

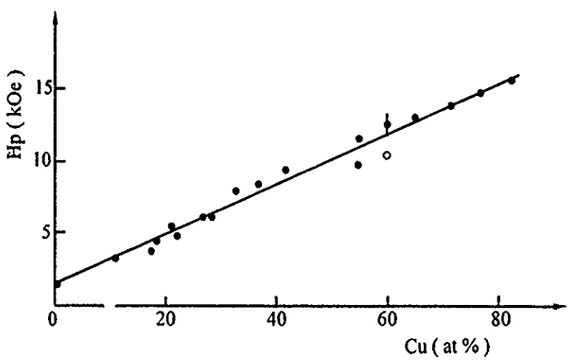

FIG. 5. The Cu content dependence of the perpendicular anisotropy H_p assuming a demagnetization field of $4\pi M$. corresponds to after annealing at 405 °C. See the text.

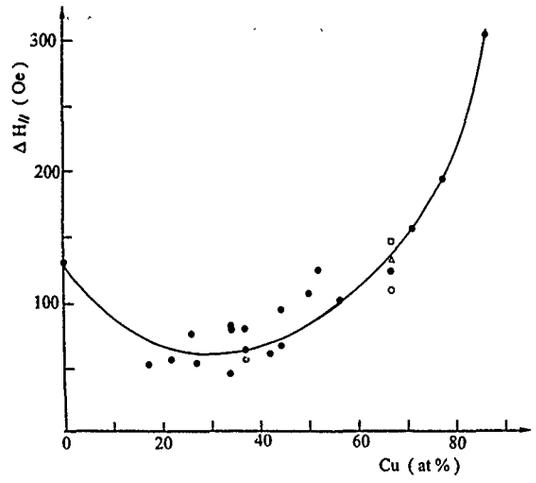

FIG. 6. The Cu content dependence of the parallel FMR line width ΔH_{para}. Also are shown data for $x=67$, for film thicknesses □ 300 Å, △ 720 Å, ● 1200 Å, ○ 2600 Å, respectively.

The FMR spectra in composite films are to be distinguished from those on multilayers where oscillatory coupling exists between the magnetic layer and where supplementary resonance modes have been observed.[6] The FMR spectra with H in the film plane showed a single intense mode except in the very few cases where a very small shoulder could be observed at the lower field side which we have neglected for the present discussion. However, the perpendicular spectra of all the samples consisted of an intense mode followed at lower fields by two or sometimes, three satellite modes of smaller (~5%) intensity as compared to the first one. These modes are not standing spin waves as shown by the absence of a quadratic behavior in their field positions and the random way in which their intensities varied. No clear correlation could be established between the spacing of the modes and either the Cu content or the film thickness. Apparently the composite nature of the samples perturbs these modes which could be eigenmodes. From the parallel and perpendicular resonance fields we calculated the g factor and effective demagnetization $4\pi M' = 4\pi M - H_p$, where we have implicitly assumed that the demagnetization factor corresponds to that of a thin film. For the calculation we considered only those resonance modes which yielded the g factor close to 2.2 typical of Co. From $4\pi M'$ one can calculate H_p, provided one knows the value of $4\pi M$. If we consider only the Co clusters which are participating in the resonance then $4\pi M$ has to be taken as 17.5 kG based on the measured M values. In this case H_p increases almost linearly with the Cu content as shown in Fig. 5. These H_p values are unreasonably large because the in-plane loops study shows that the magnetization is essentially in the film plane. One might therefore ask what would be the real demagnetization factor in such composite films which consist of clusters and are not homogeneous. From TEM studies we had inferred that the average cluster size was about 240 Å. Considering the films thickness, which is 1200±100 Å, the aspect ratio is not anymore that of a thin film. Therefore the demagnetization factor N which creates the internal field $N(4\pi M)$ should be much less than one normally used for thin films. Calculation of the exact demagnetization factor is quite complex for the clusters with which we are concerned.[7] If one assumes as a first approximation, $N=0.5$ which is reasonable then the demagnetization field becomes $2\pi M$. In this case the H_p values reported in Fig. 5 will have to be halved. These H_p values are more reasonable and consistent with the easy plane loops observed. There could be some contribution to H_p from magnetoelastic energy ($\sigma\times\lambda$) (where the first and second terms represent the stress and the magnetostriction) due to stresses arising from the Cu clusters which surround the Co ones. Of course some stress would also be created by the sputter growth process. Indeed we annealed some samples in a vacuum of about 5×10^{-6} Torr for a duration of 3 h and studied the effect on the magnetic properties. No change was observed for annealing temperatures up to 300 °C. However annealing at 405 °C produced some changes in the FMR properties. No change in the magnetization was observed as was expected because the magnetization cannot exceed that of bulk cobalt but a decrease in H_p was observed as shown in Fig. 5 for $x=60$ at. %. This reduction could be attributed to the relieving of some of the stress hence a reduction in the magnetoelastic anisotropy. Annealing at 405 °C also leads to a small increase in coercivity of about 15%. The coercivity depends on the microstructure which was possibly modified by the annealing treatment. More structural work is needed to interpret this result.

As regards the Cu concentration dependence of the linewidth, the ΔH_{perp} remains constant at 80±20 Oe for $17\leqslant x\leqslant 60$ and for $x\geqslant 60$ it increases rapidly to a value of 200 Oe. But ΔH_{para} shows a totally different behavior as shown in Fig. 6. It decreases initially with the Cu addition and after showing a broad minimum starts increasing rapidly for $x\geqslant 60$ to reach a value of 300 Oe for $x=82$. In the same figure is also shown the linewidth for samples with $x=67$, with thicknesses 300, 720, 1200, and 2600 Å, the highest linewidth being for the thinnest sample as mentioned earlier. More structural studies are needed to understand the above results and are in progress.

We wish to thank Y. Dumond for the determination of composition and Dominique Imoff for helping with STM studies.

Nanocrystalline $Cu_{80}Co_{20}$ powders were fabricated using a chemical precipitation technique. As-prepared powders consist of metal-oxides having an average particle size of 100 Å. When appropriately heat treated, these powders reduce to form a CuCo face-centered cubic alloy; heat treatments at higher temperatures (≥400 °C) facilitate the phase separation of the alloy to its elemental components. Concurrent with an increase in annealing temperature, the coercive field decreases while the magnetization increases, reflecting particle coarsening and the relative amount of free cobalt in the mixture.

I. INTRODUCTION

Nanoscale particles have proven useful in a very diverse range of applications ranging from catalysts and composites to magnetic storage media. Our interest in CuCo nanoparticles is to investigate the possibility of expanding the limited miscibility region of the Cu-Co equilibrium phase diagram using chemical processing. A related interest is to investigate if such metastable alloys, after appropriate heat treatments, show an enhanced magnetoresistance effect similar to that exhibited by metastable alloys processed via vapor-quenching[1,2] and melt-spinning techniques.[3,4]

In this paper we report the fabrication of nanostructured metastable CuCo particles via a chemical reduction technique. In this technique, transition metal-oxides are precipitated from solution and reduced to a metallic alloy by heat treatment at 400 °C under H_2 gas flow. Heat treatments at temperatures ≥400 °C cause this alloy to phase separate to its elemental components. Magnetoresistance (MR) measurements of compacted annealed powders show a modest MR effect of 1% at 2 K in high-porosity compacts.

II. EXPERIMENTAL

Metallic powders consisting of Cu and Co were prepared using a chemical precipitation technique. Details of the sample processing will be presented elsewhere.[5] Samples were heat treated under flowing H_2 gas at temperatures ranging from 200 to 650 °C for a period of 60 min. This heat treatment procedure was found to be effective in selectively removing the oxygen from the samples reducing them from oxides to metals. Structural, chemical, and magnetic measurements of the as-prepared and heat-treated samples were performed *ex situ* under ambient conditions. Structural characterization was performed using extended x-ray absorption fine structure (EXAFS), x-ray diffraction (XRD), and electron microscopy measurements. The magnetic properties of the samples were measured using a vibrating sample magnetometry (VSM). Cold-pressed pellets made from the heat-treated powders were measured for their MR [$\Delta\rho/\rho=(\rho-\rho_0)/\rho_0$; ρ_0=zero field applied] properties using a collinear four point probe technique at a temperature of 2 K and an applied field strength of 5 T.

We limit our discussion here to include XRD, EXAFS, and VSM results. We find that the use of both a long-range structural probe, XRD, and a short-range structural probe, EXAFS, are needed to obtain a coherent picture of the structural evolution of these powders with heat treatment. XRD analysis was performed using a $Cu_{k\alpha}$ source operating in a θ-2θ diffractometer while EXAFS measurements of the Co and Cu K absorption edges were performed at the National Synchrotron Light Source in transmission mode on NRL's beamline, X23B. EXAFS analysis procedures follow those outline in Ref. 6 leading to Fourier transforms of the Co and Cu EXAFS data. In this form the EXAFS data are analogous to a partial radial distribution function where the position and amplitude of Fourier peaks typically correspond to atoms in the local environment around the absorbing atom.

III. RESULTS AND DISCUSSION

A. Structural evolution with heat treatment

Figure 1 is a plot of the XRD patterns for $35°\leq 2\theta \leq 55°$ for the samples heat treated at 265, 330, 400, and 650 °C. All features in the diffraction scans can be identified with metallic-oxides or an fcc metallic phase. Dark field transmission electron microscopy (TEM) images of the as-prepared powder show particles to be spherical in shape and range in size from 50 to 100 Å in diameter. A smaller number of larger particles, ranging in size from 200 to 400 Å, were also observed. Selected area diffraction showed broad diffuse rings characteristic of nanocrystalline structures.

After an anneal at 265 °C, the XRD pattern indicates that the powder has been substantially reduced, with only weak diffraction features corresponding with the precipitate phase. The dominant phase in this annealed sample is the Cu_2O phase with evidence for small amounts of CuO and possibly free fcc Cu. It is unclear in which phase the Co atoms reside. Several stable CuCo-oxides exist and some have diffraction features which overlap those in Fig. 1. However, no match was made to the diffraction files of these phases leading us to conclude that the Co has been incorporated into the Cu_2O phase but has not formed an ordered $(Cu_xCo_{1-x})_2O$ structure.

Fourier transformed Co EXAFS data for the sample annealed at 265 °C are presented as the solid curve in Fig. 2(a).

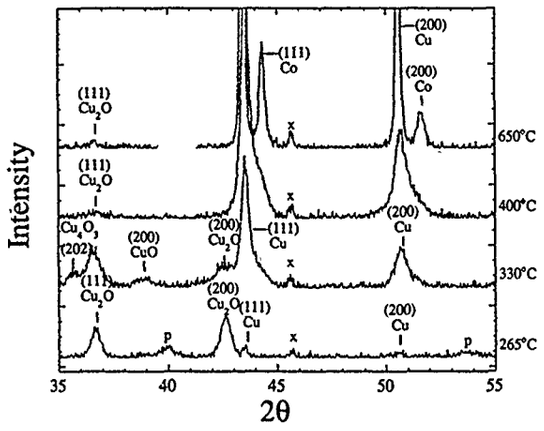

FIG. 1. X-ray θ–2θ diffraction patterns for heat-treated powder samples. All diffraction features are identified on the plot. (x: contamination from processing; p: precipitate phase).

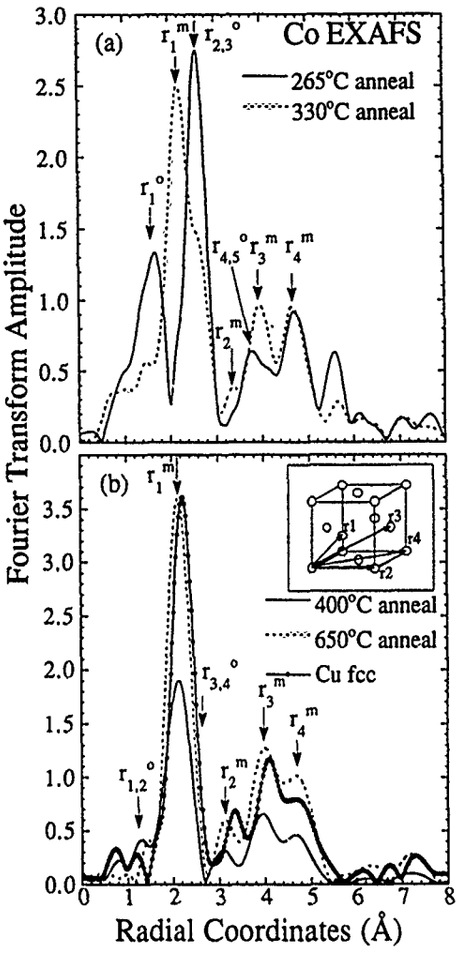

FIG. 2. Fourier transformed Co EXAFS data for samples heat treated at (a) 265 and 330 °C, and (b) 400 and 650 °C. Fourier transformed EXAFS data for a fcc Cu standard is presented in (b) to allow qualitative comparisons. Fourier transforms were performed using k ranges of 2.5–14 Å^{-1} and a k^2 weighting. Electron phase shift corrections have not been incorporated in these data therefore radial distances do not represent true bond lengths.

The dominant features of the data presented in Fig. 2 have been identified by comparison to Fourier transformed EXAFS data collected from an empirical standard. The Fourier peaks labeled with a superscript "o" correspond to neighbors in an oxide phase while those labeled with a superscript "m" correspond with neighbors in a close-packed metal phase. The subscript defines the number of the atomic shell relative the absorber. Figure 2(a) indicates that the 265 °C annealed sample has only oxide neighbors in its local environment. Although, higher order neighbors may include transition metals they appear at distances and with relative amplitude which match those of the oxide phases.

The diffraction pattern following an anneal at 330 °C is dramatically different, having strong diffraction peaks at 2θ values of 43.5° and 50.7°, corresponding with the (111) and (200) lines of the fcc-Cu phase. Concurrent with the heat treatment, the diffraction features for the Cu_2O phase are seen to decrease in intensity and those corresponding with the precipitate phase are no longer visible. Small diffraction features exist which correspond with minority phases of CuO, Cu_2O, and Cu_4O_3. Again no evidence is seen for the presence of any Co phase. The very broad Cu lines, having a slight asymmetry on the right-hand side corresponding with a smaller d spacings, suggests that the Co may reside with the Cu in the fcc structure. The Fourier transformed Co EXAFS data for the 330 °C sample, presented as the dashed curve in Fig. 2(a), support this interpretation. In contrast to the 265 °C Fourier transformed data, these data illustrate a well-resolved, large Fourier peak centered at 2.2 Å corresponding to a transition metal near neighbor in the fcc structure (uncorrected for electron phase shifts). Peaks appearing at higher radial distances (3 Å$\leq r \leq$5 Å) also correspond with fcc sites. The small peak centered near 1.5 Å and the shoulder on the left-hand side of the 2.2 Å Fourier peak indicates that not all of the Co atoms occupy fcc sites, some remain in oxide phases. Taken together, the results of the XRD and the EXAFS indicate that the Co atoms in the sample annealed at 330 °C predominantly occupy lattice positions within a metallic, close-packed, structure having a lattice parameter very close to that of fcc Cu. This suggests that the Co atoms have transformed with heat treatment from the Co-oxide to a disordered CoCu-oxide and finally to a CuCo alloy.

A heat treatment at 400 °C is seen in Fig. 1 to further reduce the oxide content of the powder; the diffraction features of the minority Cu-oxide phases have nearly been eliminated. The dominant features of these data are identified with the Cu-rich fcc phase. The asymmetry seen in the XRD data for the 330 °C annealed sample appears as a pronounced shoulder in the XRD scan of the 400 °C annealed sample suggesting that the Co in the Cu matrix has begun to chemically separate from the Cu matrix but has not yet formed fcc Co particles. The Fourier transformed Co EXAFS data for this sample are presented as the solid curve in Fig. 2(b) together with the data for the sample annealed at 650 °C and the fcc Cu data; the latter presented for qualitative comparison purposes. The inset graphic defines the relationship between the Fourier peaks and the fcc lattice sites. All Fourier

features are seen to correspond with the metallic fcc structure. The excessive broadness of the near neighbor peak hints that the structure is disordered and likely exists as small grains only a few unit cells in diameter. Supporting this interpretation, TEM analysis and selected area diffraction were insensitive to the presence of the Co fcc phase.

