Thin films of magnetically uniaxial barium hexaferrite and its analogue strontium hexaferrite have many applications in microwave devices;[1–3] they also have potential applications as recording media.[4–6] So far, the synthesis of these films has involved expensive epitaxial growth on either substrates of the structurally related spinels or through the matching of the oxygen planes of metal oxides in the film and the substrate.[1–7] As expected from epitaxial growth, strong crystallographic orientation in the film has been achieved for such cases. Generally, in cases where the films were synthesized through sputter deposition, crystallization was achieved through postdeposition annealing of an amorphous deposit, in an oxygen atmosphere at a relatively high temperature, in excess of 800 °C. Good quality crystalline films were formed in this fashion.[7] In recent years, there has been great progress in the nonepitaxial sputter synthesis of uniaxial, high-energy product rare-earth–transition-metal (RE-TM) permanent magnet films. The c-axis orientation of the crystallites in these polycrystalline metallic films could be controlled through sputter process control.[8] Control of the c-axis orientation in nonepitaxial films of these uniaxial RE-TM films results only when the deposition is carried out at temperatures above the minimum crystallization temperature. Anisotropic nonepitaxial films could not be formed by crystallization of originally amorphous deposits.[8] It would be interesting to explore the feasibility of synthesizing the dielectric hexaferrites through a similar procedure. In this article, we report the nonepitaxial synthesis of strontium hexaferrite films on polycrystalline Al_2O_3 substrates. The c-axis orientation of the crystallites in our polycrystalline films was controllable through sputter process control. We were successful in synthesizing crystalline hexaferrite films at temperatures as low as 500 °C. In-plane coercivities as high as 3.8 kOe were achieved.

II. EXPERIMENT

All films in this study were synthesized onto polycrystalline Al_2O_3 substrates having grain sizes in the 1–2 μm range. Films were deposited through planar diode sputter deposition with a target-to-substrate distance of about 6 cm, with substrate temperatures from 500 to 650 °C. The strontium hexaferrite phase could not be formed from bulk sputtering targets of the same composition. For films deposited from commercially available strontium hexaferrite targets, the sputter deposition was carried out for pressure ranges 20–100 μm and gas mixtures of Ar and up to 10% O_2. At the deposition temperatures required to crystallize these films, they were found to be extremely deficient in Sr and the hexaferrite phase could not be formed. With 100% Ar, at a pressure of 100 mTorr for deposition temperature of 500 °C, the Sr to Fe atomic ratio was about 30% of the stoichiometric value. The strontium concentration dropped monotonically with increasing substrate temperature, decreasing gas pressure, and increasing oxygen gas concentration in the sputtering gas. All of these parameters affect the exposure of the growing films to energetic bombardment of O^- ions. These results indicated there was a large preferential resputtering of Sr due to bombardment of the film by energetic O^- ions. To compensate for the loss of Sr in the film, custom-made oxide targets greatly enriched in Sr with approximate composition Sr:Fe:O 1:4:7 were used. When sputtering from these targets, hexaferrite films were formed without the use of O_2 in the sputter gas. The oxygen content of the target was sufficient to directly crystallize the films in hexaferrite form.

III. RESULTS AND DISCUSSION

Hexaferrite films were synthesized for Ar gas pressures of 100 mTorr and deposition temperatures from 500 to 650 °C. While all the films were crystalline as deposited, many films were further annealed at the same temperature as their deposition temperature, in an O_2 atmosphere of 500 Torr pressure for about 30 min. All films had a deposition rate of around 0.1 μm/h, and thicknesses around 2–3 μm.

All films deposited from the Sr-rich targets at temperatures of 500 °C and above formed in the basic hexaferrite structure of $PbO \cdot 6(Fe_2O_3)$ as determined from x-ray-diffractometer traces, using Cu$K\alpha$ radiation; however, the coercivities of the films increased dramatically on annealing the films in an oxygen atmosphere at a pressure of 500 Torr,

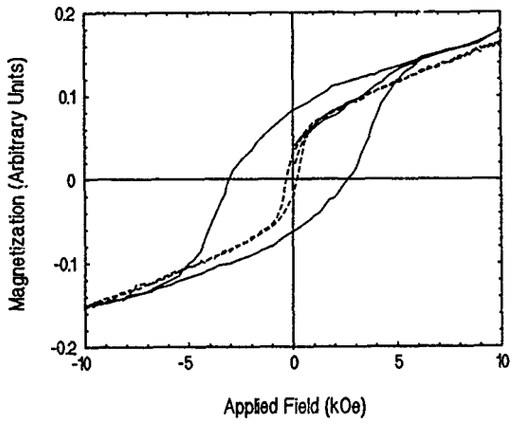

FIG. 1. Hysteresis loops of film deposited at 550 °C, before (dashed) and after (solid) annealing in 500 Torr oxygen for 30 min, at 550 °C.

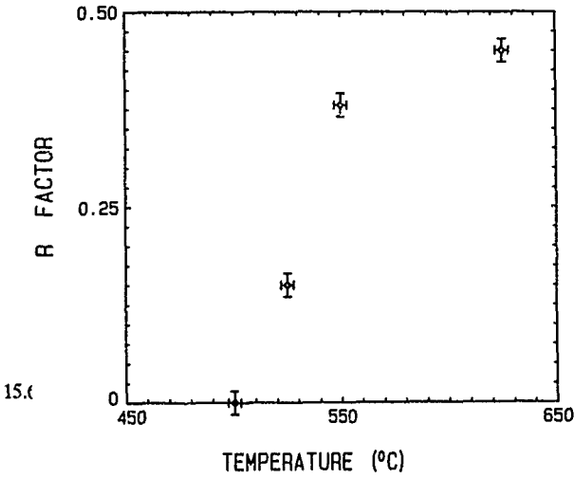

FIG. 3. Change in R value with deposition temperature.

for about 30 min. The in-plane hysteresis loops of films deposited at 550 °C temperature, before and after annealing, are given in Fig. 1. The in-plane coercivity increased from ≈0.5 to 3.8 kOe during the oxygen annealing. The typical grain size in the polycrystalline films was 2500 Å for deposition temperature near 550 °C as determined from the scanning electron microscopy (SEM) micrograph shown in Fig. 2. No change in the grain size or x-ray patterns was noticeable as a result of the postdeposition annealing in oxygen.

The film easy-axis orientation, as dictated by the average c-axis orientation of the hexaferrite crystallites in the film, was found to be strongly dependent on the deposition temperature. The x-ray-diffraction patterns of the films showed large departures from the powder diffraction pattern. As an estimate of the degree of anisotropy in the film, we define a function R given by

$$R = N \sum_i \cos \Theta_i^* (I_i / I_{0i}),$$

and

$$N = 1 \left[\sum_i \left(\frac{I_i}{I_{0i}} \right) \right]^{-1}.$$

Θ_i is the angle between the c axis of a particular crystallite and the normal to the film plane, I_i are the intensities of x-ray-diffraction lines of the film, and I_{0i} are the corresponding powder diffraction pattern intensities.

Function R gives a measure of the average c-axis orientation with respect to the film plane. The function R is unity for a pure perpendicular texture such as $(00l)$, zero for $(hk0)$ textures, and 0.5 for random c-axis orientation as in the powder diffraction pattern. At present, we are able to synthesize the films with R ranging from close to zero to 0.5. The best parallel value was achieved for the lowest crystallization temperature, 500 °C, and on the other end, an R value of ≈0.5 was achieved for crystallization temperatures from 600 to 650 °C. In other words, for such temperatures, the film pattern resembled a random powder. For the intermediate temperatures the films exhibited mixed texture crystallites. The dependence of R value on the deposition temperature is given in Fig. 3.

The CuK_α x-ray-diffraction patterns of films synthesized at deposition temperatures of 500, 550, and 625 °C are given in Figs. 4(a), 4(b), and 4(c), respectively. The diffraction pattern of films at deposition temperatures exceeding 600 °C resemble the powder pattern of Sr hexaferrite as in Fig. 4(c). The dominant texture at 500 °C was in plane (110) as in Fig. 4(a), while at 550 °C it was (114) as shown in Fig. 4(b). The R values for patterns in Figs. 4(a), 4(b), and 4(c) were approximately zero, 0.38, and 0.45, respectively. These R values correspond to average c-axis orientations away from the film normal of 90°, 68°, and 63°, respectively.

FIG 2 SEM micrograph of the surface of a strontium hexaferrite film deposited at 550 °C. Each division of the scale given corresponds to 1500 Å.

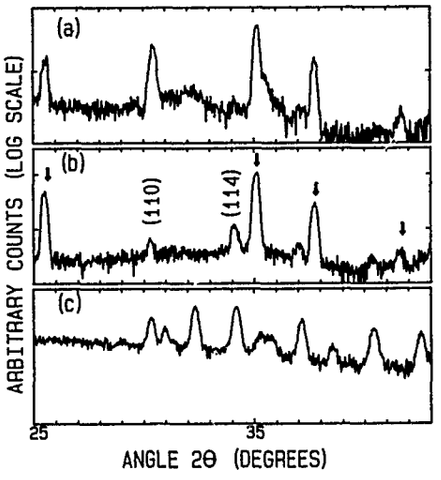

FIG. 4. Cu$K\alpha$ x-ray-diffraction patterns of films synthesized at temperatures (a) 500 °C, (b) 550 °C, and (c) 625 °C. In (a) and (b) substrate lines are indicated through arrows.

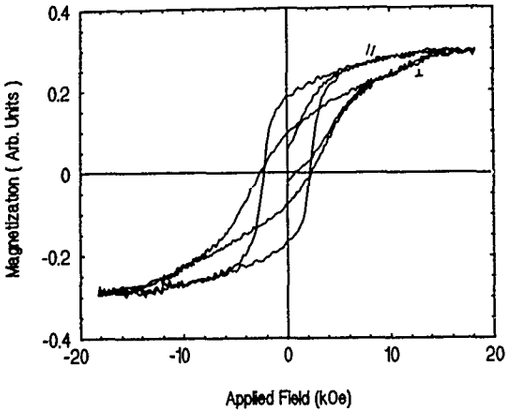

FIG. 5. Hysteresis loops parallel and perpendicular to film plane for film synthesized at 525 °C in 100 mTorr of Ar. X-ray-diffraction trace of film showed predominant (110) reflection with some (114) reflections.

Magnetic hysteresis loops measured parallel and perpendicular to the plane of a film synthesized at 525 °C are shown in Fig. 5. The diffraction trace of the film showed predominant (110) with some (114) reflections. The R value was estimated to be around 0.15, corresponding to a c-axis orientation of 81° with respect to the film normal. For the film, the remnant to saturation ratio was 0.62 in the plane, and 0.31 perpendicular to the plane direction.

IV. CONCLUSION

Crystalline films of strontium hexaferrite were synthesized nonepitaxially by rf diode sputtering in Ar onto polycrystalline Al_2O_3 substrates for substrate temperatures from 500 to 650 °C. To counter severe Sr depletion during sputtering, targets highly enriched in Sr were utilized. After deposition large increases in coercivity up to 3.8 kOe, but with no apparent changes in x-ray patterns, resulted from annealing the films in 500 Torr O_2. The films produced in these studies exhibited crystallites with well-defined c-axes orientations. For deposition temperatures near 500 °C, the films consisted of random in-plane c-axes grains. For deposition temperatures from 600 to 650 °C, the films consisted of grains with random c-axes orientations in three dimensions.

Order-disorder and magnetic exchange interactions in substituted strontium hexaferrite $SrA_xFe_{12-x}O_{19}$(A=Ga, In)

G. K. Thompson and B. J. Evans
Department of Chemistry, University of Michigan, Ann Arbor, Michigan 48109-1055

The unusual magnetic behavior of the $12k$ site in $SrGa_xFe_{12-x}O_{19}$ ($0.3 \leq x \leq 6.0$) and $SrIn_xFe_{12-x}O_{19}$ ($0.3 \leq x \leq 1.4$) has been investigated by means of ^{57}Fe Mössbauer spectroscopy at 298 K. The bifurcation of the $12k$ Mössbauer subspectrum into $12k_1$ and $12k_2$ components of widely differing intensities has been confirmed for both Ga^{3+} and In^{3+}. The bifurcation is apparent at x values as low as 0.3, and the less intense $12k_2$ pattern corresponds to an abrupt drop in the hyperfine magnetic field H_{eff}, of 50 and 75 kOe for Ga^{3+} and In^{3+}, respectively. H_{eff} for the more intense $12k_1$ pattern is virtually unchanged from that of pure $SrFe_{12}O_{19}$ for x values as high as 1.0. Room-temperature Mössbauer spectra confirm that the Ga^{3+} and In^{3+} ions preferentially occupy the $4f_2$ octahedral site. There are indications, however, that the dopants also enter the $2b$ trigonal-bipyramidal site. The change in H_{eff} at the $12k$ sites indicates that complex and competing exchange interactions are present, and that the splitting of the $12k$ magnetic hyperfine spectrum is not due simply to random disruptions of the exchange interactions. The intensities of the $12k_1$ and $12k_2$ subspectra have been used to model the exchange interactions at the $12k$ site.

I. INTRODUCTION

The magnetoplumbite structure, $MFe_{12}O_{19}$ (M=Sr, Ba, Pb), consists of alternating hexagonal ($R=MFe_6O_{11}^{2-}$) and spinel subunits ($S=Fe_6O_8^{2+}$) stacked along the hexagonal c axis. Within the R block are the trigonal-bipyramidal $2b$ and octahedral $4f_2$ Fe^{3+} sites, while the S layer contains the octahedral $2a$ and tetrahedral $4f_1$ Fe^{3+} ions; the $12k$ octahedral Fe^{3+} ions exist at the R-S interface.[1]

In addition to the $2b$ Fe^{3+} site, the octahedral $12k$ site of the M-type hexaferrites exhibits very unusual crystal chemical and magnetic properties. It is clear that an understanding of the high magnetocrystalline anisotropy and of the rapid decrease in the bulk magnetization of the magnetoplumbite hexaferrites depend to a great extent on an understanding of the structure/property relationships for these two sites.

In previous investigations, it was reported that $SrFe_{12}O_{19}$ and $BaFe_{12}O_{19}$ substituted with Sc^{3+}, Ga^{3+}, and In^{3+} exhibited Mössbauer spectra with the $12k$ subpattern split into two components.[2,3] However, there is still some question as to how low a dopant level is required to produce the $12k$ bifurcation. In addition, further analysis of this phenomenon could give valuable insights into the magnetic exchange interactions of the octahedral $12k$ Fe^{3+}. We present the results of such an investigation in this article.