Annealing at a temperature of 650 °C facilitates a phase separation of the CuCo alloy to Co and Cu fcc phases. The shoulder features seen in the 400 °C XRD data now appear as resolved peaks at lower d spacings corresponding to the fcc Co phase. A small diffraction feature appears at a d spacing which matches that of the Cu_2O phase. This is the only evidence that oxidation has occurred in these powders. TEM analysis of the powders annealed at 650 °C show a slight coarsening of the particles to a mean diameter size ranging from 100 to 200 Å; a smaller number of larger particles ranging in size from 400 to 600 Å are also observed. The distances and relative amplitudes of the peaks in the Fourier transformed Co EXAFS data for this sample match closely with those of the Cu fcc standard. The shifts in the distances of the Fourier peaks over the 1–5 Å range between the Cu standard and the Co EXAFS of the annealed sample are expected due to the Co-Co and Co-Cu correlations; Co being a slightly smaller atom than Cu.

B. Magnetic properties

The magnetic properties of powders annealed at 265–650 °C are presented in Fig. 3 with the magnetization versus applied field (M vs H) curves presented as the inset plot to Fig. 3. VSM measurements of the as-prepared and 265 °C annealed samples show them to be paramagnetic with no evidence of a ferromagnetic component. The sample annealed at 400 °C illustrates a ferromagnetic behavior in its M vs H curve. This corresponds with the appearance of the metallic CuCo alloy in the XRD and EXAFS data indicating that some of the Co has chemically segregated from within the Cu lattice to form ferromagnetic particles or regions.

The M vs H curves for annealed samples appear to nearly saturate at an applied field of 8 kOe but a paramagnetic slope is clearly present. The paramagnetic slope is likely caused from those Co atoms remaining within the Cu lattice and surrounded predominately by Cu atoms. A similar paramagnetic signature was observed in vapor-quenched films and melt-spun ribbons having similar composition and heat treatment histories; this was also attributed to Co atoms stabilized in the Cu matrix.[1–4] Figure 3 illustrates the trend in magnetic properties with annealing temperature. The coercive field decreases while the magnetization values increase reflecting the particle coarsening and the segregation of fcc Co, respectively.

In an attempt to investigate the magnetotransport properties of these samples the CuCo powder annealed at 650 °C for 60 min was compacted using an uniaxial pressure of approximately 500 MPa. The resulting compact was measured to have a density of 61% (of the theoretical bulk) and a room temperature electrical resistivity of ≈300 $\mu\Omega$ cm (200 $\mu\Omega$ cm at 2 K). A modest MR of 1% was measured at 2 K. We believe the high electrical resistivity and lower than expected MR effect are related to the high porosity of the compact. Following a cold-forging procedure which increased the pellets density from 61% to approximately 70% the room temperature electrical resistivity was reduced to 30 $\mu\Omega$ cm (18 $\mu\Omega$ cm at 2 K); an order of magnitude decrease. Hot-isostatic pressing improved the density of the compact to ≈95% and lowered the electrical resistivity to 4.5 $\mu\Omega$ cm (2.5 $\mu\Omega$ cm at 2 K). However, the MR effect decreased by a factor of 2 as a result of the improved densification. The lack of a "giant" MR in this compacted $Cu_{80}Co_{20}$ powder can be attributed to: (1) the large field independent component of the MR arising from the scattering across the particle interface, possibly enhanced due to a thin oxide layer, or (2) the mixing of particle interfaces brought about by sample heating during forging. Investigations are underway to further explore the processing dependence of the magnetic and transport properties of these powders.

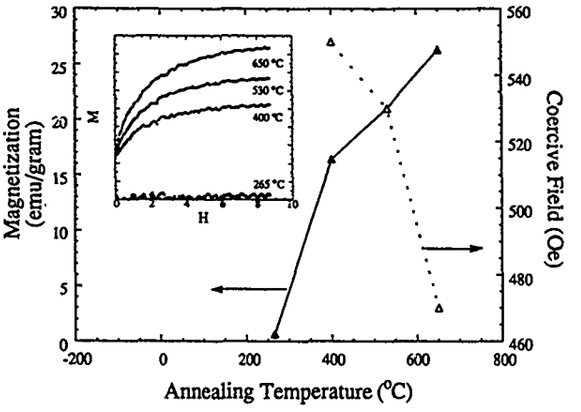

FIG. 3. Magnetization and coercive field values for annealed powders as a function of annealing temperature. Inset plotted data are M vs H curves for annealed samples illustrating the trend of increasing magnetization with annealing temperature.

ACKNOWLEDGMENTS

We thank Dr. A. E. Erhlich for valuable discussions concerning the magnetoresistance data. This research was carried out in part at the National Synchrotron Light Source (Brookhaven National Laboratory, Upton, NY), which is sponsored by the U.S. Department of Energy (Division of Materials Science and Division of Chemical Science of the Office of Basic Energy Sciences). Relaxation measurements and particle size determination in Co–Ag heterogeneous alloy films

S. B. Slade, F. T. Parker, and A. E. Berkowitz
Center for Magnetic Recording Research, Mail Code 0401, University of California, San Diego, La Jolla, California 92093-0401

Magnetic properties of dilute Co–Ag heterogeneous alloy films are investigated to test the Néel model of magnetic relaxation. The static properties indicate a narrow particle size distribution for each sample. Dynamic susceptibility measurements indicate a frequency dependence for the susceptibility peak that is not consistent with the Néel model.

INTRODUCTION

There exists a need to test the Néel model of magnetic viscosity[1] on well-characterized samples.[2] An impressive body of experiments on ferrofluids,[3] for example, indicates a logarithmic time dependence for the magnetization, even though the Néel model predicts an exponential decay with time. A wide distribution of relaxation times is usually cited as the cause of the logarithmic decay,[4] with deviations from $\ln(t)$ behavior attributed to interactions or the distribution itself.[5] Because of the wide distribution and interactions, the basic expression is not usually questioned. Our work focuses on characterizing dilute Co–Ag granular films in detail, so that a theoretical model can be developed from the data using a minimum of adjustable parameters.

SAMPLE PREPARATION

Heterogeneous Co–Ag alloy films were produced using dc magnetron sputtering from separate targets onto a rotating planetary substrate heated to 80 °C. Films approximately 1 mm thick were deposited onto 1 ml Kapton substrates after back-sputtering for 15 min. Films of pure Ag were also prepared under identical conditions to serve as references. Atomic absorption measurements indicated a film thickness of 9000 Å and a Co concentration of 5% by volume. Samples of the films were annealed in flowing hydrogen for 8 h at 200 °C. Preliminary TEM analysis indicates the films consist of FCC Co precipitates dispersed in a polycrystalline FCC Ag matrix.

dc MAGNETIC MEASUREMENTS

Static magnetic measurements as functions of field and temperature were performed using a SQUID magnetometer in order to determine the Co particle sizes and distributions. In each case the data were corrected for Kapton and Ag contributions. Figure 1 shows magnetization curves measured at 50, 100, 200, and 300 K for both samples. These temperatures are well above each sample's blocking temperature, allowing a superparamagnetic analysis to be performed. The data at each temperature were fit to a Langevin function having a lognormal distribution of particle volumes. No additional anisotropy or susceptibility terms were used in the fit. The adjustable parameters for these fits are the sample's saturation magnetization M_s, the geometric mean volume $\langle V\rangle_G$, and the distribution width parameter σ_v. In the figure the value of $\langle V\rangle_G$ is given as $\langle D\rangle_G$, the diameter of a particle with volume $\langle V\rangle_G$. All the Co is assumed to contribute to the moment, and the magnetization of each Co cluster is fixed at 1435 emu/cm Co, a value determined by measuring the moment of the annealed sample at 1.75 K in 70 kOe. The fits were all of a high quality, as evidenced by the low uncertainties in the fit parameters, reasonable values of M_s, and low values of chi squared. The results for each sample at $T=100$ K, which are typical of the fits at all temperatures, are indicated in the figure.

Figure 2 shows the dc susceptibility measured after cooling in zero field to 6 K (ZFC), and the susceptibility measured after cooling in 50 Oe to 6 K (FC) for each sample. For both ZFC and FC the susceptibility was determined by calculating a linear fit to the moment measured in fields of 10, 20, 30, 40, and 50 Oe at each temperature. Annealing is seen to shift the peak in the ZFC susceptibility from 11 K to 8.5 K. Similar downward shifts have been reported for more concentrated Co–Ag films.[6] The temperature of the peak in

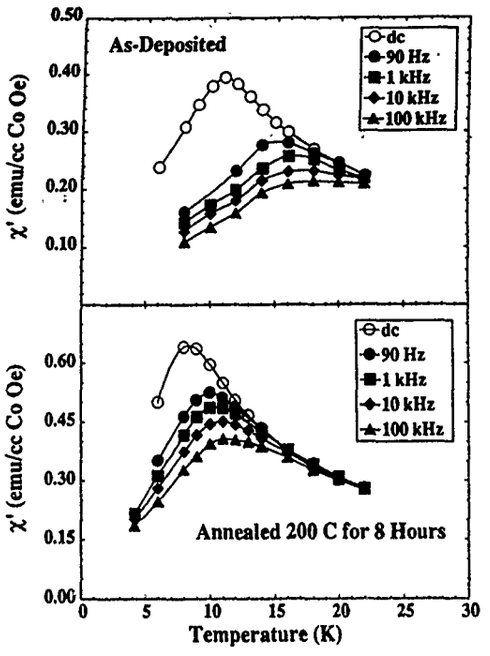

FIG. 3. In-phase ac susceptibility, χ', measured in the 3 Oe field. Also shown is the dc ZFC susceptibility. The lines are guides for the eye.

the ZFC data is identified as the blocking temperature, T_b, for the mean particle volume in the sample. No divergence is seen between the ZFC and FC data until the ZFC peak in the as-deposited film. The annealed film shows divergence between the ZFC and FC below 11 K. This divergence is small, and may not be apparent in the figure. The onset of irreversibility is indicated by the divergence of the FC and ZFC susceptibilities. The field applied during cooling partially aligns the moments of the particles, and once those particles are cooled to below their blocking temperatures they will exhibit irreversible behavior. With decreasing temperature, this irreversibility will first appear in the largest particles in the sample, and as such may help to indicate the width of the size distribution. The data from the annealed film indicate a very narrow distribution of particle sizes, with the largest particles becoming blocked at 11 K, and the majority blocked at 8.5 K. The as-deposited data indicate a still narrower distribution, with essentially all the particles blocking at 11 K. The inset of Fig. 2 shows the inverse of the ZFC susceptibility. Extrapolation to the temperature axis determines the value of the Curie–Weiss constant θ_{CW}, which is a measure of the strength of particle interactions. The as-deposited data extrapolate to $\theta_{CW}=-4\pm1$ K, while the annealed sample extrapolates to $\theta_{CW}=1\pm1$ K. These data indicate there may be some weak net antiferromagnetic interactions in the as-deposited sample, presumably from interparticle exchange, while the annealed sample is noninteracting within the uncertainty of the extrapolation. The total anisotropy, K, assumed to be uniaxial, can be estimated from T_b and the known volume distribution using a simulation of the dc susceptibility (discussed below) and the Néel relation[1] $K=k_B T_b \ln(t_{meas}/\tau_0)/V$. Here k_b is the Boltzmann's constant, t_{meas} is the measurement time, taken to be 100 s, and τ_0 is taken to be 10^{-10} s, representing the inverse of an attempt frequency for switching over the anisotropy barrier to reversal. The anisotropy analysis assumes the peak in the ZFC susceptibility is entirely due to the blocking of superparamagnetic particles. This assumption seems reasonable, given the very small values of θ_{CW}. The value of K for each sample is determined by matching the experimental data to the simulation, with K the only adjustable parameter. The result is $K=4.1\times10^7$ erg/cm^3 for the as-deposited and 2.4×10^7 erg/cm^3 for the annealed sample. These values are higher than the 1.2×10^6 erg/cm^3 maximum cubic crystalline anisotropy reported for FCC Co[7] or the maximum uniaxial shape anisotropy of 6×10^6 erg/cm^3. Similar high anisotropy values have been reported for other granular films[8,9] and attributed to surface anisotropy or a stress-induced anisotropy. If part of the observed anisotropy is stress related, then the lower value for the annealed sample may be due to stress relief. However, the value of M_s used will not reflect the true particle moment if some of the Co is in the Ag matrix, or if the matrix contributes a separate susceptibility due to the presence of Co in the matrix. A different M_s value would change the particle size, which, in turn, would change K.

ac SUSCEPTIBILITY

Measurements of the ac susceptibility taken after four decades of frequency in a 3 Oe (zero-to-peak) field as a function of temperature after cooling in the zero field were made using an ultrahigh sensitivity ac susceptometer.[10] This instrument allows for the simultaneous measurement of the in-phase and out-of-phase signal components with a noise level below 10^{-8} emu. Figure 3 summarizes the susceptibility data for each sample. In general, the susceptibility peak

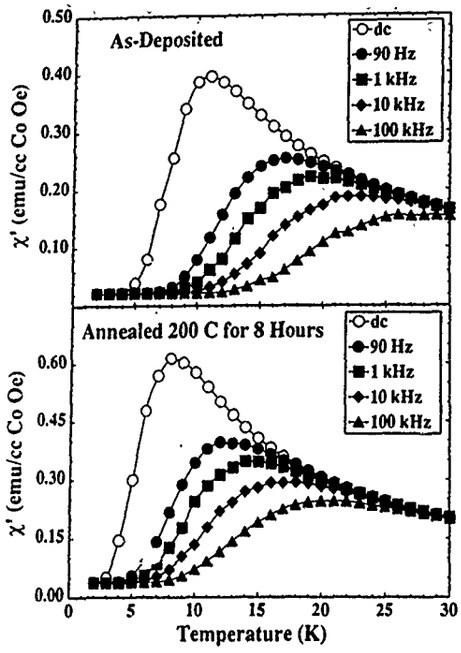

FIG. 4. Numeric simulations based on the Néel model of magnetic relaxation. The lines are a guide for the eye.

shifts to higher temperatures and broadens with increasing measurement frequency. At $T=T_b$, the relaxation time, τ, is equated to the measurement interval, t_{meas}, taken to be the half-period of the applied field. The frequency dependence of T_b can be used to investigate the relaxation time, predicted by the superparamagnetic Néel model for isolated particles as $\tau=\tau_0 \exp(\text{KV}/k_B T_b)$. The shift of T_b with increasing measurement frequency is an excellent method of verifying the functional form of this equation. However, given the highly nonlinear dependence of τ on V, and a sample having a distribution of particle volumes, it is not reasonable to expect the value of τ found from using $V=\langle V\rangle_G$ will accurately predict the relaxation time for the entire distribution.

Numeric simulations on particle assemblies having a lognormal distribution of particle volumes and the parameters found from fitting the magnetization curves were studied to determine if the Néel relaxation time expression accurately predicts the observed ac susceptibility. The simulations calculate τ for each particle in the distribution and then assign a blocked or superparamagnetic susceptibility depending on whether $\tau>t_{\text{meas}}$ or $\tau<t_{\text{meas}}$, respectively. Figure 4 shows the simulated susceptibility for each sample. The numeric simulations have a much greater frequency dependence of T_b than the experimental data. Comparison with the experimental data clearly indicates the Néel relaxation time equation does not have the correct functional form to account for the observed frequency dependence of T_b. Assuming the functional form of the relaxation time equation involves a simple exponential, a plot of $\ln(\tau)$ vs $1/T_b$ for each frequency will provide a measure of the frequency prefactor, τ_0. The values calculated by this method are 3×10^{-26} s for the as-deposited film and 2×10^{-26} s for the annealed film. Both values are unphysical within the Néel model. The much smaller frequency dependence of the experimental data results in the unphysical values of τ_0 determined above. Several different models for the relaxation time equation have been proposed in the study of spin glasses.[11] In particular, a Vogel–Fulcher analysis is often used on ac susceptibility data which has a small frequency dependence of T_b. This type of analysis leads to an ordering temperature of $T_0=2.5$ K for the as-deposited sample and $T_0=8$ K for the annealed sample, both of which are inconsistent with our χ^{-1} data.

CONCLUSION

Static and dynamic magnetic measurements have been performed on dilute Co–Ag heterogeneous alloy films, both as-deposited and annealed. The dc data indicate a very narrow size distribution that can be fit using the basic equations of superparamagnetism for a sample having a lognormal distribution of particle volumes. The ac susceptibility data from both samples exhibit much less frequency dependence of T_b than predicted by the Néel model of magnetic relaxation, resulting in unphysical values of the exponential prefactor, τ_0.

Studies of magnetic interactions between Gd granules in copper matrix

J. H. Hsu and Y. H. Huang
Department of Physics, National Taiwan University, Taipei, Taiwan, China

Ultrafine Gd particles in the Cu metallic material have been obtained by rapid annealing of sputtered metastable Gd_xCu_{1-x} alloys. The particle shape and size were measured by a transmission electron microscopy. The evolution of crystal structure with annealing temperature has been investigated by x-ray diffraction and electron diffraction. It has been found that the Gd granules have formed following annealing above 300 °C and the granular size increases with rising annealing temperature. The magnetic data show that the as-sputtered metastable $Gd_{0.1}Cu_{0.9}$ and $Gd_{0.2}Cu_{0.8}$ alloys obey a Curie–Weiss law at high temperature with a negative value of θ. After annealing, the θ value varies with annealing temperature according to an oscillatory function. The evolution of the magnetic properties and microstructure during annealing are described in detail.

INTRODUCTION

Recently, the magnetic behaviors of ultrafine particles in the thin films have been investigated extensively.[1] Granular solids consist of small metal particles embedded in an immiscible medium which may be insulating or metallic. Examples of insulating medium are SiO_2, Al_2O_3, and MgO which are poor conductors. On the other hand, granular solids with a conducting matrix offer both good magnetic and electrical properties, e.g., high magnetization and coercivity with very low resistivity. In order to obtain such materials, however, two metal constituents must be mutually immiscible under equilibrium conditions. Gd with Cu is such an example.[2] From our previous studies,[3] we have demonstrated that sputtering is a powerful technique for preparing metastable alloys from two mutually immiscible elements. And after post-annealing of these sputtered metastable alloys at an elevated temperature, the phase separation will occur and nanostructured composite films can thus be obtained. Besides, the granule sizes can be properly controlled by annealing conditions such as temperature and time.

The study of a copper medium containing Gd granules is also interesting from a more fundamental point of view. Single-domain particles are realized in a granular solid with low magnetic volume fraction. All moments within the particles are ferromagnetically aligned and the interactions of magnetic Gd granules in the nonmagnetic conducting material is expected to be Ruderman–Kittel–Kasuya–Yosida (RKKY) type via conduction electrons of Cu. The strengths and types of magnetic coupling strongly depend on the distance between Gd granules. By varying sputtering and annealing conditions, we can systematically study the processing effects on magnetic properties as well as microstructures. In this manner various magnetic states from these composite materials will be observed.

EXPERIMENT

The metastable Gd_xCu_{1-x} alloys ($0.4 \leq x < 1$) were prepared by dc magnetron sputtering with homogenously mixed composite targets. The kapton foils were used as the substrates which were cooled by liquid nitrogen during sputtering. The Ar pressure was maintained at 8 mTorr. Throughout this work, the Gd_xCu_{1-x} samples are denoted by their Gd relative volume fraction x.

After the alloy films were made, they have been annealed, respectively, at various temperatures in a computer-controlled furnace in a flowing argon atmosphere. Starting from 100 °C, the annealing temperature (T_A) was raised in 100 °C increments to as high as 500 °C. At each temperature, the samples were annealed for a preset time of 12 min, then cooled to room temperature. One sample was removed from oven for measurements, and other pieces were quickly heated again for annealing at the next higher temperature.

The film structures were examined by x-ray diffraction. Transmission electron microscopy (TEM) studies were used for determination of both crystal structure and microstructure of the samples. The magnetic measurements were performed on a superconducting quantum interference device in the temperature range between $5 \leq T \leq 300$ K with a maximum applied field of 5 T.

RESULTS AND DISCUSSIONS

In Fig. 1 it indicates that the structures of the film with kapton substrate for as-sputtered metastable $Gd_{0.1}Cu_{0.9}$ and $Gd_{0.2}Cu_{0.8}$ contain only a face-centered cubic phase, the same as in Cu. Annealing below 300 °C does not change the microstructure appreciably as shown in Fig. 2. After annealing above 300 °C, a small broad peak at $2\theta \approx 30°$ starts to appear, signaling the recrystallization of the metastable alloy into fcc Cu and hcp Gd. It is an indication that the Gd grains have formed which can be also confirmed from TEM results as shown in Fig. 3. Furthermore, the broad peaks of Gd become more significant with increasing annealing temperature (T_A). As a result it can be determined that a rapid growth of Gd grains occurs as T_A is increased. Figure 4 illustrates the evolution of microstructure with annealing

temperature. The fcc structure is preserved up to T_A=300 °C. Following annealing above 300 °C, the hcp lines of Gd suddenly appear, which continue to grow with increasing annealing temperature.

The magnetic field dependence of magnetization at 5 K for as-sputtered $Gd_{0.1}Cu_{0.9}$ and $Gd_{0.2}Cu_{0.8}$ is plotted in Fig. 5. A linear behavior has been observed for the fields smaller than 15 000 Oe and the magnetic moments of Gd atoms are not aligned even under the applied field of 5 T. Figure 6 shows the dependence of reciprocal magnetic susceptibility $(1/\chi)$ on temperature for as-sputtered metastable $Gd_{0.1}Cu_{0.9}$ as well as $Gd_{0.2}Cu_{0.8}$. It indicates that there is excellent agreement with the Curie–Weiss law[4] for both samples at temperatures above 80 K with a negative value of the constant θ which is related to parameters characterizing the magnetic interactions in the solid. In addition, a magnetic ordering occurs below 5 K which is the lower limit of our measurement temperatures. After annealed, as indicated in Fig. 7, the annealed samples exhibit the similar behavior with the as-sputtered samples as explained above. However, the Gd granules form superparamagnetic particles.[5] Besides, a drastic change of θ values have been found. The θ value versus T_A is plotted in Fig. 8. The θ value first becomes more negative at 200 °C for both samples but does not continue to decrease further with annealing temperature. It becomes less negative at higher T_A and furthermore a positive value has been discovered at 500 °C. As is known, the average granules size and distance have been found to vary with annealing conditions.[6] It is apparent that the oscillatory behavior of θ with T_A is due to the variation of film microstructure. And the dependence of θ on T_A is related to RKKY interactions in the solids. The detailed studies of magnetic ordering below LHe-temperature are underway.

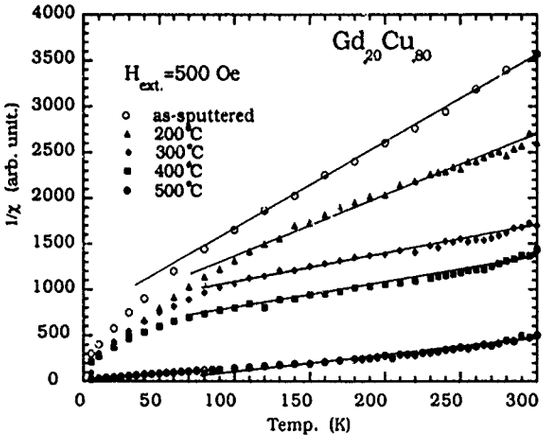

FIG. 7. Reciprocal magnetic susceptibility for as-sputtered and annealed $Gd_{0.2}Cu_{0.8}$ alloys as a function of temperature with an applied field of 100 Oe.

In summary, we have synthesized Gd/Cu composite metal films with nanometer sizes of Gd. The ability to control the size of Gd granules has been demonstrated. And the annealing effects on magnetic properties have been determined.

Magnetic reversal in small structures

D. I. Paul
Department of Materials Science, M.I.T., Cambridge, Massachusetts 02139

A. Cresswell
Department of Physics, Gettysburg College, Gettysburg, Pennsylvania 17325

In this paper we establish a model explaining the experimentally observed anomalous enhanced coercivity of granular magnetic solids and thin films or multilayers that have pinned surface magnetic moments. We also predict a normalized critical length for the material, above which the magnetic reversal mechanism is coercive and below which it occurs by a switching mode which is non-energy dissipative. The model used assumes a dependence of the magnetization along the small dimension of the granule or the depth of the layer. The contribution of the exchange term is obtained using the Landau semi-classical formalism, and thus we do away with the mean field approximation. The coercivity is defined in such a manner as to retain its nonreversible nature. Results are presented in dimensionless units. When applied to cobalt and iron, they show coercivities larger than the theoretical maximum obtainable without pinning in accord with experimental data.

The magnetic properties of thin films and multilayers bounded by oxidizing layers and of small metal granules embedded in an immiscible medium which may be insulating (i.e., iron and cobalt in SiO_2, Al_2O_3, etc.), are currently active fields.[1–3] At sizes and packing fractions sufficiently small to exhibit single domain behavior and isolation of one granule from the other, the materials show coercivities considerably in excess of the zero temperature rotational coercivity due to crystalline anisotropy, (i.e., $2K/M$). Micromagnetic calculations[4] and further experimental studies[5] on passivated γ-Fe_2O_3 particles have shown that the thickness and magnetic state of the surrounding oxide surface affects the coercivity. In this paper, we show that, when the surface atoms of these granules or layers have their magnetization pinned to the strong-bonding insulating matrix either through surface stress or some form of exchange coupling, such enhanced coercivity is predictable.

We consider a ferromagnetic material of length, L, along the X axis in the presence of an external uniform magnetic field in the negative Z direction. The angle of magnetization, θ, is in the YZ plane and is assumed to vary as a function of X only. Further, we assume that the magnetic moments at the ends or surface of the material ($X=0$ and L) are rigidly pinned such that they point in the $+Z$ direction due either to very large stresses such as in the granular Fe-SiO_2 systems[1,2] or to surface exchange pinning as in multilayers.

The exchange field is utilized in the semiclassical form originally proposed by Landau. Our calculation, being done at 0 K, we do not consider superparamagnetism in our model, and one must be careful with the interpretation of our work for lengths less than about 200 Å. We note that we could have done a three dimensional calculation for the sphere including temperature variation using mean field theory[6,9] for the exchange Hamiltonian. However, mean field theory tends to falsely mask the effect of spin correlations and thus fluctuations while, at the same time, giving an artificial dependence of the coercivity on the exchange energy. Although valid for the coercivity in those cases where the effect of surface pinning is small and the magnetization rotates in a coherent fashion,[6] the mean field approximation would clearly be in contradiction with the geometry of our problem (the average magnetization not staying parallel to the Z axis).

We note that the symmetry imposed implies that the direction of magnetization at the midpoint, $X=L/2$, is a maximum, θ_m, and it suffices to consider only the region $0<X<L/2$. Our energy per cross sectional area is

$$E=2\int_0^{L/2}[A(d\theta/dx)^2+K\sin^2(\theta-\Theta)+2\pi NM^2\sin^2\theta - HM\cos\theta]dx. \quad (1)$$

The extremum energy path is determined from the Lagrange–Euler equation,

$$-2A(d^2\theta/dx^2)+K\sin 2(\theta-\Theta)+2\pi NM^2\sin 2\theta + MH\sin\theta=0. \quad (2)$$

A first integral is easily obtained, which, upon imposing the boundary conditions at $x=L/2$, yields

$$L/L_0=\int_0^{\theta_m}[\cos 2(\theta_m-\Theta')-\cos 2(\theta-\Theta') + h'(\cos\theta_m-\cos\theta)]^{-1/2}\,d\theta, \quad (3)$$

where the effective anisotropy constant, normalized external field, and anisotropy angle, in the presence of demagnetization, are given by

$$K'=[(2\pi NM^2+K\cos 2\Theta)^2+K^2\sin^2 2\Theta]^{1/2}, \quad (4a)$$

$$h'=2HM/K', \quad (4b)$$

$$\tan 2\Theta'=K\sin 2\Theta/(2\pi NM^2+K\cos 2\Theta), \quad (4c)$$

and where $L_0=(2A/K')^{1/2}$. Note that these terms revert to unprimed parameters in the absence of such demagnetization. We shall now drop the primes, remembering that our values for K, h, and Θ can always be converted to include the demagnetization energy by use of Eq. (4). Inasmuch as, for a given material, L/L_0 and Θ have fixed values, the existence of a Lagrange-Euler path is dependent on the values

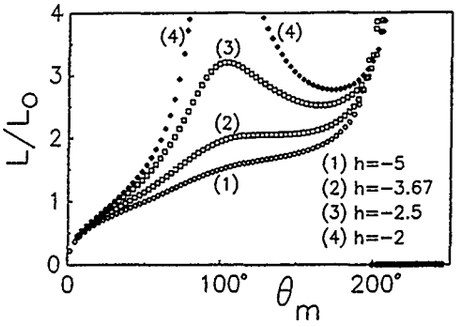

FIG. 1. Reduced sample length, L/L_0 vs θ_m, the maximum angle of magnetization. The anisotropy angle is 45° and the reduced external field $h=2HM/K$.

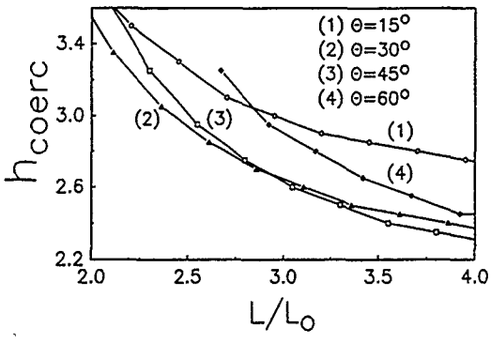

FIG. 2. Plot of reduced coercivity as a function of reduced sample length for anisotropy angles, 15°, 30°, 45°, and 60°.

of the two parameters, h and θ_m, in the integral. The integral in Eq. (3) is computed numerically, and the results are discussed in the next section.

The various behaviors of the materials under consideration can be understood from studying Fig. 1 where the anisotropy angle Θ has for illustrative purposes been placed equal to 45°. Each θ_m corresponds to a unique and well defined configuration of moments characterized by their corresponding length L/L_0. We note that there exists regions of forbidden θ_m's (corresponding to values of θ_m leading to negative square roots in the distance integral). For $0>h>-2$, there exists two such regions—one for large θ_m ($\theta_m>$ about 240° and indicated with zeros in Fig. 1)—and the other with θ_m centered at approximately 100°. As h increases from zero to -2 in the negative Z direction, this second forbidden region of θ_m's yields to a local maximum which in turn disappears completely at the *critical field* h_c of -3.67, [corresponding to a *critical length*, $(L/L_0)_c$ equal to 2.05 at a θ_m of 133°], and leaves L/L_0 as a monotonically increasing function of θ_m. Increasing h past this value does not change the general shape of the plot. Also, materials of an arbitrarily large length will always have at least one stable configuration by choosing θ_m close enough to the singularities of the integral.

(1) *Materials with lengths* $L/L_0>(L/L_0)_c$*:* For these materials, Fig. 1 shows that the number of possible configurations depends on the value of the external field parameter h. For h small enough (e.g., absolute h less than 2.5 for a material whose $L/L_0=3.2$), there exists three Lagrange–Euler configurations that optimize the energy: these correspond to three maximum angles, θ_{m1}, θ_{m2}, and θ_{m3} (where $\theta_{m1}<\theta_{m2}<\theta_{m3}$). Of these, however, only θ_{m1} and θ_{m3} minimize the energy. (θ_{m2} maximizes the energy.) As h increases negatively, two of the configurations coalesce and disappear leaving only θ_{m3} as an allowed configuration.