II. EXPERIMENT

Polycrystalline samples of $SrGa_xFe_{12-x}O_{19}$ (x=0.3, 0.5, 0.8, 1.0, and 6.0) and $SrIn_xFe_{12-x}O_{19}$ (x=0.3, 0.4, 0.8, and 1.4) were prepared from $SrCO_3$, Fe_2O_3, Ga_2O_3, and In_2O_3, using solid-state syntheses similar to those used in earlier reports.[2,3] Electron microprobe analysis (EMPA) and x-ray powder diffractometry were employed to determine the composition, phase purity, and lattice constants of the samples. For each of the substituted hexaferrites, room-temperature ^{57}Fe Mössbauer spectra were collected and analyzed as described in detail in a previous article.[4]

III. RESULTS AND DISCUSSION

The lattice parameters of substituted $SrFe_{12}O_{19}$ are presented in Table I; as evident in Fig. 1, Vegard's law is followed by both solid solution series.[5] As expected, increasing

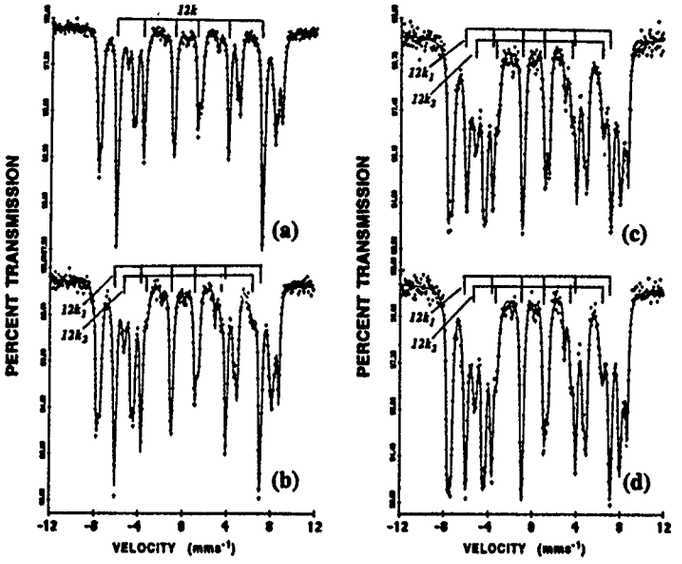

FIG. 2. ^{57}Fe Mössbauer spectra of polycrystalline $SrGa_xFe_{12-x}O_{19}$ at 298 K: (a) $x=0$; (b) $x=0.3$; (c) $x=0.5$; (d) $x=1.0$.

substitution of Fe^{3+} by the smaller Ga^{3+} ions results in a gradual decrease in the dimensions of the unit cell, while introduction of the larger In^{3+} ions has the opposite effect.

Selected Mössbauer spectra of $SrGa_xFe_{12-x}O_{19}$ and $SrIn_xFe_{12-x}O_{19}$ at 298 K are shown in Figs. 2 and 3, respectively; the hyperfine interaction parameters are presented in Tables II and III. In the case of both substituted hexaferrites, the bifurcation of the $12k$ subspectrum is visible at a dopant concentration as low as 0.3 mol per formula unit. H_{eff} for $12k_1$ in $SrGa_xFe_{12-x}O_{19}$ is essentially unchanged from that of the unsplit $12k$ pattern in $SrFe_{12}O_{19}$. However, as the In^{3+} ion concentration increases in $SrIn_xFe_{12-x}O_{19}$, H_{eff} for the $12k_1$ does decrease somewhat from that of the $12k$ pattern in $SrFe_{12}O_{19}$.

For the $12k_2$ subspectrum of $SrGa_xFe_{12-x}O_{19}$ and $SrIn_xFe_{12-x}O_{19}$, H_{eff} is roughly constant at, respectively, 50 and 75 kOe lower than that of the $12k$ pattern for $SrFe_{12}O_{19}$. Despite the near constancy of H_{eff} for the $12k_2$ subspectrum, its intensity exhibits remarkable increases as x increases. Indeed, for $x\approx 1.0$ and 0.8 for Ga^{3+} and In^{3+}, respectively, the $12k_1$ and $12k_2$ subspectra have comparable relative intensities. By the time x reaches a value of 6.0 for $SrGa_xFe_{12-x}O_{19}$, the Mössbauer spectrum at 298 K consists only of a pair of partially resolved quadrupole doublets, indicating a significant drop in the Curie temperature T_C.

Analysis of the area ratios of the Mössbauer spectra (Tables II and III) confirms that the dopant ions are entering the octahedral $4f_2$ site. In compensation for the loss of in-

[a]Estimated errors in H_{eff}, ΔE_Q, and δ (relative to Fe metal) are ±1 kOe, ±0.03 mm s^{-1}, and ±0.02 mm s^{-1}, respectively.

tensity in the $4f_2$ pattern, the areas of the octahedral $2a$ and tetrahedral $4f_1$ subspectra increase with the dopant concentration; the area of the combined $12k_1$ and $12k_2$ subspectra remains essentially constant. There also appears to be a small decrease in the area of the trigonal-bipyramidal $2b$ pattern, suggesting the occurrence of some substitution in the site. The large uncertainties of the area-percent values in the various subspectra, however, do not allow for a more definitive conclusion in the case of the $2b$ pattern.

IV. CONCLUSION

This investigation has verified that doping $SrFe_{12}O_{19}$ with as little as 0.3 mol per formula unit of Ga^{3+} or In^{3+} ions results in the bifurcation of the $12k$ octahedral subspectrum. This splitting is due to a change in the magnetic exchange interactions of some of the $12k$ Fe^{3+} ions as increasing amounts of the diamagnetic dopant enter the $4f_2$ site, and possibly the $2b$ site. The fact that the magnitude of the hyperfine magnetic field of the $12k_1$ and $12k_2$ patterns remains almost constant with increasing levels of substitution implies that the $12k$ splitting is not due simply to random changes in the exchange interactions.

Enhanced remanence in isotropic Fe-rich melt-spun Nd-Fe-B ribbons

L. Withanawasam and G. C. Hadjipanayis
Department of Physics and Astronomy, University of Delaware, Newark, Delaware 19716

R. F. Krause
Magnetics International, Inc., 1111 North State Road 149, Burns Harbor, Indiana 46304

High isotropic remanences and energy products have been obtained in melt-spun Nd-Fe-B samples with a fine grained mixture of α-Fe and $Nd_2Fe_{14}B_1$ containing more than 50 wt % of α-Fe. Reduced remanences as high as 0.78 with high saturation magnetization (190 emu/g) led to $(BH)_{max}$ of 14 MGOe. The coercivities varied from 2–4 kOe for samples with 70–50 wt % α-Fe, respectively. Reversible demagnetization curves were observed consistent with the "exchange spring" mechanism.

I. INTRODUCTION

Anisotropic Nd-Fe-B magnets have been widely used in industry because of their excellent properties with energy products $(BH)_{max}$ exceeding 40 MGOe. In isotropic bonded magnets the maximum energy products are below 12 MGOe because of the low reduced remanent magnetization (M_r/M_s). However, in the past high remanence values were obtained in isotropic melt-spun Nd-Fe-B ribbons via additions of Si and Al.[1] It was shown that these high remanence values were the results of a uniform fine microstructure with small (18 nm) grain sizes and with exchange interaction between adjacent 2:14:1 grains.[2] Davis, Manaf, and Zhang[3] also observed high remanence in Nd-Fe-B ribbons without any additions of Si or Al. More recently, theoretical studies have predicted high energy products in magnets consisting of a mixture of hard and soft phases which are exchange coupled through a uniform and fine-grained microstructure.[4] Coehroon, De Mooji, and De Waard[5] obtained in $Nd_4Fe_{77}B_{19}$ a microstructure consisting of a fine mixture of $Nd_2Fe_{14}B_1$ and Fe_3B grains with a maximum energy product of 12 MGOe.

In this work we have studied the magnetic and structural properties of $Nd_2Fe_{14}B_1$/Fe composite magnets with high Fe content. The samples studied can be grouped in three categories according to the percentage of 2:14:1 and α-Fe phases present: 50 wt % α-Fe/50 wt % 2:14:1; 70 wt % α-Fe/30 wt % 2:14:1; and α-Fe/2:14:1/Fe_3B. Throughout the text these samples are referred to as A, B, and C, respectively.

II. EXPERIMENT

$Nd_xFe_yB_z$ ingots with different composition ($3 \leq x \leq 8$, $80 \leq y \leq 90$, $4 \leq z \leq 15$) were prepared by arc melting the constituent elements in an argon atmosphere. Pieces of the ingot were melt spun from a quartz tube having an orifice diameter of ~1 mm. A wheel speed in the range of 25–35 m/s was used. The resulting ribbons were heat treated at different times and temperatures to optimize the magnetic properties. X-ray diffraction (CuK_α) was used to identify the phases present and selected samples were studied using Mössbauer spectroscopy. The hysteresis loops were measured in a vibrating sample magnetometer (VSM) with a maximum field of 20 kOe on long sample pieces to minimize demagnetization effects. Selected samples were also measured in a superconducting quantum interference device (SQUID) magnetometer with a maximum field of 55 kOe. The microstructure of samples with optimum coercivity was studied by transmission electron microscopy (TEM).

III. RESULTS AND DISCUSSION

The melt-spun ribbons were found by x ray to be amorphous (and/or microcrystalline) in structure. Annealing the ribbons at around 700 °C for 20–60 min resulted in a two-phase microstructure consisting of 2:14:1 and α-Fe for samples A and B, and a three-phase mixture of 2:14:1, Fe_3B, and α-Fe in the high-boron sample (sample C) as indicated by x-ray and thermomagnetic data (see Figs. 1 and 2). Mössbauer results on sample A showed 55% 2:14:1 and 45% α-Fe. In the same sample there is an intermediate magnetic phase, formed by a low-temperature heat treatment (600 °C/20 min), with a Curie temperature of about 200 °C. Our structural data indicate that this phase is the $R_3Fe_{62}B_{14}$ bcc phase reported by Buschow, De Mooji, and Coehroon[6] with $a = 1.235$ nm.

A TEM micrograph of sample A with optimum coercivity is shown in Fig. 3. The average size of the grains is about

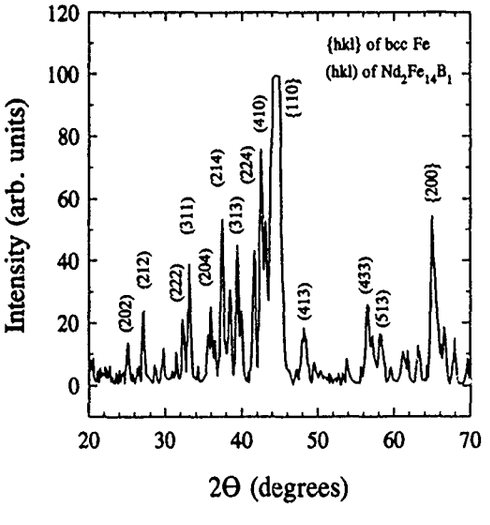

FIG. 1. X-ray diffraction ($CuK\alpha$) pattern of sample A (50 wt % α-Fe/50 wt % $Nd_2Fe_{14}B$) showing bcc Fe and 2.14.1 peaks. (Only part of the {110} bcc Fe reflection is shown.)

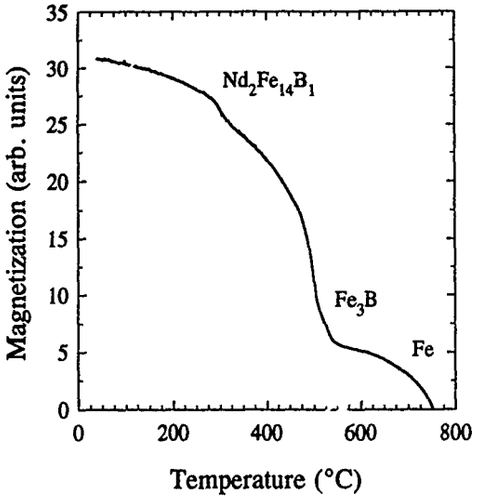

FIG. 2. Temperature dependence of magnetization for sample C (α-Fe/$Nd_2Fe_{14}B$/Fe_3B) showing the three magnetic phases.

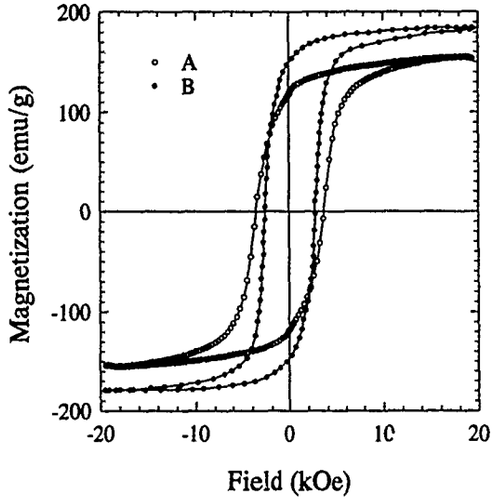

FIG. 4. Hysteresis loop showing high remanence values.

50 nm in diameter. The dark-field observations show the grains of α-Fe to be uniformly distributed in the sample.

Optimally annealed sample A had a coercivity of 4 kOe along with a magnetization of 155 emu/g at 20 kOe and a remanence value of 110 emu/g. The corresponding values for sample B were H_c=2.7 kOe, M_s=185 and M_r=145 emu/g. The reduced remanences ($m_R=M_R/M_S$) were 0.71 and 0.78, respectively, for samples A and B (see Fig. 4). These values are much higher than the 0.50 value expected for an assembly of randomly distributed and noninteracting single-domain particles with uniaxial anisotropy. Loops measured along and transverse to the ribbon length in the plane of the ribbon showed essentially the same remanence indicating that the ribbons are isotropic. The maximum energy product $(BH)_{max}$ was estimated using the second quadrant data on long ribbon samples with negligible demagnetization factors. Furthermore, the density of the material was taken to be 7.60 g/cm^3 (density of $Nd_2Fe_{14}B_1$), although the $Nd_2Fe_{14}B_1$ phase content is about 50 wt % or less, regardless of the sample composition. A summary of the magnetic data is shown in Table I.

FIG. 3. A TEM micrograph of optimally annealed sample A (50 wt % α-Fe/50 wt % $Nd_2Fe_{14}B$).

Figure 5 shows the temperature dependence of coercivity measured up to 140 °C for both A and B samples. The temperature coefficients were calculated, assuming a linear dependence, according to the following formula:

$$\frac{H_c(T_2)-H_c(T_1)}{(T_2-T_1)H_c(T_1)}100,$$

and were found to be −0.39 and −0.55 %/°C for A and B, respectively.

The variation of remanence with temperature was also measured for the same samples and is shown in Fig. 6. The corresponding coefficients calculated using the same formula are −0.06 and −0.07 %/°C. The temperature coefficients of coercivity are close to those of pure 2:14:1 ribbons while the temperature coefficients of remanence are much lower.[7] Heating the samples above the Curie temperature of the $Nd_2Fe_{14}B_1$ phases reduces the remanent magnetization to a low but nonzero value.

The high reduced remanence values indicate an exchange coupling between the grains of the hard and soft phases. As a consequence of this coupling there is a larger degree of reversibility in the demagnetization behavior. According to Kneller and Hawig[4] the magnetization would return to the remanent configuration reversibly for reverse fields lower than the nucleation field. We have measured the dc demagnetization curves by applying progressively increasing reverse fields and measuring the remanence values corresponding to each such field, thus obtaining $M_r(H)$. A plot of $[M_r(0)-M_r(H)]/2M_r(0)$ $(=-\Delta M_r/2M_r)$ versus

TABLE I. Room-temperature coercivities (kOe), remanence (kG), and estimated maximum energy product (MGOe) for the three samples.

Sample	H_c	H_{ci}	B_r	$(BH)_{max}$
50 wt % α-Fe/50 wt % $Nd_2Fe_{14}B$	3.10	3.80	10.4	9.78
70 wt % α-Fe/30 wt % $Nd_2Fe_{14}B$	2.60	2.70	14.5	14.45
$Nd_2Fe_{14}B$/Fe_3B/α-Fe	2.18	2.40	12.3	9.10

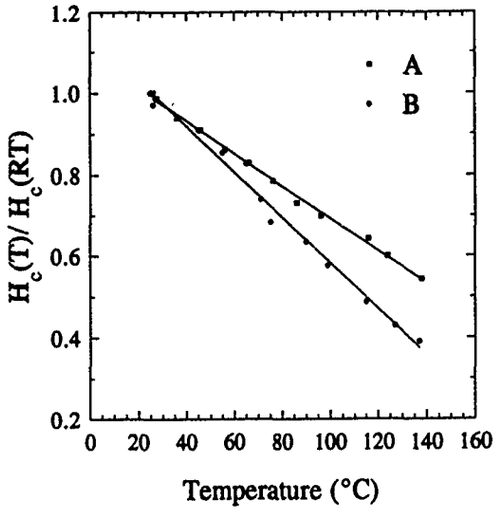

FIG. 5. The variation of coercivity (normalized by their room-temperature value) with temperature.

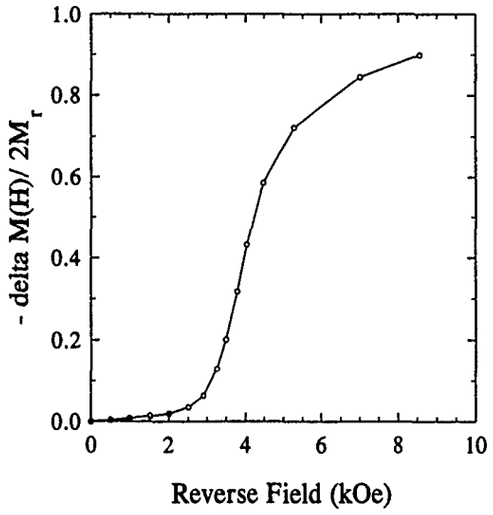

FIG. 7. A plot of $[M_r(0)-M_r(H)]/2M_r(0)$ $(=-\Delta M_r/2M_r)$ vs reverse field for sample A (50 wt % α-Fe/50 wt % $Nd_2Fe_{14}B$) with a coercivity of 3.6 kOe showing reversibility in the demagnetization curves.

reverse field is shown in Fig. 7 for sample A with a coercive field of 3.6 kOe. The change in ΔM_r is very small up to fields of about 2.6 kOe which corresponds to the reversible region of the demagnetization curve. At higher reverse fields ΔM_r increases rapidly due to the irreversible rotation of magnetic moments.

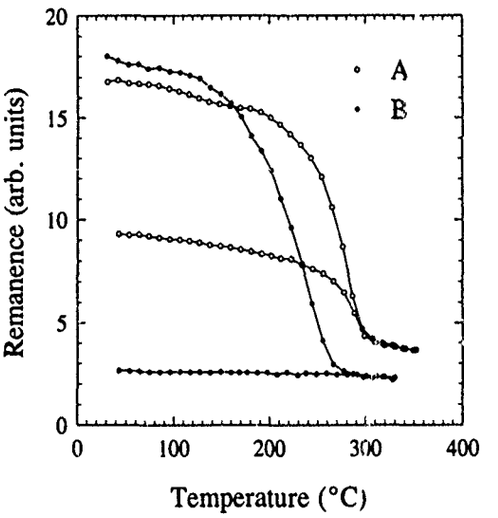

FIG. 6. Temperature dependence of remanent magnetization for samples A (50 wt % α-Fe/50 wt % $Nd_2Fe_{14}B$) and B (70 wt % α-Fe/30 wt % $Nd_2Fe_{14}B$).

IV. CONCLUSIONS

High reduced remanences (up to 0.78) and energy products (up to 14 MGOe) have been obtained in Fe-rich Nd-Fe-B samples with a mixture of α-Fe and $Nd_2Fe_{14}B_1$ grains which are believed to be the result of exchange coupling across the grain boundaries.

The magnetic and structural properties of mechanically alloyed $Nd_2Fe_{14}B$+ (Fe, FeCo) powders have been investigated over a wide range of temperatures. X-ray diffraction patterns on samples milled for 48 h showed that the powders had a two-phase structure consisting of a disordered Nd-Fe-B alloy and α-Fe with a fine grain size about 140 Å. Enhanced magnetic remanence in the range of 95–105 emu/g with reduced remanence $\alpha=M_r/M_s=0.60-0.68$ and a coercivity $H_c=4-6$ kOe have been obtained after annealing at 650–750 °C. This behavior is the result of an exchange coupling between the hard and soft phases with small grain sizes, about 500 and 200 Å, respectively.

I. INTRODUCTION

Mechanical alloying has been widely used in a number of laboratories as an attractive technique for manufacturing permanent magnets. With this process ultrafine composite particles are formed during milling in a high-energy ball mill with leads to very high coercivities after a suitable heat treatment.[1–7] A possible way to increase the remanence in mechanically alloyed powders is to use nanocrystalline materials consisting of a mixture of hard and soft magnetic phases. The composite magnets may retain high values in both remanence and coercivity when an exchange coupling extends across the interface of the hard and soft phases.[8,9]

In this article, the magnetic and structural properties of mechanically alloyed Nd-Fe-B nanocomposite powders have been investigated over a wide range of temperatures.

II. EXPERIMENT

Alloys of $R_xFe_yB_zM_w$ (R=Nd, Tb; M=Nb) with $5\leqslant x\leqslant 15$, $77\leqslant y\leqslant 90$, $5\leqslant z\leqslant 8$, $0\leqslant w\leqslant 3$ and Fe-Co were prepared by arc melting using high-purity elements. The mechanically alloyed samples were prepared in a high-energy ball mill (SPEX 8000 mixer/mill) using powders with a particle size about 150 μm and pure Fe powders with a particle size of about 40 μm. The mechanically alloyed powders were heat treated in the temperature range of 600–900 °C for 15–60 min under a vacuum of 10^{-6} Torr.

The structure of the powders was determined using a Phillips x-ray diffractometer (APD3520). The mean grain size of the powders was measured from the x-ray line broadening using the Scherrer formula.[10]

The magnetic properties of the powders were measured with a vibrating sample magnetometer (VSM) in fields up to 20 kOe and with a superconducting quantum interference device (SQUID) magnetometer in fields up to 55 kOe. A rough estimate of the saturation magnetization M_s was made using the law of approach to saturation by plotting M as a function of $1/H^2$ and extrapolating the infinite fields with a relative error less than 5%. The remanence was measured at $H_{\text{eff}}=0$, where the effective magnetic field $H_{\text{eff}}=H_a-H_d=H_a-4\pi NM$, and N is the demagnetization factor. For the samples measured with the VSM, N was determined from the diameter/length ratios of the cylindrical compacted samples. For the SQUID powdered samples, an $N=1/3$ was used because of the nearly spherical shape of the particles.

III. RESULTS AND DISCUSSION

A. $Nd_2Fe_{14}B$ and $Nd_2Fe_{14}B$+Fe

The Nd_2Fe_4B system was chosen for the initial detailed study. After ball milling for 48 h the $Nd_2Fe_{14}B$ alloy powders had a mixture of an amorphous Nd-Fe-B structure and α-Fe with a fine grain size about 140 Å [see Fig. 1(A)]. The mechanically alloyed powders were heat treated in the temperature range of 600–900 °C to form the 2:14:1 phase. The diffraction pattern of powders heat treated at 800 °C for 30 min is shown in Fig. 1(B). A small amount of α-Fe was still found in the powders to coexist with the 2:14:1 phase forming a nanocomposite magnet. An addition of 10 wt %α-Fe was used to increase the amount of Fe in the nanocomposite $Nd_2Fe_{14}B$+Fe samples. The $Nd_2Fe_{14}B$ and $Nd_2Fe_{14}B$+Fe powders were prepared with the same milling and heat-treating conditions. The coercivity H_c and the reduced remanence $\alpha=M_r/M_s$ of the two powders after a heat treatment at 600–900 °C are shown in Fig. 2. The highest coercivity 7.4 kOe was obtained in the $Nd_2Fe_{14}B$ after a heat treatment at a

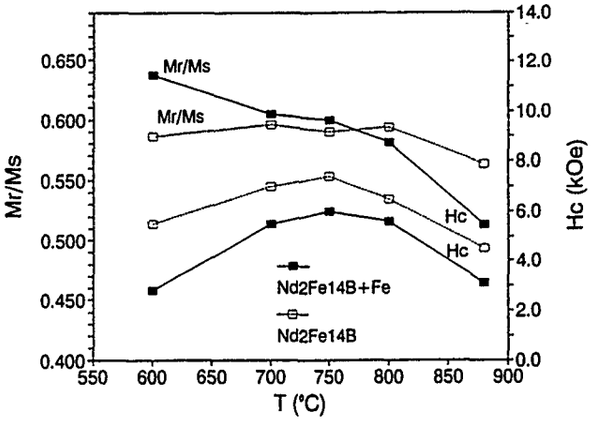

FIG. 2. The coercivity H_c and the reduced remanence $\alpha=M_r/M_s$ of the $Nd_2Fe_{14}B$ and +Fe powders heat treated at different temperatures.

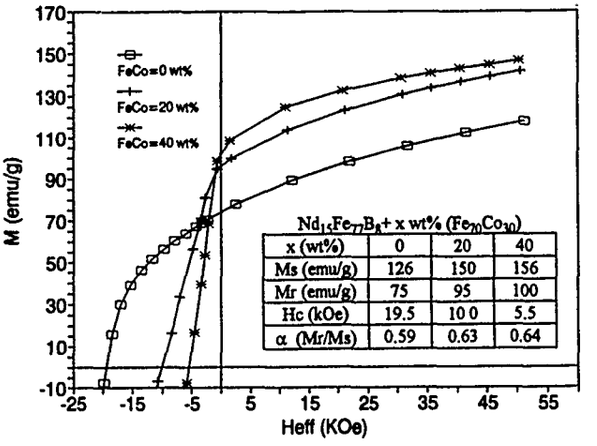

FIG. 3. Magnetization curves of the $Nd_{15}Fe_{77}B_8+x(Fe_{70}Co_{30})$ with samples $x=0$, 20, and 40 wt %.

temperature of 750 °C. The grain size of the $Nd_2Fe_{14}B$ phase was about 500 Å and it did not depend on the milling intensity but on the annealing temperature.[11] The coercivity was low in samples annealed at both lower and higher temperatures because the grain size was either too small or too large, respectively. The coercivity of $Nd_2Fe_{14}B$+Fe powders was reduced by 1–2 kOe as compared to the $Nd_2Fe_{14}B$ powders. However, a strong exchange coupling between the hard and soft phase was observed for annealing at temperatures below 700 °C which led to an increase in remanence. The reduced remanence of the powders was very high ($\alpha=0.64$) when the grain size of the soft phase was about 150–200 Å and it decreased drastically with annealing temperature dropping to 0.51 at 880 °C which is below that of $Nd_2Fe_{14}B$ powders (see Fig. 2). It appears that the exchange coupling decreases substantially at the higher heat-treatment temperatures because the grain size of α-Fe is much larger than the critical dimension for optimum coupling. For the optimum properties, it is important that the soft phase has a small grain size close to that of the magnetic hard phase. Typical magnetic properties of $Nd_2Fe_{14}B$ and $Nd_2Fe_{14}B$+Fe samples are summarized in Table I. With the addition of 10 wt % Fe the saturation magnetization and the reduced remanence was increased from 153 to 158 emu/g and from 0.59 to 0.60, while H_c was reduced from 7.4 to 6.0 kOe.

B. $Nd_{15}Fe_{77}B_8+x$ wt %$(Fe_{70}Co_{30})$

An attempt was made to increase the coercivity of the nanocomposite magnets by using Nd-rich Nd-Fe-B alloys which have been known to have high coercivities in mechanically alloyed $Nd_{15}Fe_{77}B_8$ samples.[12] Also, a mechanically alloyed $Fe_{100-x}Co_x$ sample showed the highest saturation magnetization with x about 30 at %,[13] which is very close to that of as-cast alloys.[14] The magnetization curves of $Nd_{15}Fe_{77}B_8+x(Fe_{70}Co_{30})$, $x=0$, 20, and 40 wt %, nanocomposite magnets after optimum heat treatment are shown in Fig. 3. The saturation magnetization M_s was increased from 126 to 156 emu/g when x varied from 0 to 40 wt %, and the coercivity H_c was decreased from 19.6 to 5.5 kOe. However, an increase in the magnetic remanence has been observed in the $Nd_{15}Fe_{77}B_8+Fe_{70}Co_{30}$ samples. In reality, the total ratio in the weight percent of transition element (Fe or FeCo) and rare-earth Nd was almost the same (Fe/Nd and FeCo/Nd 3.07) in both samples of $Nd_2Fe_{14}B$+Fe 10 wt % and $Nd_{15}Fe_{77}B_8+(Fe_{70}Co_{30})$ 40 wt %; but, the remanence of the $Nd_{15}Fe_{77}B_8+(Fe_{70}Co_{30})$ 40 wt % ($M_r=100$ emu/g) was higher than that of $Nd_2Fe_{14}B$+Fe 10 wt % ($M_r=95$ emu/g). This increase in M_r was accompanied by a similar increase in the reduced remanence α, $\alpha=0.64$ for

TABLE I. Magnetic properties of the mechanically alloyed powder samples.