Starting from a saturation of the magnetization by a strong field initially in the positive Z direction, let us consider what happens when that field is turned off and then made to increase in the negative Z direction. For h still small (but now pointing in the negative Z direction) the moments relax to the nearest minimum and occupy a configuration defined by θ_{m1} corresponding to a net positive magnetization, (e.g., for $L/L_0=3.2$ and $h=-2$, $\theta_{m1}=75°$). As the field increases in the negative Z direction, the moments stay trapped initially in the θ_{m1} configuration while it remains a secondary minimum of energy. Coincidently, the energy minimum of the θ_{m3} configuration deepens. There exists a field reached wherein θ_{m1} and θ_{m2} coalesce and the associated configuration minimum and maximum disappear. (In our example of $L/L_0=3.2$, this field is given in Fig. 1 as -2.5.) Since θ_{m1} is no longer a valid maximum angle of a stable configuration, the moments are forced to rotate to the lower hemisphere in a nonreversible fashion. Thus, we are justified in calling this the coercive field, h_{coerc}. The value of h_{coerc} is determined uniquely by the value L/L_0, the normalized length of the given material.

Depending on the material, the energy thus released could overcome the surface pinning, leading to an equilibrium configuration in the lower hemisphere, opposite from the initial configuration, with moments pinned along $-Z$. In this case, the symmetry of the problem would clearly yield a symmetrical hysteresis loop. If the energy available is not sufficient to overcome the pinning, then the moments simply rotate (still in a nonreversible way, of course) to the θ_{m3} configuration leading to a nonsymmetrical hysteresis for this particular set of boundary conditions. However, we should point out that, in actual physical situations where pinning at the surface is caused by stresses, etc., there are granules with surface spins pinned "up" and there are granules with surface spins pinned "down," and therefore on the average the hysteresis loop is symmetrical. Thus, except in special circumstances, we should not expect to see this asymmetry.

Figure 2 shows the normalized coercive field as a function of the normalized length for several different anisotropy angles. With increased length, the moments have room to rotate against the exchange and thus h_{coerc} is a decreasing function of length.

(2) *Switching behavior for materials with* $L/L_0<(L/L_0)_c$*:* For this range of lengths, the combination of pinned moments at the surface and short distances prevents the existence of two minima. Thus, for a given h, there exists a unique Lagrange–Euler path of magnetization angles from 0 to θ_m, i.e., the quantity θ_m is a single valued function of h. As the h field is decreased from a positive value to zero and then increased in the negative Z direction, θ_m remains a stable configuration and increases continuously, eventually

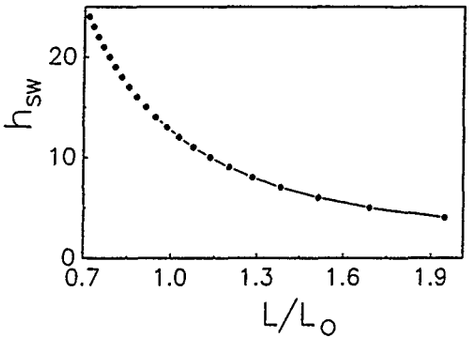

FIG. 3. Reduced switching field as a function of L/L_0 at $\Theta=45°$.

bringing the average magnetization of the materials towards the negative Z axis. We define the switching field, h_{sw}, as the field necessary to bring θ_m to a value of 135° which will bring the magnetization of the material to approximately zero. Assuming that the end moments stay pinned, the process is reversible and the "hysteresis" curve has a vanishing enclosed area. This behavior justifies calling h_{sw} a switching field rather than a coercive field. (One should remark that a coercive behavior of materials with lengths in this range could be achieved by assuming a breakdown of the surface pinning of the moments.) Figure 3 is a plot of the switching fields versus the reduced length for the specific example $\Theta=45°$.

To illustrate further the dependence on the anisotropy angle, we have graphed in Fig. 4 the critical length, $(L/L_0)_c$, as a function of the anisotropy angle. We note that our curve separates the space into two regions. As the anisotropy angle approaches 0°, i.e., as the anisotropy direction becomes parallel to the direction of the applied external field and that of the pinned magnetic moments at the surface, $(L/L_0)_c$ becomes very small and the coercivity mechanism dominates for practically all lengths. The reverse situation occurs as the anisotropy angle approaches 90°. Thus, in a sense, this curve

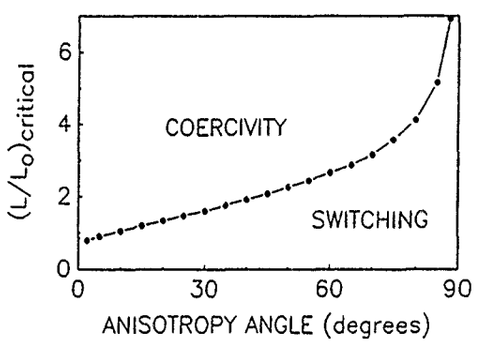

FIG. 4. Critical sample length as a function of anisotropy angle showing the regions of different magnetic reversal mechanism.

represents a "phase transition" with respect to energy dissipation, and to the best of our knowledge is the first time that any quantitative representation of this phenomenon has been given, (although the concept of a switching mode and the absence of hysteresis loops for this mode was pointed out by Gota *et al.*, in 1965[8]). Of course, one must apply caveats to our result such as that the surface moments remain pinned during the reversal process, that there are no material inhomogeneities nor acoustic emission to yield energy dissipation, etc.

We apply our results to iron and cobalt, (using $\Theta=45°$). For iron they show coercivities larger than the theoretical maximum without pinning, i.e., larger than the anisotropy field. For a length of 800 Å we obtain a coercivity of ~400 Oe. At smaller lengths, we are in the switching field regime. At $L=500$ Å, the switching field is ~590 Oe, while at $L=200$ Å, the switching field increases to ~3500 Oe. The coercivity of cobalt gives higher values. For a length of 450 Å, the coercivity is ~3900 Oe, while at $L=150$ Å the switching field is ~11 000 Oe. Fields larger than the anisotropy fields have similarly been observed experimentally in these materials though it is difficult to compare the actual values due to indefinite information regarding the particle dimensions in these experiments.[1-4]

Further, we must consider the experimental dependence of the coercivity on the size of the granules. These experiments show an increase in $Fe_{75}(SiO_2)_{25}$ from 1500 to 3000 Oe as the substrate temperature is increased from about 300 to 800 K, and then a rapid drop beyond this.[1,2] (Increasing substrate temperature is correlated with increasing granule size.) We attribute the initial increase in coercivity to the change from superparamagnetism to ferromagnetism—or, to place it in context with our work, we attribute our continued rise in coercivity, as the length continues to decrease, to the fact that our model does not contain the effect of temperature fluctuations—our calculations being done at 0 K.

The difference in our results compared to those of Schabes and Bertram[4] is of course attributable to our restriction to a one dimensional functional dependence of the magnetization angle and thus the absence of multidimensional demagnetization effects such as flower states, etc. Another major factor is the difference in boundary conditions. We have assumed that stresses and exchange fields have pinned our surface states such that their directions of magnetization are fixed.

Exchange interactions among ferromagnetic clusters in Cu-Co heterogeneous alloy films (abstract)

A. E. Berkowitz
Physics Department and Center for Magnetic Recording Research, University of California at San Diego, La Jolla, California 92093

F. T. Parker and D. Rao
Center for Magnetic Recording Research, University of California at San Diego, La Jolla, California 92093

Sputtered thin films of Cu-Co contain ferromagnetic clusters, even in the as-deposited condition, due to the immiscibility of Co and Cu. This structural heterogeneity is indicated by diffraction data, transport properties, and strongly temperature dependent magnetization and hysteresis behavior. In addition, these films exhibit some unusual properties that suggest the existence of both strong intercluster ferromagnetic exchange interactions and features usually associated with an exchange anisotropy coupling of ferromagnetic and antiferromagnetic materials. Some of these properties are (a) field-cooled samples exhibit strongly shifted hysteresis loops in measuring fields of 7 T, (b) coercive force depends on the magnitude of the cooling field, (c) initial susceptibility measurements given an interparticle ordering temperature >100 K, (d) Curie–Weiss analysis above the interparticle ordering temperatures indicates cluster sizes of a few nm and interparticle molecular fields ≈10 T, (e) fitting the magnetization curves with a Langevin analysis above the interparticle ordering temperatures yields similar cluster sizes and molecular fields. Thus, the films exhibit behavior associated with both "micromagnetism"[1] and "superferromagnetism".[2] We shall discuss our attempts to model this behavior in a consistent manner.

Ferromagnetic resonance studies of granular materials (abstract)

Mark Rubinstein, Badri Das, D. B. Chrisey, J. Horwitz, and N. C. Koon
U. S. Naval Research Laboratory, Washington, D.C. 20375-5000

We have investigated the ferromagnetic resonance (FMR) spectra of several granular alloys displaying giant magnetoresistance (GMR). For this task, we have produced melt-spun ribbons of $Fe_5Co_{15}Cu_{80}$ and $Co_{20}Cu_{80}$ by rapid quenching and thin films of $Co_{80}Cu_{20}$ by pulsed laser deposition. The salient feature of the FMR spectra is the increase of the resonance linewidth as a function of increasing annealing temperature. We have deconvoluted the FMR spectra to a single-domain powder pattern and a multidomain powder pattern. As a function of annealing temperature, the GMR of these samples attains a maximum value. Near the peak of the GMR curve, the FMR spectrum reveals that the ferromagnetic particles are half mono- and half multidomain. Since the maximum size of a single-domain particle is known, this enables us to estimate the spin diffusion length of the Cu conduction electrons. We have also demonstrated, theoretically and experimentally, that the appropriate demagnetizing field to apply to the ensemble of spherical magnetic particles that comprise our granular thin film is simply the field corresponding to the average magnetization.

Magnetic properties of cobalt clusters deposited on MgO substrates by molecular beam epitaxy (abstract)

R. Morel, A. Barthélémy, F. Charrière, J. R. Childress, and A. Fert
Laboratoire de Physique des Solides, Université Paris-Sud, 91405 Orsay Cédex, France

B. Bellamy and A. Masson
Laboratoire de Physico-Chimie des Surfaces, ENSCP 11, rue Pierre et Marie Curie, Paris, France

We report on the preparation and characterization of clusters of Co deposited on MgO(001) and MgO(110) substrates. The preparation is by cell evaporation in ultrahigh vacuum. The size of the clusters is controlled by the substrate temperature and deposition rate or, after deposition, by annealing. This results in clusters with diameters ≈100–1500 Å and heights ≈30–200 Å. The characterization is by Rutherford backscattering, photoemission spectroscopy, and atomic force microscopy. The magnetic properties have been investigated by SQUID magnetometry. Depending on the size of the clusters, we have observed superparamagnetic or ferromagnetic behaviors. When the cluster diameter is much smaller than its height, the magnetization is much easier for in-plane fields, due to the demagnetization energy. In some of the samples, we have combined clusters of Co and nonmagnetic Ag, with sufficient density for metallic percolation, and we present their magnetoresistance properties.

Particle interactions in granular Co films (abstract)

A. Tsoukatos, H. Wan, and G. C. Hadjipanayis
Department of Physics and Astronomy, University of Delaware, Newark, Delaware 19716

The interparticle interactions of hcp-Co particles embedded in silica (SiO_2) and boron nitride (BN) matrices have been studied via isothermal remanence curve measurements. The films were prepared by a combination of dc/rf magnetron sputtering. The strength of the interaction fields was varied as a function of metal content (x_v) and temperature. The average particle size was kept below 10 nm for all the samples investigated. The volumetric fraction of Co was varied between 0.035 and 0.66. Henkel plots[1] (normalized M_r vs M_d plots) showed that in hcp granular Co the interactions are negative, i.e., they have the tendency to destabilize the saturation state. Switching field distribution (SFD) plots showed a decreased width with increasing x_v and temperature. In the low metal volume fraction specimens, magnetizing and demagnetizing SFD curves indicate that the dominant interactions are dipolar in origin due to the fact that they nearly overlap. However, as x_v increases, the presence of exchange interactions is also evident. A detailed discussion of these studies will be presented in an effort to determine the interaction mechanisms controlling the magnetic behavior of these films as compared to existing theoretical models.[2,3]

Giant magnetoresistance (GMR) at room temperature was found in granular thin films such as Co-Cu, Fe-Ag, Co-Ag, etc., which has stimulated intense research activity. It is still unclear whether the as-deposited Ag-rich (75%-90%) thin films are an alloy or are two separate phases. We have investigated the microstructure of granular Ag-Fe and Ag-Co thin films by atomic resolution transmission electron microscopy (TEM) and nanochemical analysis scanning transmission electron microscopy (STEM). Transition metal particles with a size of less than 1.5 nm in the as-deposited granular Ag-rich thin films were directly observed and were separated by the nanosize of Ag particles. The structure of the as-deposited thin films was metastable, and it changed by annealing. The GMR strongly depends on the nanostructure in the films, and their relationship will be discussed.

Measurements are reported of the longitudinal and transverse elastic moduli of the $R_2Fe_{14}B$ compounds having rare-earth component R=Ce, Pr, Nd, and Er. A resonant ultrasound technique was used to determine the elastic constants on hot-pressed, melt-spun samples which are essentially isotropic, polycrystalline specimens of the four compounds. The results for $Nd_2Fe_{14}B$, which agree well with previous studies, and $Er_2Fe_{14}B$ exhibit clear signatures of the spin reorientations which occur in those compounds. No such signature appears in the data for $Pr_2Fe_{14}B$, consistent with the fact that no spin reorientation occurs in that material. The ultrasonic attenuation of each sample has also been measured and it has been found that it shows features in the vicinity of spin reorientations ($Nd_2Fe_{14}B$, $Er_2Fe_{14}B$) and the Curie point ($Ce_2Fe_{14}B$).

Numerous scientific investigations have centered on the structural and magnetic characteristics of the tetragonal $R_2Fe_{14}B$ compounds (R≡rare earth) since the prototypical representative, $Nd_2Fe_{14}B$, is the essential constituent of the most powerful permanent magnets yet developed.[1] The elastic properties of the $R_2Fe_{14}B$ materials have received much less attention. Dadon *et al.*[2] determined the Young modulus, shear modulus, and adiabatic compressibility of polycrystalline $Nd_2Fe_{14}B$ from sound velocity measurements between 77 and 300 K. Shiga *et al.*[3] measured the longitudinal and transverse moduli of $Y_2Fe_{14}B$ and $Nd_2Fe_{14}B$ from 4 K to the Curie temperature T_c, employing sintered samples with highly aligned *c*-axes.

Using a novel resonant ultrasound spectroscopy (RUS) technique,[4] we have determined, and here report, longitudinal and transverse elastic constants and ultrasonic attenuation coefficients as functions of temperature for polycrystalline samples of four $R_2Fe_{14}B$ compounds: $Pr_2Fe_{14}B$ and $Nd_2Fe_{14}B$ (100–200 K), $Er_2Fe_{14}B$ (300–350 K), and $Ce_2Fe_{14}B$ (400–450 K). For the Nd, Er, and Ce materials the temperature intervals were chosen to include the two types of spin reorientation observed in the $R_2Fe_{14}B$ series and a Curie point transition. As T decreases through $T_s \cong 140$ K the easy direction of magnetization in $Nd_2Fe_{14}B$ gradually cants away from the *c* axis toward a ⟨110⟩ basal plane direction by an angle θ which increases to a maximum of $\theta \sim 30°$ at 4 K; a similar transition occurs in $Ho_2Fe_{14}B$ ($T_s \sim 58$ K). In $Er_2Fe_{14}B$ the easy direction abruptly changes from a ⟨100⟩ basal-plane direction below $T_s \cong 323$ K to a ⟨001⟩ direction above T_s; analogous spin reorientations take place in $Tm_2Fe_{14}B$ ($T_s \sim 313$ K) and $Yb_2Fe_{14}B$ ($T_s \sim 115$ K). The Curie temperature of $Ce_2Fe_{14}B$ is $T_c \cong 424$ K.