Samples	M_s (emu/g)	M_r (emu/g)	α (M_r/M_s)	H_c (kOe)
$Nd_2Fe_{14}B$	153	90	0.59	7.4
$Nd_2Fe_{14}B$+Fe (10 wt %)	158	94	0.60	6.0
$Nd_2Fe_{14}B$+FeNb (45 wt %)	162	101	0.62	4.4
$(NdTb)_2Fe_{14}B$+FeNb (45 wt %)	154	104	0.68	6.0

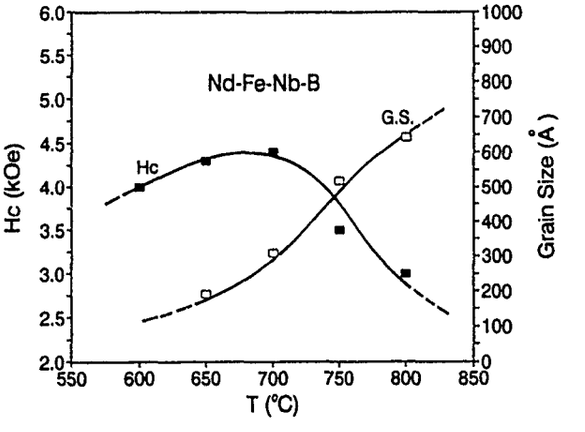

FIG. 4. The coercivity H_c and grain size of Nd-Fe-B+FeNb mechanically alloyed powders after different heat-treated temperatures.

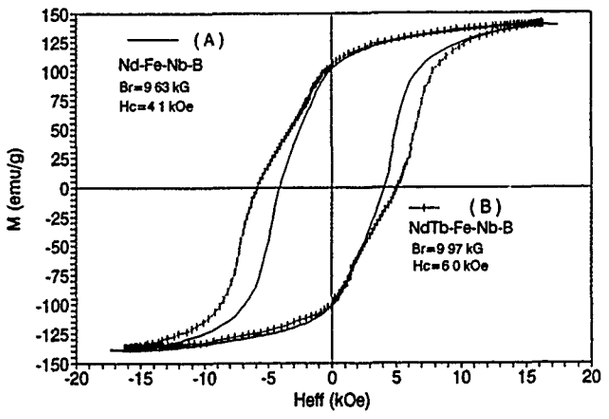

FIG. 5. Hysteresis loops of the Nd-Fe-B+FeNb and NdTb-Fe-B+FeNb mechanically alloyed powders.

$Nd_{15}Fe_{77}B_8$+($Fe_{70}Co_{30}$) 40 wt % and α=0.60 for $Nd_2Fe_{14}B$+Fe 10 wt % (see Detail data in Table I and Fig. 3).

C. $Nd_2Fe_{14}B$ with FeNb alloy

Nb additions in Nd-Fe-B alloys have been found to increase the crystallization temperature by about 100 °C and coercivity H_c significantly.[15] The enhancement in coercivity was attributed to the presence of small precipitates within the hard magnetic phase.[16] The grain size of the FeNb alloy in the amorphous Nd-Fe-B was about 140 Å after ball milling for 48 h and increased to 640 Å after a heat treatment at 800 °C for 30 min. The dependence of coercivity and grain size for $Nd_2Fe_{14}B$+FeNb on annealing temperature is shown in Fig. 4. The annealing temperature for highest coercivity H_c=4.4 kOe was about 700 °C with the grain size of the FeNb alloy around 300 Å. A typical hysteresis loop of a cylindrical shape sample with demagnetization factor N=0.23 is shown in Fig. 5(A). The experimental data showed a saturation magnetization M_s=162 emu/g ($4\pi M_s$=15.4 kG), the magnetic remanence M_r=101 emu/g ($4\pi M_r$=9.63 kG), and α=0.62. A partial substitution of Tb for Nd in mechanically alloyed powders led to increase in the coercivity up to 6.0 kOe at room temperature. A hysteresis loop of the sample with demagnetization factor N=0.295 after annealing at 650 °C for 30 min is also shown in Fig. 5(B); here, M_s=154 emu/g ($4\pi M_s$=14.7 kG), M_r=104 emu/g ($4\pi M_r$=9.97 kG), and α=0.68. The magnetic properties of the samples are also summarized in Table I. The enhancement in magnetic remanence for NdTb-Fe-B +FeNb powders can be attributed to both an increase in the magnetic anisotropy and coercivity of the hard phase and a reduction in grain size of the soft phase at the low annealing temperatures.

IV. CONCLUSIONS

Enhanced magnetic remanence has been obtained in mechanically alloyed Nd-Fe-B powders with a microstructure consisting of a mixture of hard and soft magnetic phases. The large reduced remanence α=0.60–0.68 is the result of magnetic exchange coupling between the hard and soft phases with small grain size of about 500 and 200 Å, respectively.

Microstructure of high-remanence Nd-Fe-B alloys with low-rare-earth content

Raja K. Mishra
Physics Department, GM Research and Development Center, Warren, Michigan 48090-9055

V. Panchanathan
Magnequench—Delco Remy Division, General Motors Corporation, Anderson, Indiana 46013

The microstructure and magnetic properties of bonded and fully dense magnets produced from melt-spun ribbons of the composition $RE_{4.5}TM_{76}Ga_1B_{18.5}$ have been investigated, where RE refers to a mixture of Nd and Dy, and TM refers to a mixture of Fe and Co. Results show that annealing overquenched ribbons with about 3 wt. % Dy and 3 wt. % Co at 700 °C can produce materials with $H_{ci}\simeq 4$ kOe, $B_r\simeq 11.5$ kG, and $(BH)_{max}\simeq 14.5$ MGOe, the latter being comparable to those of commercial ribbons containing three times as much Nd. The microstructure of annealed ribbons consists of about 30% $Nd_2Fe_{14}B$ grains, 65% Fe_3B grains, and 5% α-Fe grains. The grains of all the phases are nearly spherical. The grain diameters are in the 30–50 nm range. Hot-pressed magnets made from overquenched ribbons are fully isotropic, with magnetic and microstructural characteristics similar to those of the annealed ribbons. The high remanence and low coercivity correlate well with the microstructure consisting of a uniform mixture of the hard $Nd_2Fe_{14}B$ phase and soft α-Fe and Fe_3B phases.

I. INTRODUCTION

Improvement of hard magnetic properties, simplification of processing, and reduction of cost, besides others, have been the principal motivating factors for much of the research on Nd-Fe-B permanent magnet materials[1,2] since they were discovered a decade ago. Many studies of modification of chemical composition have helped improve the hard magnetic properties, Curie temperature, thermal and environmental stability, etc. Other research and studies have contributed toward streamlining preparation procedures which facilitate commercial production. There is now a sufficiently broad base of information on the $Nd_2Fe_{14}B$ magnets to help design compositions and microstructure suited for diverse applications. This article discusses the results of a study of a Nd-Fe-B magnet which is a mixture of two different ferromagnetic phases with the aim of enhancing magnetic properties while reducing overall Nd content compared to the standard $Nd_2Fe_{14}B$ magnet. Since Nd still accounts for a substantial fraction of the cost of the $Nd_2Fe_{14}B$ alloys and lower Nd content generally improves the aging behavior of the $Nd_2Fe_{14}B$ magnets, preparing viable magnets through this route is of both commercial and technological interest.

By altering the amount of Nd in the Nd-Fe-B alloy one can enter into a phase field in the Nd-Fe-B phase diagram where Fe_3B phase is one of the equilibrium phases.[3] Fe_3B has a room-temperature saturation magnetization of 16 kG, comparable to that of the $Nd_2Fe_{14}B$ phase.[4] It has planar anisotropy and it behaves as a soft magnet.[5] The Curie temperature of Fe_3B is 513 °C, nearly 200 °C more than that of $Nd_2Fe_{14}B$. European[4] and Japanese[6] researchers have reported that in a $Nd_4Fe_{78}B_{18}$ alloy containing over 50% Fe_3B, B_r of 12 kG, H_{ci} of 3.8 kOe, and $(BH)_{max}$ of 12 MGOe can be achieved. Alloying additions such as Dy, Co, and Ga are known to alter anisotropy, coercivity, and Curie temperature of $Nd_2Fe_{14}B$ magnets.[1] One of the aims in this study is to prepare and characterize an alloy utilizing the beneficial effects of both the mixing of two ferromagnetic phases as well as selective alloying modifications to improve coercivity and other characteristics. We also report here the results of microstructural characterizations of the new alloy and correlate them with the observed properties.

II. EXPERIMENT

The starting material used in this investigation was prepared from an induction melted ingot (5 pound charge) of nominal composition 13.2 wt. % Nd, 83.6 wt. % Fe, and 3.2 wt. 5% B ($Nd_{4.8}Fe_{77.5}B_{17.7}$), melt spun at wheel speeds between 4 and 22 m/s. The ribbons were annealed at temperatures between 680 and 720 °C for 5 min. Additional alloys were prepared by substituting 3 wt. % Co and 1 wt. % Ga for Fe and 3 wt. % Dy for Nd. Some alloys were made with B content up to 3.6 wt. % and Nd (Dy) content between 10.3 and 21.2 wt. %. Second quadrant demagnetization curves were measured from powder samples (demagnetization correction factor of 0.33) as well as from resin bonded magnets. Hot-pressed samples were prepared from the 22 m/s ribbons by standard procedure at 750 °C. Temperature coefficients of B_r and H_{ci} were calculated from demagnetization data at different temperatures. Loss characteristics were measured for bonded magnets held at elevated temperatures[7] for up to 1000 h.

Thin foils for electron microscopy were prepared from annealed and unannealed ribbons by ion milling. The electron transparent foils were examined in a Philips 430 microscope operating at 300 kV.

III. RESULTS

Since it is possible to prepare microcrystalline ribbons of Nd-Fe-B alloys either by directly quenching from the melt at an optimum cooling rate or by annealing ribbons which were first overquenched from the melt, we have investigated both of these paths for optimum properties. For the low Nd con-

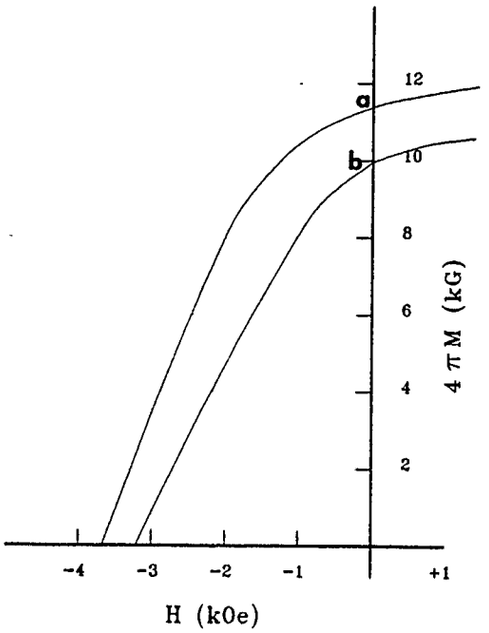

FIG. 1. Second quadrant demagnetization curve of $Nd_{3.5}Dy_1Fe_{73}Co_3Ga_1B_{18.5}$ (a) powder overquenched at 22 m/s and annealed at 700 °C with demagnetization correction factor 0.333; (b) hot-pressed magnet. The remanence to saturation magnetization ratio of 0.62 is the highest reported for any fully dense isotropic magnet.

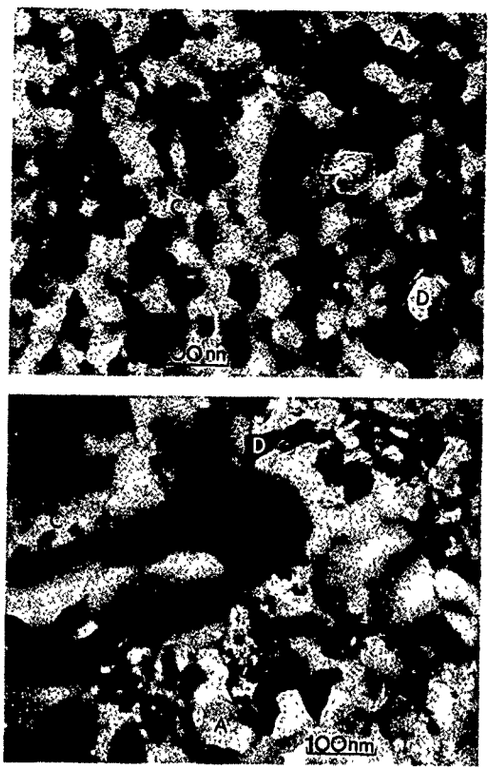

FIG. 2. Transmission electron micrographs of $Nd_{3.5}Dy_1Fe_{73}Co_3Ga_1B_{18.5}$ ribbons (a) quenched at 22 m/s and annealed at 700 °C and (b) quenched at 7 m/s. Note the nonuniform grain sizes of different phases in (b). A=Fe_3B, C=$Nd_2Fe_{14}B$, and D=α-Fe.

tent compositions studied in this article, the best properties are exhibited by ribbons that are melt spun at 22 m/s and then annealed at temperatures close to 700 °C. Transmission electron microscopy results show that the ribbons of all compositions used in this study are microcrystalline for wheel speeds of 22 m/s. Figures 1(a) and 1(b) show the second quadrant demagnetization curves for overquenched ribbons of $Nd_{3.5}Dy_1Fe_{73}Co_3Ga_1B_{18.5}$, annealed for 5 min at 700 °C and hot pressed to full density, respectively. Microstructure of annealed ribbon corresponding to Fig. 1(a) is shown in Fig. 2(a). The microstructure consists of three phases, namely $Nd_2Fe_{14}B$, tetragonal Fe_3B, and α-Fe. The grain sizes of Fe_3B and $Nd_2Fe_{14}B$ are nearly the same (average grain diameter in the 20–50 nm range) while α-Fe appears as isolated grains. The distribution of $Nd_2Fe_{14}B$ and Fe_3B phases is homogeneous. There is no evidence of intergranular phase at the grain boundaries.[8] The microstructure of the hot-pressed sample is similar to that of the annealed ribbon in all respects. In contrast, the microstructure of the best directly quenched ribbon (wheel speed of 7 m/s) of the same composition, shown in Fig. 2(b), is not homogeneous. The grain diameters of the Fe_3B grains are much larger than those of the $Nd_2Fe_{14}B$ grains. There is a clearly defined intergranular phase at the $Nd_2Fe_{14}B$ grain boundaries. α-Fe is found as isolated particles. EDX analysis failed to detect any Nd in the Fe_3B grains. Dy, Co, and Ga additives were all detected in the $Nd_2Fe_{14}B$ phase with Ga concentrations mostly near the grain boundary. Microstructural features in ribbons of different compositions are the same except for the relative amounts of the three phases.

Table I lists the temperature coefficients of B_r and H_{ci} between room temperature and 175 °C, measured using bonded magnets of composition $Nd_{4.8}Fe_{77.5}B_{17.7}$ and $Nd_{3.5}Dy_1Fe_{73}Co_3Ga_1B_{18.5}$. These values are essentially the same as those of commercial grade bonded Nd-Fe-B magnets. We also find that the structural and irreversible loss characteristics of these alloys are the same as commercial grade magnets. There is practically no loss in H_{ci} after aging for 1000 h at 100 °C and alloys without Co have no structural loss.

The initial magnetization and demagnetization curves of a bonded magnet premagnetized to two different field strengths are shown in Fig. 3. It is observed that while the coercivity of the material is not very high, the field needed for saturation is at least 10 times higher than the coercive

TABLE I. Temperature coefficients of B_r and H_{ci} in bonded magnets. Composition A: $Nd_{4.8}Fe_{77.5}B_{17.7}$; composition B: $Nd_{3.5}Dy_1Fe_{73}Co_3Ga_1B_{18.5}$.

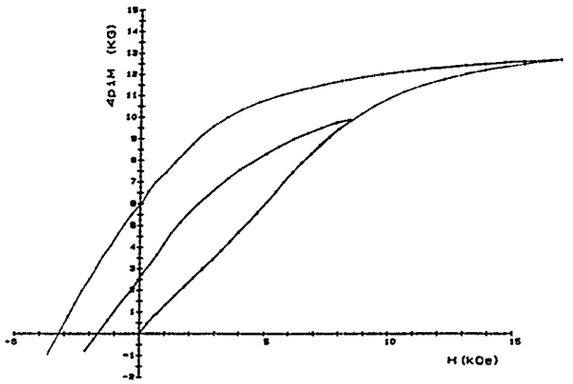

FIG. 3. Initial magnetization and second quadrant demagnetization curves for $Nd_{3.5}Dy_1Fe_{73}Co_3Ga_1B_{18.5}$ bonded magnet after magnetizing up to (a) 9 kOe and (b) 18 kOe. The kinks in (a) and (b) are characteristic of the two-phase material.

field. The initial magnetization curve is linear up to a field at least twice the coercive field. The demagnetization curves for the material magnetized up to 9 and 18 kOe are nearly parallel. The entire demagnetization curve shifts toward higher B_r and H_{ci} if the magnet is premagnetized to 45 kOe.

IV. DISCUSSION

Microstructural measurement shows that the material consists of approximately 30% $Nd_2Fe_{14}B$, 65% Fe_3B, and 5% α-Fe phase. These volume fractions are consistent with what one would expect from atomistic considerations if one assumes that all the Nd atoms are incorporated ito the $Nd_2Fe_{14}B$ phase, the remaining B atoms are incorporated into the Fe_3B phase and the remnant transition metal atoms are left behind in elemental form. The saturation magnetization values of the three phases are roughly the same, close to 16 kG. Tetragonal Fe_3B has planar anisotropy, and the maximum contribution to remanence from isotropic distribution of the Fe_3B grains will be $\pi/4$ or 0.79 of saturation value if the basal plane of the tetragonal Fe_3B structure is assumed to contain no preferential direction for the magnetization vector.[5] Since there are at least two grains of Fe_3B for every $Nd_2Fe_{14}B$ grain, in spite of the strong uniaxial anisotropy of the $Nd_2Fe_{14}B$ grains, the demagnetization characteristics of the material will be dominated by that of Fe_3B phase, giving a remanence close to 0.79 of the saturation value. If the $Nd_2Fe_{14}B$ phase were to determine the demagnetization behavior, the remanence would be in the range of half of the saturation magnetization value. Clearly, the high remanence in the material observed here and by others suggest the latter not to be the case.

The coercivity of the material is dominated by the crystallite distribution. Grain size plays a role in changing the value of H_{ci}. The moderate value of H_{ci} must be a result of the influence of the $Nd_2Fe_{14}B$ phase since the planar anisotropy of the Fe_3B phase makes that phase a soft ferromagnet. Application of a reverse field in this system can easily nucleate reverse domains and these domain walls can move relatively freely in the Fe_3B grains while $Nd_2Fe_{14}B$ grains will act as barriers to domain-wall motion. Approach to saturation in such a material will be determined by the flipping of the magnetization vector in individual $Nd_2Fe_{14}B$ grains. The approach to zero magnetization at the coercive field will be a result of a sufficient amount of Fe_3B with reverse magnetization canceling out the contribution from the $Nd_2Fe_{14}B$ phase. Such an explanation is consistent with the large field (compared to the coercive force) needed for full saturation. This is also consistent with the observation of parallel demagnetization curves (a) and (b) in Fig. 3.

The phase distribution is a result of both the chemistry and the kinetics of crystallite formation during quenching or annealing. The grain size distribution in the directly quenched alloy suggests that grain growth kinetics for Fe_3B and $Nd_2Fe_{14}B$ are different at elevated temperatures encountered during melt spinning. The grain growth kinetics of the two phases are similar at temperature and time intervals encountered during annealing of the overquenched alloy. It is also possible that nucleation of $Nd_2Fe_{14}B$ phase takes place in pockets which are saturated with Nd after Fe_3B grains have formed and grown in the directly quenched ribbons. Excess α-Fe is left behind in both cases at the end of solidification as a terminal phase. That no Nd atoms were detected in the Fe_3B phase contrary to the suggestion in Ref. 9 indicates that the Fe-B trigonal prism which forms the building block in Fe_3B and $Nd_2Fe_{14}B$ does not readily permit substitution of Fe by Nd. This is also consistent with the observation that various substitutions to the starting alloy do not alter the microstructure in any significant way. Most of the substituted atoms are incorporated ito the $Nd_2Fe_{14}B$ phase. Fe_3B phase or boundaries between Fe_3B grains does not show any segregation of Dy, Co, or Ga. We find Ga associated with the $Nd_2Fe_{14}B$ phase, mostly at the boundary between $Nd_2Fe_{14}B$ and Fe_3B grains. The changes in the temperature coefficient of B_r and H_{ci} and the loss properties with various alloying additions are thus considered to be primarily due to changes to the $Nd_2Fe_{14}B$ phase upon alloying. Finally, these results indicate that further research on optimization of hard and soft magnet mixtures can potentially yield improved permanent magnets.

Magnetic properties of sintered Alnico 5 magnet via rapid solidification technology

C. J. Yang, W. Y. Lee, and S. D. Choi
Electromagnetic Materials Laboratory, Research Institute of Industrial Science and Technology, P.O. Box 135, 790-330 Pohang, Korea

A process for making Alnico magnets (grade 5–8) via rapid solidification technology has been developed. The process includes extractive melt spinning of alloy powders, press forming, heat treatment under a magnetic field, and aging. The Alnico 5 magnets made by this process showed superior magnetic properties to those of cast magnet of the corresponding composition. The superior magnetic properties of the sintered magnets with B_r=13.2 kG, H_c=680 Oe, and $(BH)_{max}$=6.02 MGOe are due to the spinodal decomposition which is completely free of γ phase.

I. INTRODUCTION

The magnetic behavior of Alnico alloys is governed by two metallurgical transformations. The more important of the two is the decomposition of the bcc α matrix, which is stable at high temperature, into two phases, α_1 and α_2, which are also bcc. The ferromagnetic α_1 phase, which is rich in Fe and Co, is finely dispersed throughout the weakly magnetic α_2 phase by spinodal decomposition.[1] The composition, orientation, and distribution of the α_1 precipitates determine the magnetic properties of the alloys. At high temperature, the second transformation occurs which has detrimental effect on the magnetic properties, i.e., the fcc γ phase precipitates from the α matrix upon cooling from about 1200 °C. Many investigations[2–4] have reported the $\alpha \rightarrow \gamma$ precipitation and have pointed out that it causes a considerable decrease in the magnetic properties because it takes place at the expense of the α matrix.

In our recent investigation, the possibility of formation of γ phase was completely avoided by our proprietary extractive melt-spinning technique.[5] In addition, the simple process based on melt-spun powders which are press formed and heat treated under a magnetic field renders these magnets economically competitive with existing magnets produced by powder metallurgy using elemental metal powders. We report the details of part of our recent investigations on the newly developed sintered Alnico 5 type magnet.

II. EXPERIMENT

Alloys of 14% Ni-24% Co-8% Al-3% Cu-51% Fe were prepared by argon plasma arc melting from each element of 99.95% purity. The arc-melted ingots were remelted three times to assure homogeneity, and extractively melt spun into powders of 60 mesh. Cooling substrate speeds of 8.5–33 m/s were used to give average grain sizes in the range 2.5–25.6 μm in the precursor powders. Magnetic measurements on the powder samples were carried out using a Toei vibrating sample magnetometer while compacted magnets were evaluated by a LDJ B-H loop tracer. A Perkin-Elmer thermomagnetic analyzer was used to study thermomagnetic behaviors and phase transitions. Electron microscopy was done using a Philips high-resolution 400 kV transmission microscope. The heat treatment under a magnetic field was carried out using an in-laboratory assembled furnace; the magnetic fields (H_a=5–10 kOe) were applied using an electromagnet.

III. RESULTS AND DISCUSSION

A. Sintering, solutionizing, and magnetic properties

Figure 1 shows the variation of magnetic properties and density as a function of sintering temperature. The compact was made by pressing the melt-spun powders having an average particle size of 38 μm in a uniaxial pressure of 9.8×10^7 N/m^2. The grain size of the precursor powders was 10 μm. The magnet samples were prepared by sintering for 1 h, solutionizing at 1250 °C for 10 min, cooling from 900 to 600 °C at the cooling rate of 1.26 °C/s under the magnetic field of 7 kOe, and aging at 600 °C for 4 h. The magnet

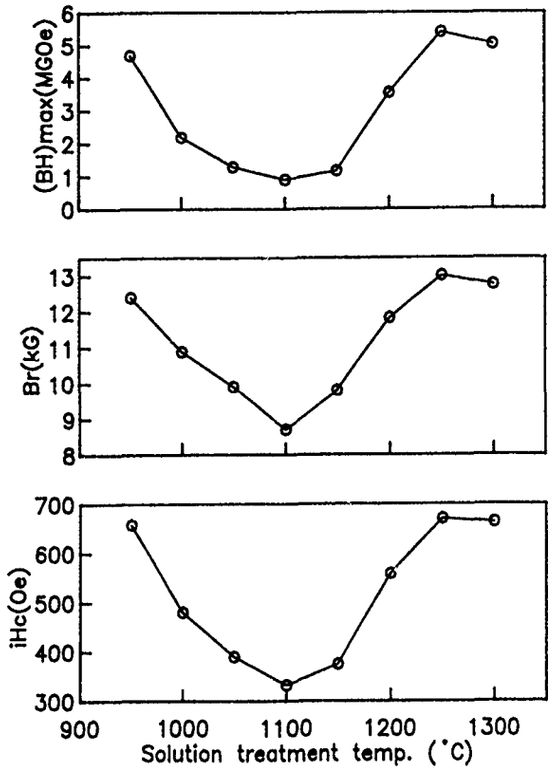

FIG. 2. Variation of magnetic properties of the sintered Alnico 5 magnets as a function of solutionizing temperature.

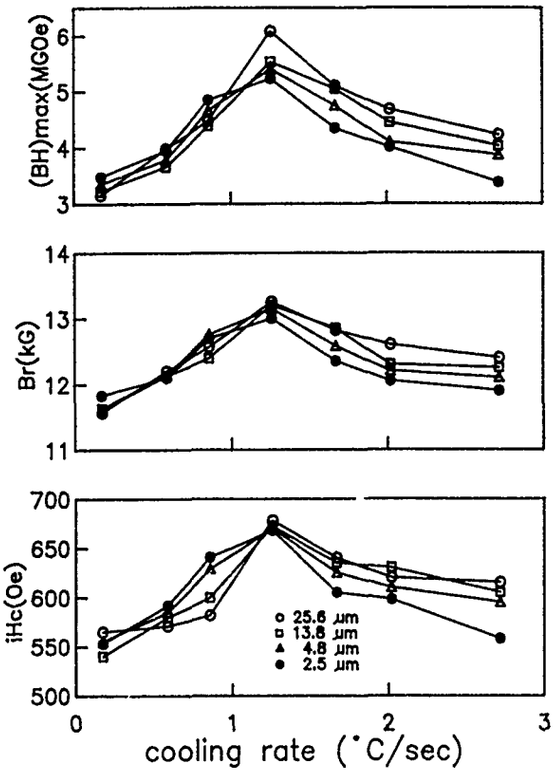

FIG. 3. Variation of magnetic properties of the sintered and aged magnets as functions of cooling rate during magnetic annealing and precursor grain size.

sintered at 1300 °C already shows properties superior to those of sintered magnets made by the existing process [$(BH)_{max}$=5–5.5 MGOe],[6–8] and the magnet sintered at 1350 °C exhibits an energy product, $(BH)_{max}$=6.0 MGOe which is higher than that of cast-type Alnico 5 magnets [$(BH)_{max}$=4.8–5.5 MGOe].[9,10] The superior magnetic properties were found to result from the high densities ρ of the green compacts (ρ>7.3 g/cm^3). In the existing process of making sintered-type Alnico magnets, a mixture of powders of elemental Ni, Co, FeAl, Cu, FeTi, Fe, and returned Alnico powders from cast magnets is used as precursor. The compactability of this mixture is inferior to that of the melt-spun powders. The microstructures of melt-spun precursors and the grain aspect of the magnet sintered at 1300 °C commonly showed uniform, equiaxed grains which were free from any observable γ phase. Only a few pores could be seen for the magnet sintered at 1300 °C.

The effect of solutionizing temperature on the magnetic properties is shown in Fig. 2. The magnet samples were prepared by sintering at 1350 °C for 1 h, solutionizing at the indicated temperature for 30 min, cooling from 900 to 600 °C at the cooling rate of 1.26 °C/s under the magnetic field of 7 kOe, and aging at 600 °C for 4 h. This figure indicates that, in spite of the rapidly solidified precursor powders, the selection of appropriate solutionizing treatment after sintering enhances the magnetic properties. The drastically poorer magnetic properties obtained for sintering temperatures in the range 1000–1200 °C are due to the martensitic transformation of (α_γ) of the γ phase from the α matrix during cooling.[3] The most appropriate solutionizing temperature for the Alnico 5 magnets made via rapid solidification process was found to be 1250 °C. No γ precipitate in α was seen in the magnets solutionized at temperature over 1250 °C.