Samples for this study were prepared by hot-pressing melt-spun R-Fe-B ribbons.[5–7] The RUS method is described elsewhere.[4]

Values of the c_L (longitudinal) and c_T (transverse, or shear) elastic constants for $Pr_2Fe_{14}B$ and $Nd_2Fe_{14}B$ in the 100–200 K temperature interval are compared in Fig. 1. It is evident that (i) $Pr_2Fe_{14}B$ is approximately 4% softer than $Nd_2Fe_{14}B$ and (ii) the moduli for the Nd compound, especially c_T, exhibit anomalous behavior in the vicinity of the

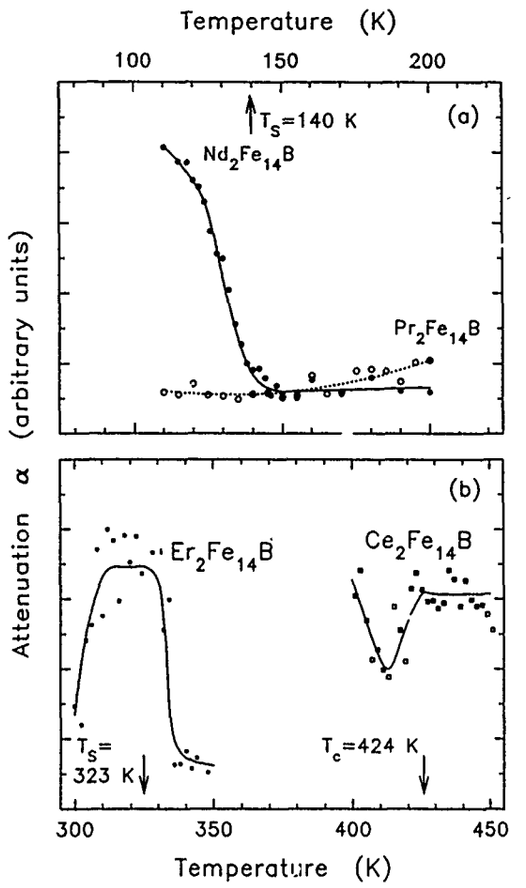

FIG. 4. Ultrasonic attenuation coefficients α of (a) $Pr_2Fe_{14}B$, $Nd_2Fe_{14}B$ and (b) $Ce_2Fe_{14}B$, $Er_2Fe_{14}B$. α is proportional to $1/Q$, where Q of a specific resonance is its center frequency divided by its full width at half-maximum.

spin reorientation temperature $T_s \cong 140$ K. Our results depart by at most 3% from previous work on $Nd_2Fe_{14}B$.[2,3] Since $Pr_2Fe_{14}B$ and $Nd_2Fe_{14}B$ are dissimilar only insofar as the latter exhibits moment canting with an onset at T_s, we can conclude unambiguously that the anomalies in the $Nd_2Fe_{14}B$ results of Fig. 1 are associated intimately with the spin reorientation.

Detailed analysis of anomalies such as those in c_L and c_T of $Nd_2Fe_{14}B$ near T_s must await single-crystal measurements, but we can make some qualitative observations. The relatively strong feature in c_T ($Nd_2Fe_{14}B$) suggests significant magnetoelastic interaction between transverse waves and the order parameter θ for the anisotropy-driven second-order spin reorientation transition. Since $c_L = K + 4c_T/3$ for

TABLE I. Values of the elastic constants c_i, corresponding sound velocities v_i, and densities ρ of the specified $R_2Fe_{14}B$ compounds at 300 K ($c_i = \rho v_i^2$).

Compound	ρ (gm/cm^3)	c_L (GPa)	v_L (10^5 cm/s)	c_T (GPa)	v_L (10^5 cm/s)
$Ce_2Fe_{14}B$	7.60	161.1	4.60	56.3	2.72
$Pr_2Fe_{14}B$	7.36	179.2	4.93	58.4	2.82
$Nd_2Fe_{14}B$	7.57	188.5	4.99	62.0	2.86
$Er_2Fe_{14}B$	8.11	193.8	4.89	65.1	2.83

an isotropic polycrystal, where K is the bulk modulus, the smaller feature in c_L ($Nd_2Fe_{14}B$) observed here likely reflects anomalies in the longitudinal as well as the transverse single-crystal elastic constants. Analyses of single-crystal experiments on orthorhombic ferrites such as $ErFeO_3$ and $TmFeO_3$, which are a^y characterized by rotation of the moment in a plane, have · monstrated that magnetoelastic couplings quadratic in θ can generate step discontinuities and couplings linear in θ can lead to softening of elastic modes.[8,9] We expect similar couplings for $Nd_2Fe_{14}B$ and the other $R_2Fe_{14}B$ systems exhibiting spin reorientations, but with differences introduced by the form of the anisotropy energy for tetragonal lattice symmetry and the specifics of the moment configuration. Moreover, a change in the magnitude of the iron moment μ_{Fe} may be involved; from anomalies in the linear and volume magnetostriction Andreev *et al.*[10] inferred a 2%–3% decrease in μ_{Fe} of $Nd_2Fe_{14}B$ in the spin reorientation region.

In contrast to the $Nd_2Fe_{14}B$ results, c_L undergoes larger excursion than c_T in the neighborhood of T_s for the $\langle 001\rangle \leftrightarrow \langle 100\rangle$ spin reorientation in $Er_2Fe_{14}B$ (Fig. 2). Furthermore, with declining temperature c_L ($Er_2Fe_{14}B$) in Fig. 2 shows a decrease beginning near 325 K and a subsequent increase near 310 K with recovery to the linear contribution which is evident from extrapolation of the $T \geq 330$ K measurements; only a single peak at $T_s \cong 323$ K appears in our DSC data. These features resemble the single-crystal analogs observed by Gorodetsky and Lüthi[8] in $ErFeO_3$, wholse magnetization rotates from the (orthorhombic) c-axis completely into the a direction on cooling. The elastic constants of $ErFeO_3$ (and $TmFeO_3$, in which the rotation is from the a to the c direction on cooling) are anomalous at temperatures T_1 and T_2 corresponding to the onset and the completion of the spin reorientation,[8,9] and on the basis of Landau-type free-energy considerations two second-order phase transitions, one at T_1 and another at T_2 are to be expected.[11] Our results indicate that analogous behavior occurs in $Er_2Fe_{14}B$, c_L exhibiting, over a linear background, a step down at ~325 K and a step up at ~310 K which are smeared by polycrystalline effects; i.e., two second-order phase transitions, separated by only ~15 K, characterize the spin reorientation. This suggestion departs from the prevailing opinion in the literature, based on magnetization and other measurements, that one transition is involved and calls strongly for further single-crystal work on $Er_2Fe_{14}B$.

Only one second-order transition takes place near T_s in $Nd_2Fe_{14}B$, whose spin reorientation is not completed in a symmetry direction. In this respect $Nd_2Fe_{14}B$ resembles elemental gadolinium, the elastic properties of which also exhibit one anomaly in the region of its similarly incomplete spin reorientation.[11,12] It is clear from Fig. 1 that c_T ($Nd_2Fe_{14}B$) shows a single step down as T decreases through T_s and does not recover to the linear behavior for $T > T_s$.

Figure 3 displays our results for $Ce_2Fe_{14}B$ in the 400–460 K interval encompassing $T_c \cong 424$ K. A very large softening of c_L occurs as the temperature decreases through T_c, while c_T shows a much smaller decrease. Essentially identical Curie temperature anomalie were observed by Shiga *et al.*[3] for $Y_2Fe_{14}B$ and $Nd_2Fe_{14}B$, although the moduli of those compounds substantially exceed their $Ce_2Fe_{14}B$ cognates. The softening is undoubtedly associated with the enormous volume magnetostriction (~2%) due principally to the iron sublattice (which, together with ordinary thermal expansion in the paramagnetic range, generates a strong Invar effect in the $R_2Fe_{14}B$ compounds; see, e.g., Ref. 10). Shiga *et al.*[3] have advanced a thermodynamic argument in support of this view which focuses on the difference between the bulk moduli for constant applied field and for constant magnetization.

The attenuation coefficient extracted from a given resonance can also display anomalous behavior near T_s or T_c. Figure 4 shows $\alpha(T)$ obtained from predominantly shear-type modes in each of the four samples. In the 100–200 K range α ($Pr_2Fe_{14}B$) is essentially constant, but α ($Nd_2Fe_{14}B$) increases dramatically with decreasing temperature below an onset at T_s. It is suggestive that $\alpha(T)$ for $Nd_2Fe_{14}B$ strongly resembles $\theta(T)$, the canting angle between the magnetization direction and the c axis as a function of temperature, which has been measured by, among others, Tokuhara *et al.*[13] Somewhat less striking, although still pronounced, features are evident in the attenuation coefficients of $Er_2Fe_{14}B$ and $Ce_2Fe_{14}B$ in Fig. 4(b) near T_s and T_c, respectively.

We conclude b noting an interesting hierarchy which is obeyed by the moduli at 300 K and which we conjecture to persist except possibly in the vicinity of magnetic transitions. Table I lists c_i ($i \equiv L,T$), the corresponding sound velocities v_i, and the density for each of the compounds at 300 K. It is clear that

$$c_i(Ce_2Fe_{14}B) < c_i(Pr_2Fe_{14}B) < c_i(Nd_2Fe_{14}B) < c_i(Er_2Fe_{14}B),$$

so that both the longitudinal and transverse elastic constants of these compounds have the same order as the atomic numbers of their rare-earth constituents, despite the fact that the densities and sound velocities do not.

Work at Los Alamos performed under the auspices of the U. S. DOE.

Comparison of the improvement of thermal stability of NdFeB sintered magnets: Intrinsic and/or microstructural

B. M. Ma, W. L. Liu, Y. L. Liang, D. W. Scott, and C. O. Bounds
Rhône-Poulenc Basic Chemicals, CN 7500, Cranbury, New Jersey 08512

Temperature-dependent magnetic properties of nine NdFeB sintered magnets with various Co-Nb, Co-V, or Co-Mo additions have been measured up to 175 °C using both closed-loop and open-circuit methods. The irreversible loss of induction, reversible temperature coefficient of induction (α), and temperature coefficient of intrinsic coercivity β have been related to the T_c, the B_r, and the H_{ci} at 25 and 175 °C. The irreversible loss of induction is strongly affected by the H_{ci} at 25 °C and the α has been found to be strongly dependent upon the T_c. Intrinsic coercivity of more than 25 and 7.5 kOe at 25 and 175 °C, respectively, are essential to bring the β to better than −0.5%/ °C. A magnet with a composition of $Nd_{12}Dy_3Fe_{70}Co_5Nb_2B_8$ has been found to exhibit an outstanding thermal stability: a B_r of 8.5 kG (comparable to that of $SmCo_5$ sintered magnet) and a H_{ci} of 12.9 kOe when measured at 175 °C. An α of −0.10%/ °C and a β of −0.4%/ °C have been obtained.

I. INTRODUCTION

Potential means to increase the useful operating temperature of NdFeB magnets include raising the Curie temperature T_c or increasing the intrinsic coercivity at 25 °C. The former may be achieved by incorporating Co in the alloy at the cost of reduced intrinsic coercivity and the latter may be obtained by including Dy into the alloy at the cost of decreased maximum energy product BH_{max}. Recently, incorporating V or Mo into magnets containing 5 at. % Co has been reported to increase the intrinsic coercivity H_{ci} at room temperature and to improve the thermal stability.[1,2] Additionally, the microstructure of V-Co or Mo-Co–containing sintered magnets has been drastically modified.[2–5]

It is of interest to compare the temperature-dependent properties of such magnets, using both open- and closed-circuit measurements, with conventional NdFeB magnets. The irreversible loss of induction, the reversible temperature coefficient of induction (conventionally known as α), and the temperature coefficient of H_{ci} (β) of NdFeB magnets are important for magnetic circuit design and are often reported in the literature. However, these values have not been cooperatively related to the more fundamental variables, for instance T_c, or readily measurable magnetic parameters, i.e., the remanence B_r or the H_{ci} of the magnets.

In this article we compare the thermal stability of nine NdFeB magnets with Co-Nb, Co-V, or Co-Mo additions and report their magnetic properties over a temperature range of 25–175 °C with an attempt to relate the irreversible loss of induction, α and β to the more readily measurable magnetic properties: T_c, B_r or H_{ci}. Additionally, an effort was made to identify a composition which yields a B_r equivalent to that of a $SmCo_5$ sintered magnet at 175 °C and maintains a H_{ci} of at least 10 kOe at 175 °C without a significant irreversible loss of induction.

II. EXPERIMENT

Magnets used in this study were prepared from conventionally cast ingots using classical powder metallurgy techniques. All alloys were cast by vacuum induction melting via controlled directional solidification. The cast ingots were then hydrogen decrepitated, evacuated to 2×10^{-2} Torr, and ground to less than 250 μm. The alloy powders were then attrition milled in toluene to an average particle size of approximately 3.0 μm, as measured by a Fisher subsieve sizer (FSSS). Vacuum evaporation was applied to remove toluene from the powder slurry. The dry powders were then packed into rubber molds, magnetized with a peak field of 60 kOe, and pressed cold isostatically to form consolidated pieces. All green compacts were sintered under vacuum in a temperature range from 1095 to 1100 °C for 3 h. A postsintering treatment over a temperature range of 550–650 °C was applied to obtain the optimum H_{ci}.

The T_c was determined by finding the inflection point of the temperature scan of induction using a vibrating sample magnetometer (VSM) under an applied magnetic field of 0.5 kOe. The closed-loop magnetic properties, B_r and H_{ci}, were measured using a Walker hysteresisgraph in conjunction with a temperature box capable of temperatures ranging from −100 to 300 °C. The open-circuit properties, namely the irreversible loss of induction and α, were determined by placing a 3 mm cube of fully magnetized magnets in a VSM under a zero applied field, cycled from 25 to 200 °C at a heating rate of 4 °C/min then cooled to room temperature at the same rate. The ratio of the difference in induction to its original value at 25 °C was determined to be the irreversible loss of induction. The α is determined by calculating the slope of the linear portion (the cooling part) of the temperature scan of induction. Unlike α, the β is determined from the H_{ci} measured at 25 and 175 °C using a closed-circuit measurement.

III. RESULTS AND DISCUSSION

Listed in Table I are the sample identification, the chemical composition in formula form, the T_c, the B_r, and the H_{ci} at 25 and 175 °C, and the irreversible loss and α and β of samples included in this study. The composition of these magnets ranges from a VCM grade with a T_c of 312 °C (sample no. 1) to a magnet containing 17 at. % Co with a T_c of 448 °C (sample no. 8).

As anticipated, incorporating Co into the magnet composition increases T_c by approximately 10 °C for each

atomic percentage of Co addition (from approximately 312 to 360 with 5 at. % of Co addition). However, the addition of Co has typically been limited to below 5 at. % to minimize the negative impact on H_{ci} to maintain a H_{ci} of at least 14 kOe at room temperature. The addition of Nb, V, or Mo appears to change T_c slightly suggesting that the actual Co concentration in the major magnetic phase may be less than that calculated from the alloy composition assuming random substitution of Co for Fe. It is surmised that some of the Co may appear in the grain-boundary region.

A significant loss of induction, as shown in Fig. 1, at 25 °C can be observed by exposing the magnet to a temperature of 200 °C. This loss consists of an irreversible loss that is not recoverable when the magnet is cycled again to below 200 °C, and a reversible loss which is recovered. The irreversible loss of induction of these magnets varies from the 41% of sample no. 1 to less than 5% in sample nos. 3, 5, 6, and 9. In general, magnets exhibiting low irreversible loss of induction all display a H_{ci} of at least 8 kOe at 175 °C. The H_{ci} at elevated temperatures appears to be the dominant factor affecting the irreversible loss of induction. Furthermore, the 41%, 32%, and 26% of irreversible loss of induction in sample nos. 1, 4, and 8 (T_c of 312, 360, and 448 °C, respectively) suggest that T_c has no measurable effect on the irreversible loss of induction.

Unlike the irreversible loss of induction, the reversible temperature coefficient of induction (α) appears to be strongly dependent upon T_c and weakly determined by the intrinsic coercivity, as shown in Figs. 2(a) and 2(b), as evi-

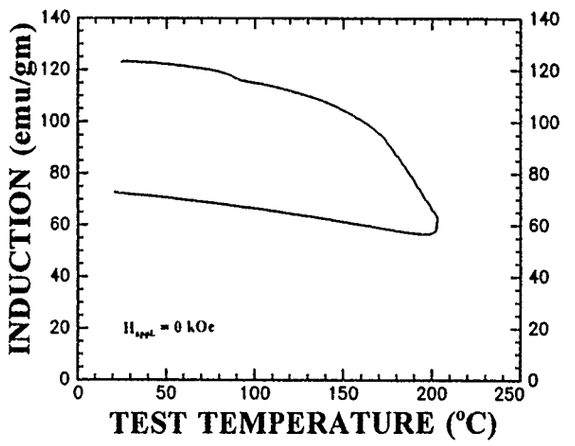

FIG. 1. A temperature scan of induction of a 3 mm cube sintered magnet under a zero applied magnetic field showing the irreversible loss of induction and the reversible induction after exposing to a temperature of 200 °C.