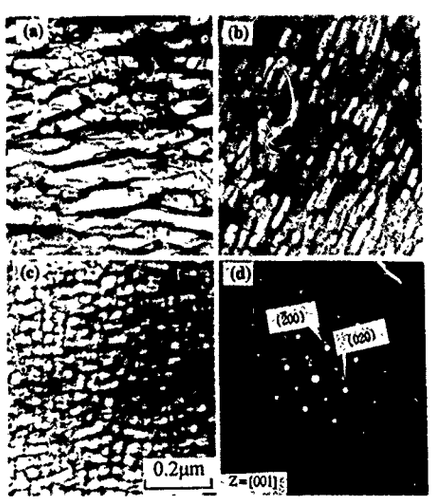

FIG. 4. TEM micrographs showing the α_1 precipitates formed during the magnetic annealing. (a), (b), and (c) are for cooling rates of 0.17 °C/s, 1.26 °C/s, and 1.67 °C/s, respectively; (d) is a selected-area-diffraction pattern from (b).

B. Magnetic annealing under an external field

The variation of magnetic properties is shown in Fig. 3 as a function of cooling rate during the magnetic annealing. The magnet samples were prepared by sintering at 1350 °C for 1 h, solutionizing at 1250 °C for 10 min, cooling from 900 to 600 °C at the rate of indicated speed in Fig. 3, and aging at 600 °C for 4 h. The initial grain sizes of the precursor powders are shown in Fig. 3(c). It can be seen that cooling rates below or above 1.26 °C/s during magnetic annealing influence the final magnetic properties in dissimilar ways. This is because the aspect ratio, distribution, and frequency of the magnetically hard, (Fe-Co)-rich α_1 precipitates are dependent upon the cooling rate. At a rate below 1.26 °C/s, the α_1 precipitation during the spinodal decomposition takes a coarse rod-type morphology with a small aspect ratio resulting in poor magnetic properties. Cooling rates faster than 1.26 °C/s, on the other hand, prevent the precipitates from growing into well-developed Co-rich particles having a high shape anisotropy. High Co concentration within the α_1 precipitates is known to enhance the magnetic properties of the Alnico-type magnets.[11] High cooling rates also prevented the axial alignment of the α_1 particles along the ⟨100⟩ orientations during magnetic annealing. It is of interest to note in Fig. 3 that the principle magnetic properties increase as the grain size of the precursor powders decreases for the magnets cooled at the rates below 1.26 °C/s, but that the magnetic properties (especially the coercivity) decrease as initial grain size decreases for the magnets cooled at the rates above 1.26 °C/s.

Figure 4 is the TEM micrographs showing the α_1 precipitates aligned along the [100] direction. The micrographs were taken from the longitudinal section with respect to the applied field direction. The [100] corresponds to the magnetic field direction during annealing. The long white islands are the α_1 precipitates, and the grey matrix corresponds to the α_2 phase which is high in (Ni-Al). The magnet cooled at 0.17 °C/s shows α_1 precipitates that are 200 nm long and 50 nm wide. A cooling rate of 1.26 °C/s which was found to be optimal resulted in well-aligned and finely distributed precipitates [Fig. 4(b)] with an aspect ratio of (length/width) =(200 nm/30 nm)=6.7. At a cooling rate of 1.67 °C/s, however, the α_1 precipitates took place in random orientations with malformed shapes. Figure 4(d) shows the electron-diffraction pattern obtained from the area corresponding to Fig. 4(b). The critical magnetic field above which the α_1 precipitates are aligned effectively in the melt-spun Alnico 5 type magnets was found to be 5 kOe.

IV. CONCLUSION

An economical process for producing the Alnico 5 type magnets using a rapid solidification technology has been developed. Sintered magnets made by this powder metallurgical method exhibited superior properties to those of cast magnets having corresponding compositions. The optimized process produced magnets with properties of B_r=12.8–13.2 kG, $_iH_c$=630–680 Oe, and $(BH)_{max}$=5–6 MGOe.

Effect of additives on thermal stability of Nd-Fe-B bonded magnets (abstract)

T. Nishio, H. Yagi, T. Furuya, and Y. Kasai
Research and Development Division, Daido Steel Co., Ltd., Nagoya 457, Japan

Effects of Zr and Nb on magnetic properties and thermal stability were studied for Nd-Fe-B bonded magnets. Bonded magnets with a composition of $Nd_x(Fe_{94-x-y})B_6T_y$, where T=Zr and Nb; x=11.0, 11.5, and 12.0; y=0, 0.5, 1.0, 1.5, and 2.0; were prepared by using melt spun ribbons. The addition of Zr up to 0.5 at .% increased the (BH)max of the bonded magnets, and further addition of Zr decreased the (BH)max at each Nd content level. Hci increased monotonously with an increase in Zr. (BH)max and Hcj of the Nb containing bonded magnets also showed similar behavior. Irreversible flux loss after exposure at 180 °C for 1000 h significantly reduced with an increase in the Zr content at each Nd content level. Both the structural flux loss and the thermal fluctuation flux loss were reduced with an increase in the Zr content. An irreversible flux loss of about 5% was obtained when the Nd and Zr content were 11.5 at .% and 2.0 at. %, respectively. A similar value of irreversible flux loss was also obtained in Nb containing bonded magnets with the same composition. It was found that the oxygen pickup by the bonded magnets during the heat resistant test was well correlated to the structural loss of the bonded magnets. A structural flux loss of less than 3% was obtained when the oxygen pickup was less than 0.4 wt. % for both additives. SEM studies revealed that the grain size of the 2-14-1 phase observed in the additive-containing specimens was finer than that of the base alloy.

Coercivity in hard magnets based on Sm_2Co_{17} (abstract)

Eric Lectard, Claire Maury, and Colette H. Allibert
L.T.P.C.M.-INPG, 38402 St. Martin d'Hères, France

Lew Rabenberg
University of Texas, Austin, Texas 78712-1063

Despite the research devoted to new compounds, the Sm-Co-Cu-Fe-Zr alloys with the 2:17 type are, as yet, the only hard magnets to be used above 200 °C. However, these materials are not optimized because their coercivity mechanism is not clearly understood. Their typical microstructure consists of a network of 2:17 cells separated by 1:5 boundaries. Their coercivity is ascribed to the domain wall pinning by the 1:5 cell boundaries. The compositions of the 1:5, 2:17 phases during the cell microstructure genesis were recently[1] evaluated for the alloy $Sm(Co_{0.66}Fe_{0.25}Cu_{0.06}Zr_{0.03})_{7.6}$. In the present work, the coercivity behavior of this alloy is analyzed from the comparison of the domain wall energies γ1:5, γ2:17. Sintered samples, heat-treated in various conditions, are characterized by transmission electron microscopy and hysteresis curves. γ2:17 and γ1:5 are calculated from measured and published data of magnetization and anisotropy. The different treatments generate similar cell microstructures but two ranges of coercivity (about 600 and 2200 K A m^{-1}). In the two cases, γ1:5 is larger than γ2:17: the cell boundaries appear as repelling energy barriers rather than pinning sites. The existence of a disturbed anisotropy layer along the 1:5/2:17 interface is proposed to explain the higher coercivity state. The evaluation of Hc using the usual models[2] is attempted.

Orientational dependence of the exchange biasing in molecular-beam-epitaxy-grown $Ni_{80}Fe_{20}/Fe_{50}Mn_{50}$ bilayers (invited)

R. Jungblut, R. Coehoorn, M. T. Johnson, J. aan de Stegge, and A. Reinders
Philips Research Laboratories, Prof. Holstlaan 4, 5656 AA Eindhoven, The Netherlands

The exchange biasing field (H_{eb}) and coercive field (H_c) of molecular-beam-epitaxy-grown $Cu/Ni_{80}Fe_{20}/Fe_{50}Mn_{50}$ samples in [111], [001], and [110] orientations have been investigated by longitudinal Kerr effect measurements. $Ni_{80}Fe_{20}$ and $Fe_{50}Mn_{50}$ were deposited as orthogonal wedge-shaped layers on single-crystal Cu substrates in a magnetic field, enabling the study of the thickness dependence of H_{eb} and H_c on a single sample for each orientation. A strong dependence of H_{eb} and H_c on the growth orientation is observed. The results are interpreted in terms of the observed noncollinear spin structure of the antiferromagnet and a comparison is given with the predictions from recent theoretical models.

I. INTRODUCTION

Exchange coupling at the interface between a ferromagnetic (FM) layer and an antiferromagnetic (AF) layer can cause a unidirectional anisotropy of the FM layer if the sample is grown in a magnetic field or cooled down in a magnetic field after heating above the Néel temperature of the AF layer.[1] It manifests itself by a shift of the hysteresis loop along the field axis. The size of this field shift is called the exchange biasing field, H_{eb}.

The most intensively studied systems comprise the antiferromagnetic oxidic layers CoO and NiO[2] and the antiferromagnetic metallic alloy $Fe_{50}Mn_{50}$. A unidirectional anisotropy in entirely metallic systems was first found for $Ni_{80}Fe_{20}$/NiFeMn bilayers.[3] In particular, the alloy system $Ni_{80}Fe_{20}/Fe_{50}Mn_{50}$, which was found to display the biasing effect in 1978,[4] has been studied extensively, motivated by practical industrial applications in magnetoresistive sensors based on the anisotropic magnetoresistance[5] or giant magnetoresistance ("spin-valve") effect.[6]

Investigations on the system $Ni_{80}Fe_{20}/Fe_{50}Mn_{50}$ have revealed several interesting observations concerning the hysteresis loop shift and related phenomena. An important finding was that the coupling H_{eb} varies approximately inversely with the thickness of the FM layer, t_{FM}.[7] This provides evidence of the interfacial nature of the interaction effect that gives rise to exchange biasing. Balancing the Zeeman energy and the unidirectional anisotropy energy results in a phenomenological expression for the loop shift

$$H_{eb}=\frac{\Delta\sigma}{2\mu_0 M_{FM} t_{FM}}, \tag{1}$$

where M_{FM} is the saturation magnetization of the ferromagnetic layer and $\Delta\sigma$ is the change of the interfacial exchange energy upon a reversal of the magnetization of the FM layer. H_{eb} has been observed to decrease linearly with increasing temperature and becomes zero at the "blocking temperature," slightly below the Néel temperature of the AF layer.[7] Other interesting observations concern (i) the influence of the interfacial exchange coupling on the coercive field H_c (half-width of hysteresis loop at zero net magnetization) of the FM/AF double layer, (ii) the different loop shifts of FM/AF layers grown in a magnetic field and AF/FM layers cooled through the Néel temperature of the AF layer in a magnetic field,[8] and (iii) the initial reduction of H_{eb} and H_c with the number of hysteresis loop cycles ("magnetic training effect").[9]

In spite of the continuing interest in the exchange biasing effect, its microscopic origin has remained a subject of debate.[10] In a first model[1] it was assumed that the interface magnetization of the AF layer is "uncompensated" (only one of two antiferromagnetic sublattices adjoins the interface) and remains fixed when the magnetization of the FM layer is rotated. In that case, the change of the interfacial exchange energy is given by $\Delta\sigma=2J/a^2$, where a is the lattice parameter and J is the exchange constant. In an order of magnitude calculation we use Eq. (1) and values for J typical for exchange interactions in Fe-based alloys ($J\approx10^{-21}$ J). Expressing the normalized value of the exchange coupling by the product $H_{eb}t_{FM}$, we obtain $\approx1.6\times10^5$ kA/m Å, being much larger than the experimental values for the $Ni_{80}Fe_{20}/Fe_{50}Mn_{50}$ system, summarized in Table I. Furthermore, for cases in which the AF interface is compensated this model predicts no loop shift. As will be discussed in more detail, this is the case for $Fe_{50}Mn_{50}$ (100) and (111).

Mauri *et al.*[11] modified this model by showing that the energy of the reversed state can be lowered by the introduction of a domain wall into the AF layer parallel to the interface. $\Delta\sigma$ is now equal to the wall energy, $4(A_{AF}K_{AF})^{1/2}$, where A_{AF} is the exchange stiffness and K_{AF} is the uniaxial anisotropy per unit volume in the antiferromagnet. It has been remarked that this model predicts a loop shift which is in good agreement with experiments, if A_{AF} and K_{AF} are chosen comparable to the values for permalloy ($A_{AF}\approx2\times10^{-11}$ J/m and $K_{AF}\approx1.6\times10^3$ J/m^3). However, this choice of parameters is not consistent with the observation by polarized neutron diffraction experiments[12] that the ferromagnetic exchange stiffness and anisotropy are large enough

[f]Not reported.

to confine the domain wall to the AF layer, i.e., $(A_{AF}K_{AF})^{1/2} \ll (A_{FM}K_{FM})^{1/2}$. Consequently, this model predicts an H_{eb} which is too small. Another inconsistency with the assumed values of A_{AF} and K_{AF} is that the exchange biasing effect is usually measured for AF thicknesses much lower than the expected domain wall width $\pi(A_{AF}/K_{AF})^{1/2} \approx 0.35$ μm. Furthermore, the model treats only the case of a perfect and uncompensated interface.

Subsequently, Malozemoff[13] presented a model which does not suffer from these shortcomings. He explained the biasing effect by assuming domains in the antiferromagnet, separated by domain walls perpendicular to the interface in conjunction with the presence of roughness of the AF interfaces which would otherwise be perfectly compensated. The interface roughness will give rise to a random exchange field. However, due to the finite size of the domains, with typically N atoms at the interface, these random fluctuations will not compensate each other completely. On the average $N^{1/2}$ spins (order of magnitude) at the interface will be uncompensated. Upon growth in a field or after cooling from a temperature above the blocking temperature, the resulting spin structure in each of the domains will support the same magnetization direction of the FM layer. Reversal of the FM layer will then cost $\Delta\sigma \approx N^{-1/2}J/a^2$. Malozemoff further argues that the domain diameter is approximately equal to the wall thickness $L \approx \pi(A_{AF}/K_{AF})^{1/2}$, which, with $N^{-1/2} = a/L$, results in

$$H_{eb} \approx \frac{\sqrt{A_{AF}/K_{AF}}}{\pi\mu_0 M_{FM} T_{FM}}. \tag{2}$$

In a later paper, Malozemoff[14] predicts an enhanced H_{eb} below a characteristic thickness of the AF, corresponding with the transition between an "Ising-domain" state where the domain diameter is in the order of the wall thickness and a "Heisenberg-domain" state with the domain diameter smaller than the wall thickness.

A shortcoming of these models, when applied to the $Ni_{80}Fe_{20}$/FeMn system, is that they do not take the details of the spin structure of the AF layer into account. Let us consider the spin structure of γ-FeMn. The average spin structure, which does not take the detailed (random) occupation of sites with Fe and Mn atoms into account, is described by the commonly accepted ⟨111⟩ model.[15] Atoms on the (0,0,0), $(\frac{1}{2},\frac{1}{2},0)$, $(0,\frac{1}{2},\frac{1}{2})$, and $(\frac{1}{2},0,\frac{1}{2})$ positions have moments which are directed to the center of the tetrahedron that is defined by these atomic positions, i.e., along the ⟨111⟩ directions. Figure 1 shows that terminating the bulk $Fe_{50}Mn_{50}$ crystal along the (111), (110), and (001) planes leads to entirely different spin configurations at the surfaces. In the (111) planes the moments are directed $\pm 19.5°$ and $\pm 90°$ out of plane with their in-plane components compensating each other. In the (001) planes the moments are $\pm 35.3°$ out-of-plane pointing along the [110] and $[\bar{1}10]$ in-plane directions. The resulting in-plane moment is also compensated. For the (110) planes we have to distinguish between two different layers: One type of layer has its moments in plane whereas for the other layer $\pm 54.7°$ out of plane moments are found. In contrast to the other two surfaces a resultant in-plane moment along the [100] directions is found: the (110) plane is uncompensated.

It would be of fundamental interest to know whether these entirely different spin structures for FeMn result in an orientational dependence of the exchange biasing effect. Here we present results of the first investigation into this issue. We have grown $Ni_{80}Fe_{20}$/FeMn bilayers on single crystal Cu substrates of different orientations by molecular beam epitaxy (MBE) in a magnetic field. The bilayers were grown as "double" wedges to enable the study of the dependence of H_{eb} and H_c on the thickness of the AF and FM layers on a single sample.

II. EXPERIMENTAL DETAILS

A schematic view of the samples used is given in Fig. 2. Fe and Ni, as well as Fe and Mn were coevaporated from

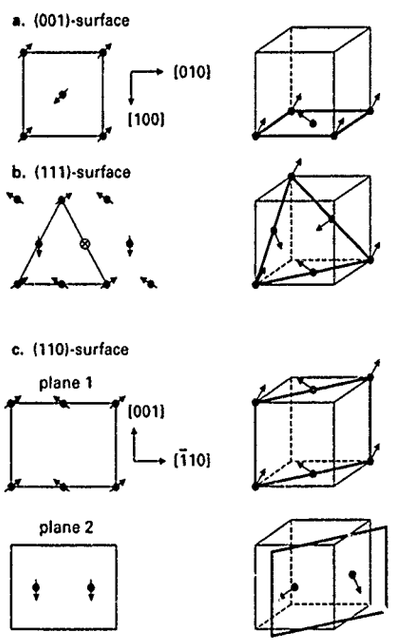

FIG. 1. Spin structure in the ⟨111⟩ model for the different orientations.

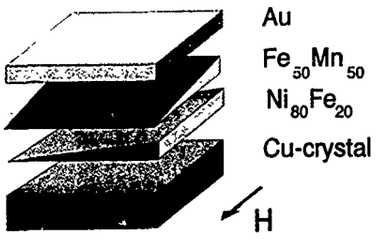

FIG. 2. Schematic view of the samples.

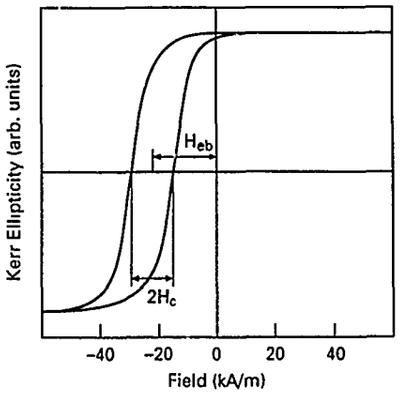

FIG. 3. Hysteresis loop of Cu(111)/68 Å $Ni_{79}Fe_{21}$/45 Å $Fe_{43}Mn_{57}$/Au.

electron beam evaporators and Knudsen cells on [111], [110], and [001] oriented Cu single crystals held at room temperature. During growth a magnetic field of ≈20 kA/m was applied along several high symmetry directions in the surface plane. The wedge shape of the layers was achieved by withdrawing an eclipsing shutter. Care has to be taken that the shutter causes equal shadows for the flux from both evaporation sources forming the alloy. Evaporation rates (FeMn and $Ni_{80}Fe_{20}$: 0.8 Å/s) and compositions were controlled by crystal thickness monitors calibrated by chemical analysis. After completion of the $Ni_{80}Fe_{20}$ wedge the sample was rotated by 90° to grow the $Fe_{50}Mn_{50}$ wedge. A thickness dependent structural study was done by low energy electron diffraction (LEED). The perpendicular and the parallel lattice spacings ($d_\perp$, $d_\parallel$) were determined kinematically by measuring the energies of the primary Bragg reflections along the [00] rod, and by analysis of LEED patterns at constant energy, respectively. The wedge starts, their slopes and finally their composition were controlled by combining secondary electron microscopy and Auger electron spectroscopy. The error in determining the composition is estimated to be ±3 at. %. The samples to be discussed had the following composition: Cu(001)/$Ni_{74}Fe_{26}$ (0–80 Å)/$Fe_{53}Mn_{47}$ (0–135 Å)/Au (20 Å), H‖ [001] and [01$\bar{1}$]; Cu(110)/$Ni_{77}Fe_{23}$ (0–80 Å)/$Fe_{41}Mn_{59}$ (0–85 Å)/Au (20 Å), H ‖ [1$\bar{1}$0]; Cu(111)/$Ni_{79}Fe_{21}$ (0–86 Å)/$Fe_{43}Mn_{57}$ (0–130 Å)/Au (20 Å), H in arbitrary direction.

The Au top layer was deposited to protect the sample against oxidation.

The magnetic characterization was done *ex situ* by the longitudinal magneto-optic Kerr effect employing a laser beam focussed to ≈100 μm. The magnetic fields applied in Kerr measurements were parallel to the fields applied during growth. By scanning the laser beam over the sample the entire AF- and FM-layer thickness dependence of H_{eb} and H_c could be studied on only one sample for each orientation. The lack of Kerr-signal restricted reliable measurements to FM layer thicknesses ≥20 Å. Before scanning the sample the magnetic field was cycled about 10 times between its maximum values to avoid possible ambiguities related to the training effect.[9]

III. RESULTS

A. Growth and structure

When MBE-depositing $Ni_{79}Fe_{21}$ (disordered $Ni_{80}Fe_{20}$: $a=3.5489$ Å) on the Cu(111) substrate (Cu: $a=3.6150$ Å, $d_\perp=2.09\pm0.01$ Å), we observed LEED patterns with fcc(111) symmetry over the whole investigated thickness range. On increasing the $Ni_{79}Fe_{21}$ thickness its perpendicular lattice parameter gradually increased to reach its bulk value ($d_\perp=2.04\pm0.01$ Å) at ≈33 Å $Ni_{79}Fe_{21}$. Between 34 and 44 Å $Ni_{79}Fe_{21}$ triangle-shaped diffraction spots, probably related to arrays of misfit dislocations occurred. Growing $Fe_{43}Mn_{57}$ ($Fe_{50}Mn_{50}$: $a=3.625$ Å) on Cu(111)/$Ni_{79}Fe_{21}$, no clear LEED pattern was observed for thicknesses between 19 and 46 Å. The quality of the LEED pattern improved over the remaining thickness interval up to 130 Å. The perpendicular lattice parameter of the $Fe_{43}Mn_{57}$ layers (on relaxed $Ni_{79}Fe_{21}$) was found to be relaxed to $d_\perp=2.09\pm0.02$ Å at thicknesses higher than 46 Å.

For the $Ni_{74}Fe_{26}$ grown on Cu(001), fcc LEED patterns were observable for the investigated thickness range, indicating epitaxial growth. From the LEED [00] reflections we derived $d_\perp=1.81\pm0.01$ Å for the Cu substrate. For $Ni_{74}Fe_{26}$ thicknesses larger than 16 Å $d_\perp=1.72\pm0.01$ Å was found, which remained unchanged over the whole investigated thickness range. When growing $Fe_{53}Mn_{47}$ on this $Ni_{74}Fe_{26}$, layer $d_\perp$ reverted to 1.81 ± 0.01 Å. At about 21 Å $Fe_{53}Mn_{47}$ cross-shaped LEED spots became visible possibly hinting to the presence of misfit dislocations along the [100] directions.

Growing $Ni_{77}Fe_{23}$ on a Cu(110) substrate ($d_\perp=1.28\pm0.01$ Å), we measured $d_\perp=1.26\pm0.02$ Å from about 15 Å up to a thickness of 85 Å. The $Fe_{41}Mn_{59}$ wedge grew coherently up to ≈20 Å. For larger thicknesses the perpendicular lattice parameter became $d_\perp=1.30\pm0.02$ Å.

B. Exchange biasing and coercive field

For each orientation, typically 120 Kerr hysteresis loops (Fig. 3) were recorded. For the [111] oriented layer the results of the Kerr measurements are summarized in contour plots for H_{eb} and H_c (Fig. 4). For an easier interpretation intersections of these plots for different FeMn thicknesses are given in Fig. 5. The onset of the biasing was found at ≈25 Å FeMn reaching saturation at ≈55 Å FeMn independently of the $Ni_{80}Fe_{20}$ thickness. For ≈70 Å $Ni_{80}Fe_{20}$ H_{eb} stays almost constant at 14.7 kA/m in the investigated FeMn thickness range above 60 Å [Fig. 5(b)]. H_c displays a sharp

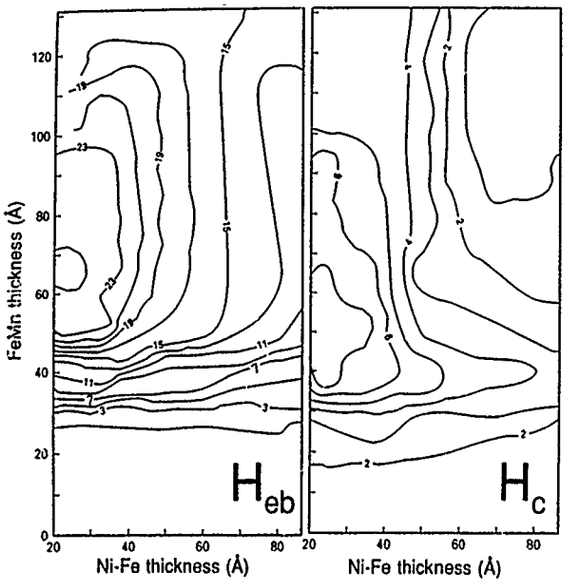

FIG. 4. Contour plots of H_{eb} and H_c for the [111] oriented sample.

maximum at the onset of the biasing effect, dropping at thicker FeMn layers. For all thickness combinations with a FeMn thickness ≥ 40 Å, H_c is smaller than H_{eb}. For $Ni_{80}Fe_{20}$ thicknesses lower than ≈ 50 Å a maximum in H_{eb} and H_c for FeMn thicknesses in the range of 60–90 Å is observed [Fig. 5(a)]. For (111) bilayers with the $Ni_{80}Fe_{20}$ thickness in the interval 20–35 Å, H_{eb} is lower than expected from the $1/t_{FM}$ behavior observed for thicker $Ni_{80}Fe_{20}$.

For the (001) orientation two different samples were grown with the field during growth and Kerr measurements applied along the [100] and [110] in-plane directions, respectively. The aim of making these two samples was to determine whether there is a correlation between the AF surface spin directions {component along the [110] in-plane directions in the ⟨111⟩ spin model, see Fig. 1(a)} and the strength of the biasing. Results for a $Ni_{80}Fe_{20}$ layer thickness of 65 Å are rendered in Fig. 6, where within the experimental error margins (±10%) the same thickness dependence of H_{eb} was found for both samples, saturating to $H_{eb}=10$ kA/m for high FeMn thicknesses. However, a much higher H_c was measured in the sample grown with the field in the [110] direction. In contrast to the [111]-oriented samples, H_c stayed at a high level even for high FeMn thicknesses. The onset of the biasing, together with an increase in H_c is found at a FeMn thickness of ≈ 20 Å, whereas constant biasing is reached at ≈ 90 Å. This result was seen to be independent of the $Ni_{80}Fe_{20}$ thickness. For a given FeMn thickness, Fig. 7 shows the dependence of H_{eb} and H_c on the $Ni_{80}Fe_{20}$ thickness and the orientation of the magnetic field. Whereas for a magnetic field applied during growth and measurement along [110] H_c and H_{eb} vary in a similar manner, for a field applied along [100] H_c became smaller than H_{eb} at ≈ 40 Å $Ni_{80}Fe_{20}$. For $Ni_{80}Fe_{20}$ thicknesses smaller than ≈ 70 Å we find a larger H_{eb} for the sample with the field during growth and measurement along the [110] direction. Biasing is stronger parallel to the surface spin direction, which supports the ⟨111⟩ spin model.

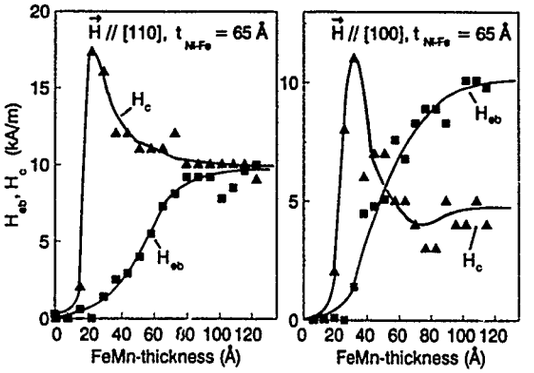

FIG. 6. $H_{eb}(t_{FeMn})$ and $H_c(t_{FeMn})$ for the [001] oriented samples grown and measured with $H\|[110]$ and $H\|[100]$.