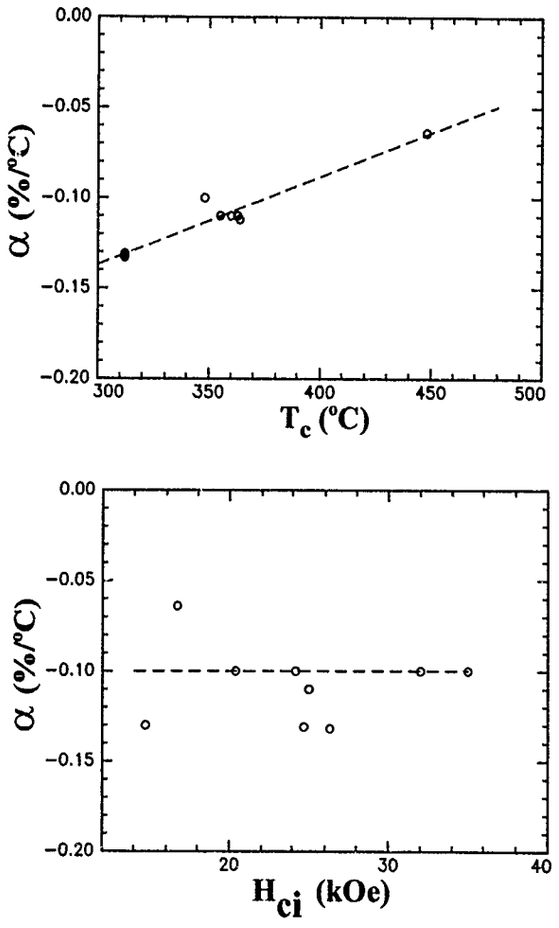

FIG. 2. The relationship of reversible temperature coefficient α to (a) a linear correlation with Curie temperature T_c and (b) a weak correlation with H_{ci} at 25 °C of NdFeB-type magnets.

denced by the α of -0.130 and -0.064 %/ °C of samples no. 1 (T_c of 312 °C and H_{ci} of 2.2 kOe at 175 °C) and no. 8 (T_c of 448 °C and H_{ci} of 3.2 kOe at 175 °C), respectively. Based on these results, it can generally be stated that magnets with a higher T_c (through Co addition) usually exhibit a lower α than those of lower T_c (without Co addition). The conventional temperature coefficients of H_{ci} (β) of samples studied are also included in Table I for comparison. They range only from -0.4 to -0.6 %/ °C regardless of the T_c. The general trend is that magnets of lower magnitude of β all exhibit a relative high H_{ci} at both 25 and 175 °C. Regardless of the alloy composition, an H_{ci} of more than 25 kOe appears to be necessary to assure an H_{ci} higher than 8 kOe at 175 °C. Despite the fact that V or Mo addition in the Co-containing alloys does slightly increase the H_{ci} at room temperature and even at elevated temperatures, it may not be the most effective means to raise H_{ci} at elevated temperature. Comparing the H_{ci} of 26.3 kOe at 25 °C and more than 30 kOe of samples no. 3 (0% Co), no. 6 (5% Co, 2% Nb), no. 7 (5% Co, 4% V), and no. 9 (5% Co, 2% Mo), respectively, it may be deduced that Dy is even more effective in increasing the H_{ci} at room temperature and in maintaining the H_{ci} at 175 °C. This is evidenced by the results that magnets exhibiting an H_{ci} of more than 8 kOe at 175 °C all contain at least 3 at. % of Dy. The fact that sample no. 3 contains no Co at all suggests that V or Mo addition into Co-containing magnets is beneficial but may not be necessary for obtaining high H_{ci} (and high B_r) at elevated temperatures.

While it is desirable to have a low irreversible loss and low magnitude of α, it is more meaningful to measure the B_r and the H_{ci} values at the desired operation temperature. Instead of plotting all data obtained in this study, representative samples are selected for illustration. Shown in Figs. 3(a) and 3(b) are the variation of B_r and H_{ci} with the test temperature for four selected samples, namely, sample nos. 1, 4, 6, and 7. Conventional VCM magnets (sample no. 1) exhibit the highest B_r but the lowest H_{ci} at 175 °C while sample no. 6 exhibits an H_{ci} of more than 10 kOe with a B_r=8.5 kG at 175 °C. The B_r of 8.5 kG at 175 °C is comparable to or better than that of $SmCo_5$ at the corresponding temperature (B_r of 8.8 and 8.2 kG at 25 and 175 °C, respectively). At 175 °C, the B_r and the H_{ci} of the Co-V–containing magnet (sample no. 7) all fall in between those of sample nos. 1 and 6. This suggests that the modification of microstructure may increase the H_{ci} to a reasonable level but the key success for achieving high H_{ci} at elevated temperature may still be the fundamental (or the intrinsic) issue—increasing the H_{ci} by raising the anisotropy field through Dy addition.

IV. CONCLUSIONS

Temperature-dependent magnetic properties, namely, the irreversible loss of induction, the B_r, the H_{ci}, the α, and the β of nine NdFeB magnets with Co, Co-Nb, Co-V, or Co-Mo addition have been measured over the temperature range of 25 through 175 °C. We have found that a high H_{ci} at 175 °C is essential for low irreversible loss and a higher T_c is beneficial for α. For magnets of similar T_c those exhibiting higher H_{ci} (or lower B_r) usually display a higher α value.

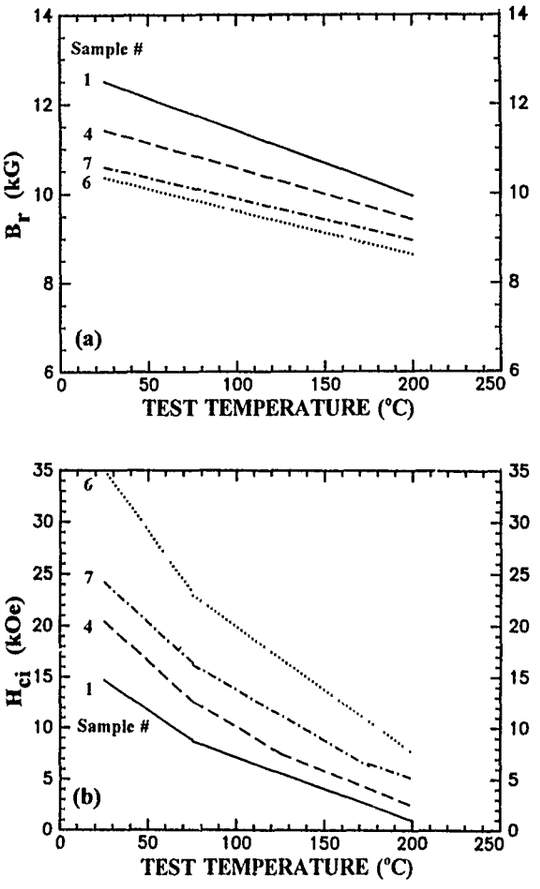

FIG. 3. Variation of (a) B_r and (b) H_{ci} of $(Nd_{14}Dy_1)$ $FeNb_{0.7}B_7$ (sample no. 1), $(Nd_{13}Dy_2)$ $FeCo_5Nb_{0.7}B_7$ (sample no. 4), $(Nd_{13}Dy_2)$ $FeCo_5V_4B_7$ (sample no. 7) and $(Nd_{13}Dy_3)$ $FeCoNb_2B_8$ (sample no. 6) with test temperature.

Regardless of alloy composition, an H_{ci} of more than 25 kOe is necessary to obtain a β of less than -0.51%/ °C. A Dy content of more than 3 at. % in the final magnet is more advantageous for obtaining a high B_r and H_{ci} at elevated temperatures than additions of Co-V or Co-Mo. A magnet with a composition of $Nd_{12}Dy_8Fe_{70}Co_5Nb_2B_8$ has been found to exhibit a B_r of 8.5 kG (superior to that of $SmCo_5$ sintered magnets) and an H_{ci} of 12.9 kOe at 175 °C.

Mechanical properties of hot-rolled Pr-Fe-B-Cu magnets

A. Arai, O. Kobayashi, F. Takagi, K. Akioka, and T. Shimoda
Advanced Materials R&D Department, Seiko Epson Corporation, 3-3-5 Owa, Suwa-shi, Nagano-ken 392, Japan

Mechanical strength and properties of thin plates were investigated for hot-rolled Pr-Fe-B-Cu magnets. Tensile strengths of the hot-rolled magnets were more than 23.7 kg f/mm^2. Bending tests were also applied and the strength of 37.7 kg f/mm^2 was obtained. The strengths obtained are definitely higher than that of commercial Nd-based sintered magnets. It was found that the mechanical strengths were enhanced by $Pr_2Fe_{14}B$ grain refinement caused by Cu addition. Related to high mechanical strength, hot-rolled Pr-Fe-B-Cu magnets show excellent machinability. Thin plate magnets up to 0.1 mm in thickness with fairly large surface area were produced without any cracking. Moderate energy products better than 20 MGOe were achieved by heat treatment after machining.

I. INTRODUCTION

In our previous articles[1,2] we introduced a new method for producing high-energy Pr-Fe-B-Cu magnets by hot working cast alloys. Columnar cast structure having fine grains was determined to be important to achieve high magnetic properties.

Hot-rolled Pr-Fe-B-Cu magnets have several unique characteristics because of their manufacturing method and composition. First, hot rolling is the most suitable method for making large-sized magnets. Second, the corrosion resistance is higher than that of sintered magnets because of the lower contamination of oxygen and the absence of voids. Third, pieces of magnets can be easily joined by liquid-phase bonding.[3]

In addition to these characteristics, this article especially focuses on the mechanical properties such as mechanical strength and machinability, and discusses the properties as compared to those of sintered magnets.

II. EXPERIMENTAL PROCEDURE

The alloys investigated were prepared using an induction furnace. The raw materials used were Pr (99 wt % pure), Fe (99.9 wt % pure), Cu (99.9 wt % pure) , and 20 wt % B-80 wt % Fe. An alloy ingot was packed into a steel capsule and then rolled at 950 °C up to 75% reduction. After rolling, the magnets were heat treated under an Ar atmosphere. For microstructural study, optical microscopy, and scanning electron microscopy (SEM) were utilized. Electron probe microanalysis (EPMA) was also used for compositional analysis of the microstructure. Tensile tests were applied using the Shimazu model AG-2000D. In the tensile tests, the cross-head speed was 0.5 mm/min. Tensile direction was the same as the rolling direction. Three-point bending tests were also applied. The sample size was 6×6×40 mm.[3] Bending direction was parallel to the press direction of the magnets. Magnetic properties were measured on a dc magnetic hysteresis loop tracer under a maximum magnetizing field of 25 kOe. Thin plate magnets were evaluated using a vibrating sample magnetometer (VSM) under a maximum field of 15 kOe.

III. RESULTS AND DISCUSSION

Figure 1 shows a SEM backscattered image of $Pr_{17.0}Fe_{76.3}B_{5.2}Cu_{1.5}$ magnet which was subjected to a two-step heat treatment (20 h at 1025 °C and 6 h at 500 °C) after rolling. A comparatively large amount of the intergranular phases is observed.[4] The microstructure consists of three phases labeled as (a), (b), and (c) in the figure. EPMA analysis of the phases was performed, and the phases (a), (b), and (c) appeared to be $Pr_2Fe_{14}B$ phase, $Pr_6Fe_{13}Cu$ phase, [5] and Pr-Cu-rich phase, respectively. Figure 2 shows the relation between iH_c and the temperature of the second treatment (designated as T) for a two-step heat treatment such as 1025 °C for 20 h+T °C for 2 h. High coercivities were obtained in the temperature range from 450 to 650 °C, causing $Pr_6Fe_{13}Cu$ formation and $Pr_2Fe_{14}B$ phase separation.[5]

Tensile tests were applied to the $Pr_{17.0}Fe_{76.3}B_{5.2}Cu_{1.5}$ magnets with tensile strengths of more than 23.7 kg f/mm^2 being obtained. Commercial Nd-based sintered magnets show tensile strengths of about 8 kg f/mm^2.[6,7] Therefore, hot-rolled magnets are about three times as strong as the sintered magnets. A SEM micrograph of the fracture surface after a tensile test is shown in Fig. 3. The fracture surface of the

intergranular region forms a dimplelike fracture, suggesting that the fracture in the region was a ductile one. In view of the microstructure and the fracture surface, the Pr-Cu-rich phase seems to permit the ductile fracture, contributing to high tensile strength.

Three-point bending tests were also applied to these magnets. The bending strength obtained was 37.7 kg f/mm^2, and is larger than that (25 kg f/mm^2) of commercial Nd-based magnets.[6,7] Nd-based sintered magnets generally contain voids formed in the sintering process. For hot-rolled magnets, however, such voids are not observed in the microstructure as shown in Fig. 4. This is because the magnets were not produced by using any powder metallurgical process, but by hot rolling alloys having a liquid phase under high isostatic pressure.

Cu content dependence of bending strength was also investigated in $Pr_{18.5-x}Fe_{76.3}B_{5.2}Cu_x$ (x=0, 0.6, 1.5) magnets. Cu-free ternary $Pr_{18.5}Fe_{76}B_{5.2}$ magnet showed only 28.9 kg f/mm^2 as illustrated in Fig. 5. Figure 6 shows that the $Pr_2Fe_{14}B$ grains of the ternary magnet are larger than those of the Cu added magnet. The large grains prevent the ternary magnets from achieving high strength. In addition, the ductile Pr-Cu-rich phase, formed in Cu-added magnets, does not exist in Cu-free magnets. The low strength in Cu-free magnets is caused by the large grain size and the lack of the ductile phase.

Compressive strength and Poisson's ratio were also measured for the $Pr_{17.0}Fe_{76.3}B_{5.2}Cu_{1.5}$ magnet. The results are listed in Table I. Among these mechanical properties, tensile strength is the most remarkable in comparison with that of sintered magnets. On the other hand, compressive strength is not higher than that of the sintered magnets. It seems that the change in intergranular phases does not influence the compressive strength very much.

Hot-rolled Pr-Fe-B-Cu magnets have such excellent machinability that thin plates up to 0.1 mm in thickness are produced without cracking. Demagnetization curves of the thin plate magnets are shown in Fig. 7 (0.25 and 0.1 mm in thickness). The direction of easy magnetization is normal to the plate. Magnetic properties measured by VSM were corrected by adopting the demagnetization factor: N=0.9. $(BH)_{max}$=18.8 MGOe and iH_c=15.0 kOe were obtained for the 0.25-mm-thick magnet. The same properties of the 0.1-mm-thick magnet, however, deteriorated severely due to the damage induced during machining. In order to recover the properties, a heat treatment (2h at 600 °C) was performed in vacuum. The demagnetization curves after the heat treatment are shown in Fig. 8. The magnetic properties obtained were greatly recovered. Even in the 0.1-mm-thick magnet, $(BH)_{max}$=20.9 MGOe was obtained, and intrinsic coercivity was also enhanced up to 14.8 kOe. SEM observations revealed that the damaged surface caused by machining turned into a relatively flat surface after the heat treatment. It seems that the Pr-Cu-rich phase, having a low melting point, became liquid during the heat treatment and removed the defects which had been formed on the $Pr_2Fe_{14}B$ grains. Therefore, high coercivities were obtained. Although a similar recovery effect in sintered magnets had been reported, the recovery was achieved up to much higher S/V (S: surface area; V: volume) in the hot-rolled magnets than in the sintered magnets.[8]

Magnetocaloric dependence of magnetic viscosity measurements in NdFeB

L. Folks, R. Street, R. Woodward, and P. G. McCormick
Research Centre for Advanced Mineral and Materials Processing, The University of Western Australia, Nedlands 6009, Australia

Measurements of the time dependence of magnetization may be analyzed by means of a constitutive equation to give information regarding the fundamental nature of magnetization reversal processes. The quantity Λ ($\equiv$ the fluctuation field H_f) may be measured and then related to the activation volumes involved in the magnetization reversal processes. These measurements are commonly made at or near room temperature for hard permanent magnet materials, since this is the usual operating temperature, and the system is assumed to be isothermal. However, the experimental work described shows for these materials the magnetocaloric effect (MCE) cannot be neglected at these temperatures. Magnetic viscosity measurements have been made in two ways which lead to different thermal behavior in the sample. Thermometric measurements were made concurrently with the magnetic viscosity measurements in a sample of sintered NdFeB. The measurements show that the calculated value of Λ can be changed by as much as 10% when isothermal conditions do not hold. This effect is particularly evident near room temperature in NdFeB-type materials because of the strong dependence of coercivity on temperature and the proximity to the Curie point (T_c~620 K) where reversible and irreversible components of MCE peak.

I. INTRODUCTION

Measurements of time dependence of magnetization, or magnetic viscosity, may provide useful information regarding the intrinsic magnetization reversal behavior in bulk materials. In permanent magnet materials, such as $Nd_2Fe_{14}B$, room-temperature measurements show significant time dependence of magnetization arising from the thermal activation of metastable magnetization events. Analysis and interpretation of viscosity data gives information regarding the origin of reversal events.

When a field is applied to a magnetic material under adiabatic conditions such that the magnetization changes, heat is evolved or absorbed in a reversible manner. This heat is manifested as an increase or decrease in the temperature of the sample which is known as the magnetocaloric effect (MCE). Andreenko *et al.*[1] attribute this "reversible MCE" to two effects, the changes in exchange energy and the changes in the magnetic anisotropy energy. The first effect will be greatest at temperatures close to the Curie point T_c where the changes in rotational behavior are pronounced. The second effect is in general smaller and becomes significant when the magnetocrystalline anisotropy constant changes rapidly with temperature.

In addition to these reversible effects, magnetically ordered materials will show irreversible thermal effects induced by irreversible changes in the magnetization. Events which might give rise to these changes include irreversible domain-wall movements and irreversible magnetization rotations. These effects give rise to the "irreversible MCE."

Because NdFeB-type materials have values of T_c close to room temperature it is possible to detect substantial reversible and irreversible MCE at ambient temperatures. The measurements described here, while not being strictly adiabatic, show that these effects have a substantial impact on measurements of magnetic viscosity. These results are discussed in light of the constitutive equation developed by Estrin, McCormick, and Street[2] for the description of magnetic state.

II. EXPERIMENT

All magnetic measurements were made using a vibrating sample magnetometer in conjunction with a 50 kOe superconducting solenoid. A cryostat was available to maintain the ambient sample temperature during the measurements, which have all been made at or near room temperature. A variety of sintered NdFeB-type materials supplied by Sumitomo Special Metals, Japan, and Electron Energy Corp., USA, has been used in this work. The magnetic viscosity tests were performed on spherical samples (demagnetization factor of $4\pi/3$ in Gaussian units) mounted in epoxy resin. To record changes in sample temperature a copper-constantan thermocouple was spot welded to the surface of the sample.

Magnetic viscosity measurements were performed in two ways. First is the multiple step per loop measurement technique (MS): (a) sample cycled in saturating field to establish a consistent magnetic state; (b) field ramped from $+H_{max}$ to the first measurement field, $-H_a$; (c) magnetization changes recorded at constant $|H_a|$ for a set period of time t_1 (here $\sim 10^2$ s); (d) field increased to next measurement field $|H_a+\Delta H_a|$, and the process repeated.

The second is the single step per loop measurement technique (SS): as for MS except that after (c) the field was ramped to $-H_{max}$ and then returned to $+H_{max}$, before establishing a new measurement field.

The results of both types of experiment have been analyzed in the manner described in Street, McCormick, and Folks[3] where it is assumed that the magnetic state of the material may be described as a function of the irreversible magnetization M_{irr}, the internal field H_i, and the time rate of change of irreversible magnetization $\dot{M}_{irr}$,

$$dH_i=(1/\chi^i_{irr})dM_{irr}+\Lambda d \ln \dot{M}_{irr}, \quad (1)$$

 0021-8979/94/75(10)/6634/3/$6.00 © 1994 American Institute of Physics

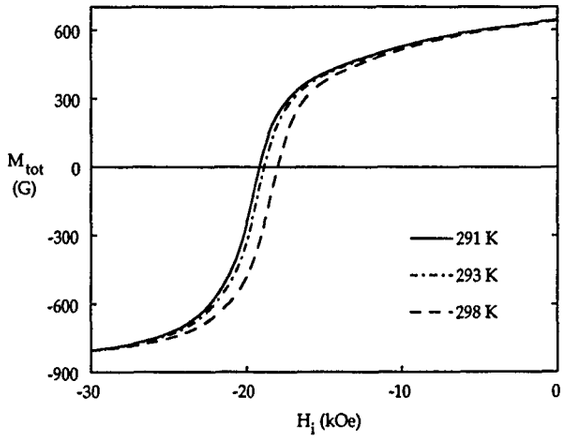

FIG. 1. M_{tot} vs H_i for $Pr_2Fe_{14}B$ at 291, 293, and 298 K, showing the large shift near H_c.

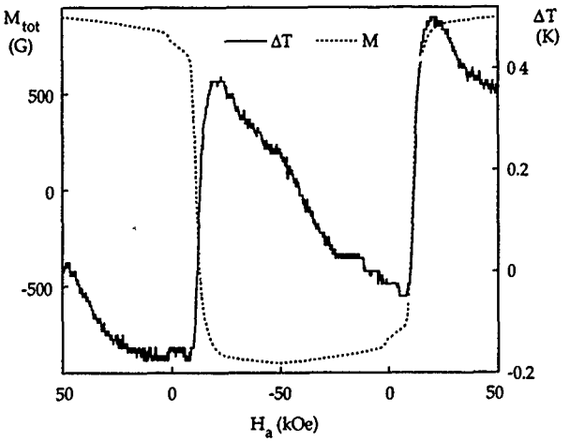

FIG. 2. Variation of M_{tot} and ΔT as H_a is cycled from +50 to −50 kOe at $\dot{H}_a$=450 Oe/s for a sample of sintered $Nd_2Fe_{14}B$ at an ambient temperature of 293 K.

where $\chi^i_{irr}=(\partial M_{irr}/\partial H_i)|_{\dot{M}_{irr}}$ is the intrinsic irreversible susceptibility and $\Lambda=(\partial H_i/\partial \ln \dot{M}_{irr})|_{M_{irr}}$.

The quantity Λ may be related to an activation volume v by the expression

$$\Lambda=(k_BT/vM_s), \tag{2}$$

where M_s is the spontaneous magnetization of the material, T is the temperature, and K_B is the Boltzmann factor. The determination of Λ was found to be independent of many of the experimental conditions, including the rate of change of the applied field between steps $\dot{H}_a$, the time over which the magnetic viscosity is recorded t_1, and the field interval between steps ΔH_a, in the ranges available.

Hysteresis curves of NdFeB-type materials exhibit marked changes in coercivity H_c with T near room temperature. Figure 1 shows the total magnetization M_{tot} versus internal field H_i curves with $\dot{H}_a$=450 Oe/s for a sample of $Pr_2Fe_{14}B$ (T_c~595 K) at ambient temperatures of 291, 293, and 298 K. The value of H_c (taken as the field at which the maximum value of susceptibility occurs) decreases by 1260 Oe between 291 and 298 K (~0.87%/K), slightly higher than the value of 0.7%/K reported by Strnat.[4] For the determination of Λ, however, it is more appropriate to consider the change in M at a fixed value of H_i for a given change in ambient temperature. For this material at H_i=−19.1 kOe (~H_c), M_{tot} changes by ~330 G between 291 and 298 K.

However, a simple calculation to approximate the MCE for the demagnetizing curve [using the expression $\Delta T=(\rho s)^{-1}\int H\,dM$, where ρ is the density and s is the specific heat] suggests that the temperature of the sample increases by ~0.9 K over this part of the curve under adiabatic and isobaric conditions. To measure the actual effect under experimental conditions a thermocouple was attached to a sample of anisotropic sintered $Nd_2Fe_{14}B$ (T_c~620 K) and the changes in temperature were monitored as the sample was cycled around the hysteresis loop. For this material H_c varies by 0.72%/K near room temperature. Figure 2 shows the measured change in sample temperature as the field was cycled at $\dot{H}_a$=450 Oe/s. Initially T decreases slightly between +50 and 0 kOe, but near coercivity there is a sudden increase in T of ~0.5 K, comparable to the calculated figure, given that some heat will be lost to the environment. The total change in temperature as the specimen is taken around a loop is ~0.36 K.

Measurements of ΔT were made on the same sample as MS and SS experiments were conducted. Figure 3(a) illustrates the variations in T as a SS experiment was performed, with five steps at 1 kOe intervals, at $\dot{H}_a$=450 Oe/s and an ambient temperature of 293 K. The sample was allowed to come to thermal equilibrium with the experimental environment before the measurement started. Again the initial part of each loop was accompanied by a decrease in T, followed by an increase in T in the second quadrant. During the first viscosity measurement T continued to rise, but during each of the subsequent steps T decreased. However, at the start of each loop the values of T varied only by ~0.3 K and at the start of each viscosity measurement T varied by only ~0.05 K. Figure 3(b) gives the equivalent data for a MS experiment under similar conditions, along with the corresponding changes in M. In this case T does not vary much over the duration of the viscosity measurements for steps after the first one, but the T at the beginning of each step drifts upward. For this material Λ from the SS measurement was ~7% smaller than from the MS measurement.

Conventional MS and SS measurements (without an attached thermocouple) were made on a variety of sintered NdFeB-type materials in spherical form mounted in epoxy resin. The values of Λ derived consistently differed, by as much as 14%, for the two methods, as shown in Fig. 4 for the sample of $Pr_2Fe_{14}B$ at an ambient temperature of 293 K. It may be seen that the form of the data is similar but that the values differ by ~10% near H_c. Similar results were found for a range of sintered NdFeB-type materials. However, there is no discernible difference in values of Λ derived from experiments at different ambient temperatures near room temperature where the experimental method is the same. Moreover, MS and SS tests on CrO_2, for which T_c~390 K, gave identical values of Λ within experimental error.

Examination of the MS and SS data for NdFeB materi-

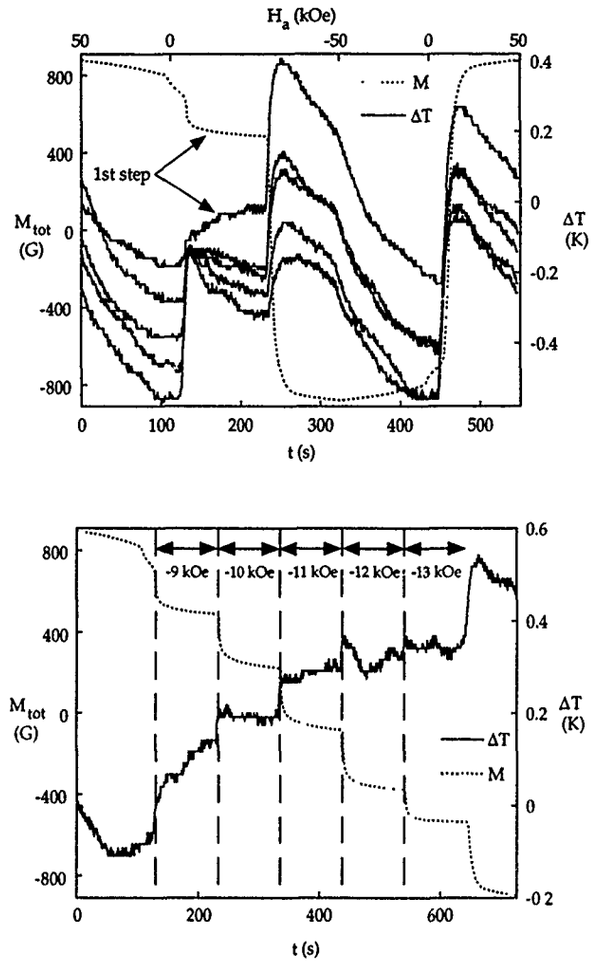

FIG. 3. Variation of M_{tot} and ΔT as a function of time t during (a) a SS experiment (M_{tot} shown for first step only) and (b) a MS experiment, on the sample of $Nd_2Fe_{14}B$ at an ambient temperature of 293 K. The period during which magnetic viscosity is measured is indicated.

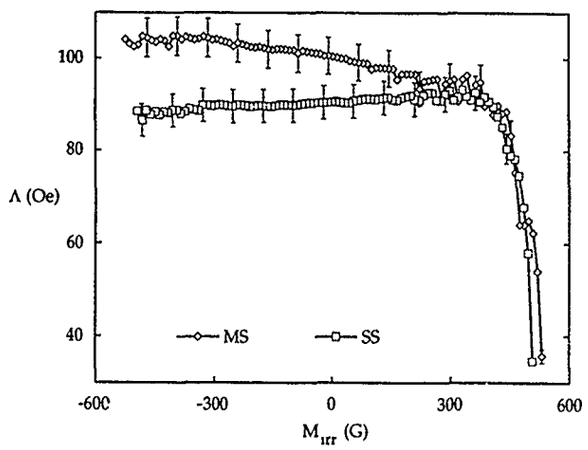

FIG. 4. Λ vs M_{irr} derived from MS and SS experiments on the sample of $Pr_2Fe_{14}B_2$. Experimental error bars are shown (~4%) for some of the data.

als, including the portions of the loops between the steps, shows that associated with the changes in sample temperature are significant deviations from the hysteresis curve at the same ambient temperature, and these are found to be dependent on H_a.

III. SUMMARY

The observation of changes in temperature associated with irreversible changes in magnetization is unsurprising and particularly striking measurements have been made by Otani *et al.*[5] in NdFeB at 2.5 K, where temperature changes associated with individual Barkhausen events have been recorded. Here, the impetus for measuring changes in sample temperature as viscosity measurements were being made arose from the observation that values of Λ, while independent of most experimental conditions, were consistently different from experiments in which the sample was cycled in a saturating field between each measurement of viscosity.

For both the MS and SS experiments, measurement of T during the first magnetic viscosity measurement gives the same result, an increase of ~0.1 K. At the beginning of this step the sample temperature is close to the ambient experimental temperature and the MCE associated with the magnetic viscosity leads to an increase in T. After the first step the thermal behavior of the sample differs between the two methods. For the MS method T does not vary by much during the viscosity measurement but for the SS method T decreases by varying amounts during each step. These differences arise from the balances between MCE, from both magnetic viscosity and changes in the applied field, and heat loss to the environment.

For all the NdFeB-type materials measured, Λ from SS measurements was ~10% smaller than that from MS measurements for a given ambient T. The thermometric measurements described here show that this may be accounted for by the different thermal behavior of the sample during magnetic viscosity experiments carried out under MS and SS conditions. Changing the ambient T in the range 291–298 K produced no change in Λ where the experimental method was the same. Similar experiments on a sample of CrO_2 showed no change in Λ with method, commensurate with the smaller energies associated with magnetization reversal in this material and the low T dependence of H_c near room temperature. That Λ should be critically dependent on changes in temperature during the measurement is clear from the definition [Eq. (1)]; Λ is proportional to changes in H, but for NdFeB, H is strongly dependent on T.

In order to eliminate magnetocaloric induced effects it is necessary to ensure that magnetic viscosity measurements of NdFeB-type materials are carried out under isothermal conditions. Nonisothermal results should be viewed with some caution.

Die-upset $PrCo_5$-type magnets: Enhanced coercivities

C. D. Fuerst and E. G. Brewer
Physics Department, GM Research and Development Center, Warren, Michigan 48090-9055

Rare-earth–cobalt alloys have been melt spun, yielding ribbons whose major phase was the hexagonal $PrCo_5$ phase. Fully dense hot-pressed magnets with essentially isotropic magnetic properties have been formed by consolidating the ribbons at high temperatures and pressures. The hot-pressed precursor was then subjected to hot deformation or die upsetting, thereby inducing partial alignment of the *c* axis along the press direction. The resulting magnets had remanences approaching ~75% of the saturation magnetization of the hexagonal $PrCo_5$ phase. Three approaches were used to optimize the coercivity of the die-upset magnets: (i) replacing small amounts of cobalt with carbon; (ii) partially substituting samarium for the praseodymium; and (iii) high-temperature heat treatment followed by a thermal quench. Coercivities near ~20 kOe were achieved with thermally quenched die-upset $(Pr_{0.6}Sm_{0.4})_{18}Co_{81}C$ magnets, while maintaining remanences above 8 kG.

There continues to be considerable scientific and technical interest in rare-earth–cobalt permanent magnets,[1,2] primarily for their high Curie temperatures and high magnetocrystalline anisotropies. Although similar to $SmCo_5$ in many respects, $PrCo_5$ has not been as successfully exploited as a permanent magnet material despite reports of sintered magnets with relatively high remanences (~10.5 kG) and energy products (26.2 MGOe).[3] This is largely due to the relatively low coercivity ($H_{ci}\approx5$ kOe) of sintered $PrCo_5$-type magnets.[4–6] Higher coercivities ($6<H_{ci}<10$ kOe) have been reported for melt-spun $PrCo_5$ ribbons,[7–10] but like melt-spun $Nd_2Fe_{14}B$ ribbons,[11] they are crystallographically isotropic with remanences ($B_r\approx6$ kG) of about half the saturation magnetization ($4\pi M_s\approx12$ kG) of the primary phase.[1]

Recently we have shown that the remanences of melt-spun $PrCo_5$ alloys[12] can be enhanced by thermomechanical alignment or die upsetting,[13] using techniques first developed for melt-spun $Nd_2Fe_{14}B$ alloys.[14] In the first step of the process, the Pr-Co ribbons are confined to the cavity of a hot die and isostatically pressed, causing ribbon fragments to deform and fill the surrounding voids. This consolidates the ribbon fragments and results in a fully dense isotropic magnet. For example, hot pressing ribbons of the composition $Pr_{18}Co_{82}$ (see Fig. 1) yielded a magnet with a density of 8.3 g/cm^3 and a remanence of just over 6 kG, both of which coincide with the values expected for an isotropic $PrCo_5$ magnet. The hot-pressed magnet can then be used as a precursor in the second process step (die upsetting), where the reheated sample is placed in an oversized die and plastically deformed by applying a uniaxial force. The degree of alignment produced during die upsetting depends on the level of deformation; we found that reducing the sample height by a little over 50% produced a remanence of ~8.3 kG in the $Pr_{18}Co_{82}$ magnet (see Fig. 1). This remanence represents a ~35% increase relative to the remanence of the hot-pressed precursor. As with die-upset Nd-Fe-B magnets, the remanence enhancement occurred parallel to the press direction (perpendicular to the direction of material flow). X-ray diffraction from the surface of the die-upset Pr-Co magnets has confirmed the crystallographic alignment of the *c* axes along the press direction.

Unfortunately, the coercivities of our binary Pr-Co melt-spun magnets, like their sintered counterparts, have remained relatively low ($H_{ci}\approx3$ kOe). In this article we summarize our efforts to optimize the coercivities of this class of permanent magnets. For example, postpress heat treatments, particularly quenching from high temperatures, can produce varying degrees of enhancement in H_{ci}; as Fig. 1 shows, the coercivity of the die-upset magnet increased by ~15% after quenching from 800 °C. In addition to heat treatments, adding carbon and samarium to the alloys can also enhance the coercivities of melt-spun $PrCo_5$-type magnets. Experimental details have been presented elsewhere.[15]

Improving coercivity by adding or substituting elements into the alloy is almost always accompanied by a decrease in remanence. At most concentrations the addition of carbon to Pr-Co alloys ($Pr_{18}Co_{82-x}C_x$) is no exception to this tradeoff.

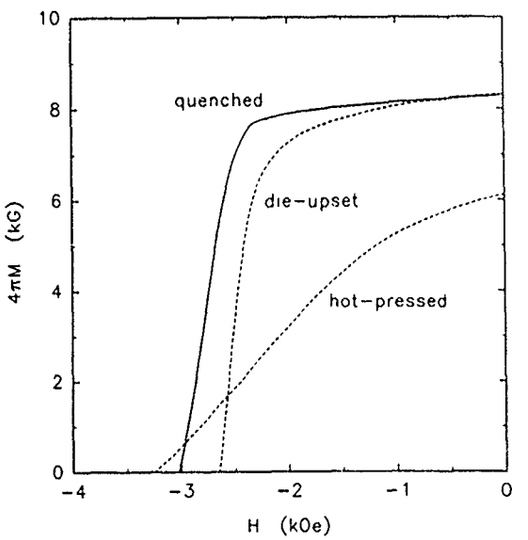

FIG. 1. Demagnetization curves for hot-pressed, die-upset, and quenched die-upset magnets having the composition $Pr_{18}Co_{82}$. The (dashed) curves labeled hot pressed and die upset were obtained from as-pressed magnets. The (solid) curve labeled quenched was obtained from a die-upset magnet heated to 800 °C before quenching in an oil reservoir. The die-upset (DU) level was 53%.

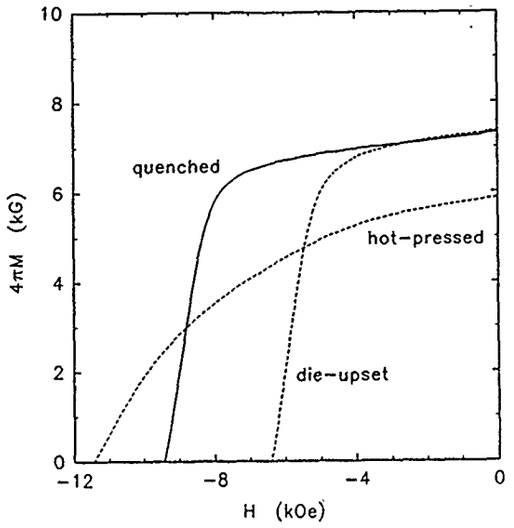

FIG. 2. Demagnetization curves for hot-pressed, die-upset, and quenched die-upset magnets having the composition $Pr_{18}Co_{78}C_4$. The (dashed) curves labeled hot pressed and die upset were obtained from as-pressed magnets. The (solid) curve labeled quenched was obtained from a die-upset magnet heated to 800 °C before quenching in an oil reservoir. The die-upset (DU) level was 53%.

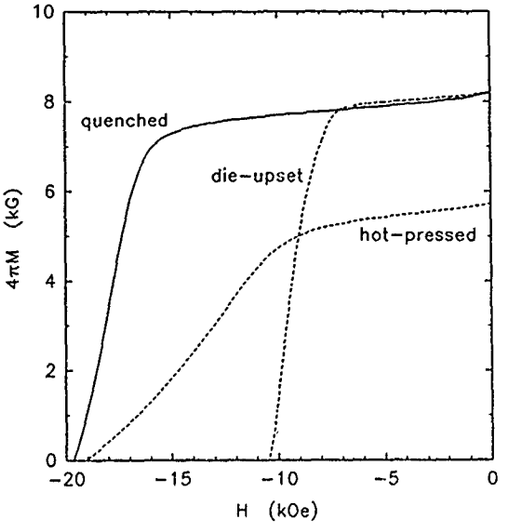

FIG. 4. Demagnetization curves for hot-pressed, die-upset, and quenched die-upset magnets having the composition $R_{18}Co_{78}C$ where $R=(Pr_{0.6}Sm_{0.4})$. The (dashed) curves labeled hot pressed and die upset were obtained from as-pressed magnets. The (solid) curve labeled quenched was obtained from a die-upset magnet heated to 800 °C before quenching in an oil reservoir. The die-upset (DU) level was 53%.

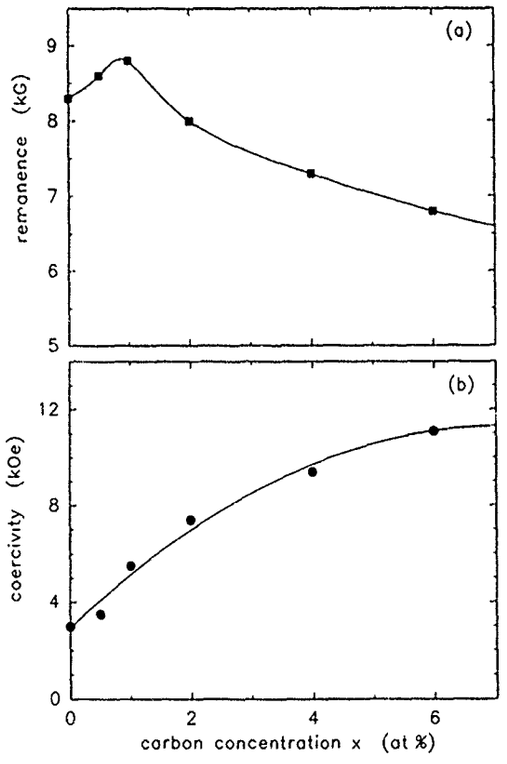

FIG. 3. (a) Remanence and (b) coercivity of die-upset $Pr_{18}Co_{82-x}C_x$ magnets vs carbon concentration x. To maximize coercivity, the die-upset magnets were first heated to 800 °C before quenching in an oil reservoir. The die-upset (DU) level was 53%.

Adding 4 at. % carbon ($x=4$) to the Pr-Co alloy more than doubled the coercivity of the hot-pressed and die-upset magnets (see Fig. 2). This gain was, however, offset by a commensurate loss of remanent moment; the remanence of the die-upset magnet ($B_r=7.3$ kG) was 12% less than that of its carbon-free counterpart ($B_r=8.3$ kG). The trend to lower remanence with increasing carbon concentration (x) was observed for all magnets with $x \geq 2$ at. % [see Fig. 3(a)]. However, for a narrow range of low carbon levels, $0.5 \leq x \leq 1$, the remanence of the die-upset magnets actually increased a moderate amount (~5%) from the carbon-free value. This makes it possible to use low levels of carbon to increase coercivity [see Fig. 3(b)] without compromising remanence.

The coercivities in Fig. 3(b) are for quenched, rather than as-pressed, die-upset magnets. The coercivities of the as-pressed magnets were sensitive to press conditions and the efficiency with which the magnets were ejected from the die, and thus tended to be inconsistent. In some cases, thermal quenching from high temperatures (~800 °C) provided substantial improvements to the coercivity. The demagnetization curve in Fig. 2 shows a ~50% increase in the coercivity of the $Pr_{18}Co_{78}C_4$ die-upset magnet after quenching. Increasing the heat treatment temperature (800–1000 °C) or lengthening the soak time (10–100 min) did not provide any further enhancement to the coercivity. Quenching from lower temperatures produced progressively less improvement, and quenching from temperatures below 600 °C produced no change in coercivity. It must be presumed that the change to the microstructure during this heat treatment were subtle since the magnetization, specifically the remanence, did not change. The quenched magnets did tend to crack and they often fractured, either upon quenching or when magnetized.

Complete substitution of samarium for praseodymium in

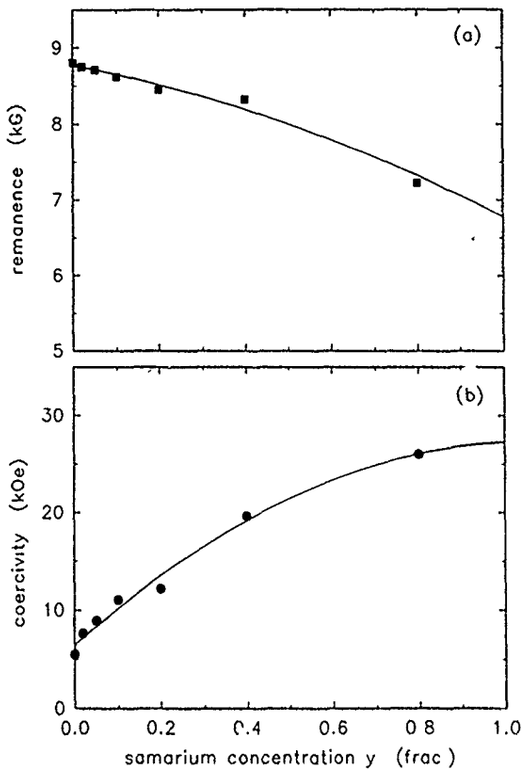

FIG. 5. (a) Remanence and (b) coercivity of die-upset $(Pr_{1-y}Sm_y)_{18}Co_{82}C$ magnets vs samarium fraction y. To maximize coercivity, the die-upset magnets were first heated to 800 °C before quenching in an oil reservoir. The die-upset (DU) level was 53%.

the hexagonal RCo_5 phase, where $R\equiv(Pr_{1-y}Sm_y)$, can double the room-temperature magnetocrystalline anisotropy with only a small loss in saturation magnetization (~10%).[16,17] Consequently, the effect of even partial substitution ($y<1$) on the coercivity of melt-spun magnets is quite substantial. The coercivities of $(Pr_{0.6}Sm_{0.4})_{18}Co_{81}C$ (i.e., $y=0.4$) hot-pressed and die-upset magnets were 19 and 10.5 kOe, respectively (see Fig. 4). After quenching the die-upset magnet had a coercivity of 19.5 kOe, nearly twice the coercivity of the as-pressed die-upset magnet and even exceeding that of the hot-pressed precursor. The remanence of the die-upset $y=0.4$ magnet ($B_r=8.3$ kG) was slightly less than that of the samarium-free ($y=0$) magnets ($B_r=8.7$ kG), and in fact the trend to lower remanences with increasing samarium levels was nearly linear [see Fig. 5(a)]. The loss of remanence extrapolates to ~20% at complete samarium substitution ($y=1$), more than expected from the change in the saturation magnetization of the RCo_5 phase.[1] Without microstructural analysis of these magnets, we can only speculate that the higher samarium levels interfere with crystallographic alignment during deformation, lowering the remanence. As expected, coercivities increased with increasing samarium levels [see Fig. 5(b)], with a slightly steeper increase at moderate levels ($y\leq0.4$). Accurate coercivity measurements at high samarium levels were limited by the field of our electromagnet.

By increasing the die-upset level to 75%, we obtained remanences as high as 9.2 kG, with coercivities near 6 kOe and energy products of ~19 MGOe for alloys containing small amounts of both carbon ($x=1$) and samarium ($y=0.02$). Although this is a significant improvement over the remanence of the isotropic magnet ($B_r\approx6$ kG), it is still only ~76% of the saturation magnetization. In comparison, die-upset Nd-Fe-B-type magnets are capable of much better alignment since the remanence can exceed 90% of the saturation magnetization of the $Nd_2Fe_{14}B$ phase.[15]

Melt-spun Pr-Co alloys can be hot pressed to produce fully dense magnets with remanences near that expected for isotropic magnets, i.e., half the saturation magnetization. Further processing by hot deformation or die upsetting creates crystallographic texture, with the c axes oriented preferentially along the press direction of the magnet. This enhances the remanence by over 35% relative to the isotropic precursor. Three methods have been identified to enhance the coercivity of these magnets: (i) replacing some of the cobalt with carbon; (ii) replacing some of the praseodymium with samarium; and (iii) brief high-temperature heat treatments followed by a thermal quench.

Nonepitaxial sputter synthesis of aligned strontium hexaferrite, $SrO \cdot 6(Fe_2O_3)$, films

H. Hegde, P. Samarasekara, and F. J. Cadieu
Physics Department, Queens College of CUNY, Flushing, New York 11367

Films of strontium hexaferrite were synthesized through rf diode sputter deposition, nonepitaxially onto polycrystalline Al_2O_3 substrates. So far such films for the analogous Ba phase have been synthesized mostly through epitaxial growth onto suitably chosen matching substrates. Crystallization of the strontium hexaferrite phase was achieved for deposition temperatures as low as 500 °C. For nonepitaxially synthesized 2–3-μm-thick polycrystalline films, a fairly high degree of variable and controlled c-axis orientation of the crystallites has been obtained. The x-ray-diffraction traces of films with a strong c-axis in-plane alignment showed predominantly (110)-type reflections. The film coercivities were increased by postdeposition annealing in O_2. The remnant to saturation flux density ratio of such in-plane anisotropy films for in-plane measurements was 0.62, with an in-plane coercivity ≈2.3 kOe.