For the (110)-oriented bilayer the onset of the biasing effect is found at ≈ 20 Å FeMn and it saturates at ≈ 50 Å independently of the $Ni_{80}Fe_{20}$ thickness [Fig. 8(a)]. A weak maximum in the biasing effect is visible for a FeMn thickness of ≈ 60 Å, reaching a H_{eb} of ≈ 8.9 kA/m at 69 Å $Ni_{80}Fe_{20}$. The coercivity again shows a sharp peak at the onset of the biasing effect and stays larger than the loop shift even for thick FeMn layers. The expected $1/t_{FM}$ dependence of H_{eb} was observed down to $t_{NiFe} \geq 20$ Å. The coupling of

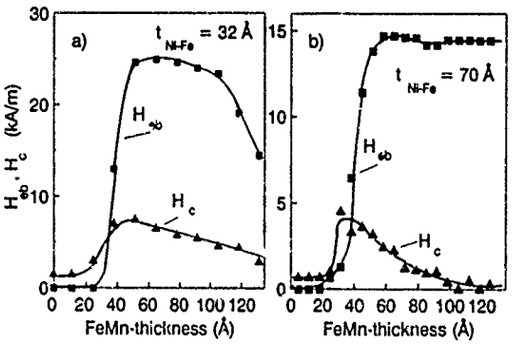

FIG. 5. $H_{eb}(t_{FeMn})$ and $H_c(t_{FeMn})$ for the [111] oriented sample for 32 and 70 Å $Ni_{79}Fe_{21}$.

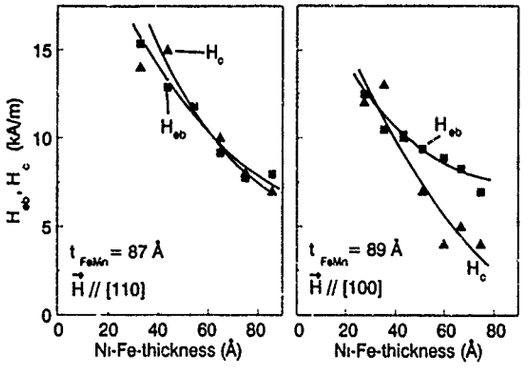

FIG. 7. $H_{eb}(t_{Ni\text{-}Fe})$ and $H_c(t_{Ni\text{-}Fe})$ for the [001] oriented samples for comparable FeMn thickness, but grown and measured with $H\|[110]$ and $H\|[100]$.

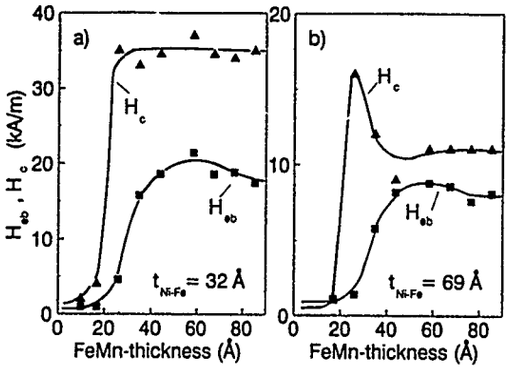

FIG. 8. $H_{eb}(t_{FeMn})$, $H_c(t_{FeMn})$ for the [011] oriented sample for 32 and 69 Å $Ni_{80}Fe_{20}$.

the $Ni_{80}Fe_{20}$ film to the FeMn introduces a remarkable in-plane anisotropy. For 30 Å $Ni_{80}Fe_{20}$ and a 70 Å FeMn layer, a field of ≈220 kA/m has to be applied along the [001] in-plane direction to obtain saturation. Details of this anisotropy and its possible explanations will be discussed elsewhere.

IV. DISCUSSION

To grow the substitutional disordered alloy $Fe_{50}Mn_{50}$ in the antiferromagnetic γ phase, a suitable fcc substrate is desired. The γ phase is metastable for Mn concentrations of more than 54 at. %. Even in the presence of a fcc seed layer such as $Ni_{80}Fe_{20}$ or Cu the FeMn α phase has been observed to form in sputtered samples beyond a thickness of a few hundred Å.[16] Our experiments show that it is possible to stabilize γ-phase FeMn on several differently oriented permalloy layers. However, for the (111) case, the LEED studies did not convincingly show that high quality epitaxial growth was realized for all FeMn thicknesses.

The growth of $Fe_{50}Mn_{50}$ on $Ni_{80}Fe_{20}$ was investigated earlier by transmission electron microscopy (TEM) on sputtered samples,[17] where an epitaxial relationship between the two layers was found. Epitaxial strain (2.4% misfit) was found to be confined locally within each grain and was accomodated by coherent strain across the interface. Therefore, we were curious whether a Cu(111) single crystal, which has a closer lattice match with $Fe_{50}Mn_{50}$ than $Ni_{80}Fe_{20}$, would be a better substrate for growing epitaxial well-oriented Fe-Mn. We found that this is not the case. MBE-evaporated layers of $Fe_{100-x}Mn_x$ alloys ($x=46-51$) on a Cu(111) substrate at 300 and 450 K still gave diffuse LEED patterns with threefold symmetry in the 0–20 Å thickness range. For thicker layers the spots became even fuzzier and disappeared at ≈45 Å. This suggests a polycrystalline growth of FeMn on Cu.

To allow a comparison of the magnetic properties of our $Ni_{80}Fe_{20}/Fe_{50}Mn_{50}$ bilayers with earlier work, Table I gives a compilation of results on sputtered and evaporated substrate/$Ni_{80}Fe_{20}/Fe_{100-x}Mn_x$ samples prepared on different substrates. The strength of the exchange biasing is expressed in terms of the product $H_{eb}*t_{FM}$. It cannot be excluded that the variation of the composition of the Fe-Mn layers slightly influences the observed variation of H_{eb} with the growth direction; this dependence is however well documented.[4,18] Hemstead *et al.*[4] find a maximum biasing for their HV evaporated $Fe_{47}Mn_{53}$ alloy. In our samples, even when taking possible differences in the FeMn compositions into account, the [111] oriented bilayers had the strongest exchange coupling. No correlation is found between the strength of the biasing and the compensated or uncompensated nature of the ideal interfaces illustrated in Fig. 1. Specifically, the [110] oriented sample, with uncompensated interface in the ideal case, shows the weakest biasing. Possible explanations include a different spin structure, modification of the interface spin structure or the presence of a rough interface. Since results on the (001) samples support the ⟨111⟩ spin model, it is perhaps most likely that roughness causes partially uncompensated interfaces in all orientations. Malozemoff's[13] proposals can then account for the presence of biasing in all three orientations.

Sputtered samples on Si and Si(001)/Ta/$Ni_{80}Fe_{20}$/Cu "substrates," i.e., in a spin-valve magnetoresistance multilayer, display the strongest biasing. The interface coupling of sputtered bilayers on glass substrates varies strongly with the sputtering conditions. Our MBE-grown samples have a well-defined sharp interface. Interface mixing due to the higher kinetic energy of the sputter-deposited atoms could cause stronger biasing similar to the effect caused by annealing, creating a Ni-Mn-Fe alloy at the interface.[19] The presence of a thin ferromagnetic layer at the interface with a magnetization different from the bulk[20] could result in a wrong determination of the "magnetic thickness." Results for thick t_{FM} are therefore more reliable.

For the observed dependence of the biasing field and coercivity on the thickness of the AF layer we present the following hypothesis: The stability of the AF spin configuration depends on the balance between the change of the interfacial energy when the FM layer is reversed and the stabilizing "coercivity" in the AF layer. Upon increasing the AF-film thickness the number of bulk inhomogeneities in the AF layer is increased leading to more effective pinning of the AF spin configuration and to biasing beyond a certain critical Fe-Mn thickness. Around this critical Fe-Mn thickness locally the spin configuration remains fixed, leading to biased FM "particles" in a matrix of magnetically soft unbiased material. This results in the high coercivity of such a magnetically inhomogeneous system.[21] Upon a further increase of the Fe-Mn layer thickness, the $Ni_{80}Fe_{20}$ layer becomes more homogeneously biased, and H_c drops. The precise nature of the inhomogeneities in the AF layer (e.g., structural, thickness or compositional randomness), is unclear. If compositional randomness in the AF leads to variations of the anisotropy constant this model coincides with an earlier suggestion by Schlenker *et al.*,[9] who proposed different types of AF regions. In some regions with large AF anisotropy the spins are blocked and responsible for the loop shift; in others with weaker anisotropy the AF moments rotate irreversibly when the FM magnetization rotates. In another interpretation, Speriosu *et al.*[22] and Parkin *et al.*[23] discuss regions with locally different blocking temperatures depending on t_{AF} which contribute to the net anisotropy as independent particles.

At Fe-Mn thicknesses where biasing is saturated we observe for the [111] orientation that H_c becomes smaller toward higher FeMn thicknesses, whereas for the [100] and [110] orientations it stays almost constant for a given $Ni_{80}Fe_{20}$ thickness. We correlate this to the in-plane anisotropy of the exchange coupled $Ni_{80}Fe_{20}$ system. The anisotropy energy is isotropic in the (111) plane, whereas there are easy and hard directions in the (100) and (110) planes.

The weak maximum in H_{eb} just after the onset of the biasing for ≈60 Å FeMn thickness found in our [111] and [110] oriented samples (Figs. 4 and 7), was also observed for sputtered glass/Ta/NiFe/FeMn and glass/NiFe/FeMn samples,[24] especially after annealing the samples. In our experiments and the earlier work it is not clear if these findings have their origin in structural properties of the bilayer, or if they confirm Malozemoff's[14] prediction of an increased H_{eb} in the "Heisenberg domain state."

V. CONCLUSIONS

In conclusion, for highly oriented MBE grown $Ni_{80}Fe_{20}/Fe_{50}Mn_{50}$ systems we have demonstrated that H_{eb} and H_c strongly depend on the crystal orientation. To obtain maximum biasing at a minimum coercive field a [111]-oriented layer system is favorable. No obvious relation between the strength of the biasing and the compensated or uncompensated nature of the FM/AF interface in the [111], [001], or [110] oriented bilayers was found. However, we observe that the (110) samples behave differently in that they show a high in-plane anisotropy. The observation that H_{eb} and H_c depends on the in-plane direction of the field applied during growth and measurement for the (001) samples, giving a higher H_{eb} for $H\|[110]$, is consistent with the ⟨111⟩ spin model for the antiferromagnetic layer.

New ultrathin epitaxial magnetic multilayers consisting of ferromagnetic τMnAl and nonmagnetic NiAl have been prepared on GaAs by molecular beam epitaxy. The magnetic and magneto-optic properties of these multilayers and the effect of incorporating nonmagnetic NiAl into the structure have been investigated. Perpendicular magnetization was confirmed and the remnant magnetization and coercivity were improved compared to τMnAl thin films. In addition, by systematically changing the thickness of the NiAl layer the magnetic properties could be controlled. We discuss these issues and compare the magnetic and magneto-optic properties of these structures with other epitaxial magnetic structures.

A variety of novel thin films and heterostructures have been made possible due to the recent progress in heteroepitaxial growth techniques. One unique combination is the epitaxial growth of ferromagnetic metals on compound semiconductors for a new class of potential devices that exploit the properties of both materials. This requires compatible materials that retain both their magnetic and semiconducting properties during growth. In recent years epitaxial growth of ferromagnetic metal films, such as Fe on GaAs have been demonstrated by Prinz.[1] This work generated a great deal of interest in the properties of single crystal ultrathin magnetic layers. Prinz[2] describes the potential of these materials for devices such as magnetic memory elements using magnetic sandwiches and spin injection devices. Although many applications require the magnetization to be in-plane, there are a number of applications that require the magnetization to be perpendicular to the film plane. This configuration not only allows higher density magnetic and magneto-optic recording, but also allows using the magnetic field to influence the electrons in an underlying semiconductor or to use the magneto-optic properties of the magnetic thin film to control underlying optoelectronic devices.

Recently, Sands and co-workers[3,4] reported successful growth of epitaxial, perpendicularly magnetized, ferromagnetic τMnAl films on {100} GaAs by molecular beam epitaxy (MBE). The τ phase of MnAl in the bulk has a Curie temperature of 380 °C, a saturation magnetization of 490 emu/cm^3 and an intrinsic coercivity of 4.6 kOe.[5] It is the only ferromagnetic phase in the bulk τMnAl system and can be formed in the bulk by rapid cooling from the high-temperature hexagonal phase. Other techniques, such as evaporation[6] and magnetron sputtering[7] have been used to deposit polycrystalline τMnAl films, but stabilizing the τ phase was difficult. It was found that heteroepitaxy helps to align the c axis of the tetragonal unit cell, which is the direction of easy magnetization, along the direction perpendicular to the substrate. The perpendicular magnetization of τMnAl thin films was demonstrated by the extraordinary Hall effect (EHE).[3] The measurements showed a hysteretic behavior with rectangular shaped loops and 100% remnance. The remnant magnetization (M_r) of the films was 171 emu/cm^3 with a coercivity (H_c) of 5.03 kOe and magneto-optic Kerr rotation of 0.16°.[8] In addition, the integrity of the interfaces between the magnetic metal and the underlying (Al,Ga)As could be maintained as indicated by the Schottky diode characteristics.[9]

Because many applications require higher M_r (>200 emu/cm^3), lower values of H_c (0.5 kOe<H_c<3.0 kOe) and a higher magneto-optic Kerr rotation (>0.3°) in addition to a square hysteresis, we have investigated other material systems. The possibility of improving the magnetic and magneto-optic properties has been explored by growing thin films such as (Mn,Ni)Al,[10,11] MnGa,[12] (Mn,Ni)Ga,[13] and magnetic multilayers.[14,15]

The addition of up to 4 at. % Ni to τMnAl sputtered films has led to higher M_r and H_c.[7] We have shown[11] that in epitaxial τMnAl films with up to 17 at. % Ni a similar increase in magnetization was not observed most probably due to the coherency that existed between the films and the GaAs. Unlike τMnAl, which is a metastable phase, thermodynamically stable epitaxial films of MnGa with 55%–60% Mn have been grown successfully.[12] An M_r of 225 emu/cm^3 and H_c of 3.15 kOe have been measured, which represents an improvement over the magnetic properties of τMnAl films. Similarly, the addition of Ni to MnGa thin films resulted in decreasing the perpendicular magnetization.[13]

In the past, semiconductor superlattices have had a tremendous impact on the fundamental physics of semiconductors and device applications. Ultrathin multilayers and heterostructures of dissimilar metallic compounds may also have the same potential. A new class of ultrathin epitaxial magnetic multilayers consisting of ferromagnetic metal τMnAl and nonmagnetic metal NiAl have been grown recently by MBE.[15] These new structures allow further exploitation of the accurately controlled thicknesses and abrupt interfaces obtained by MBE. Furthermore, the possibility of controlling the magnetic properties within these unique epitaxial structures opens up new opportunities for novel device applications.

In this paper, we discuss the magnetic and magneto-optic

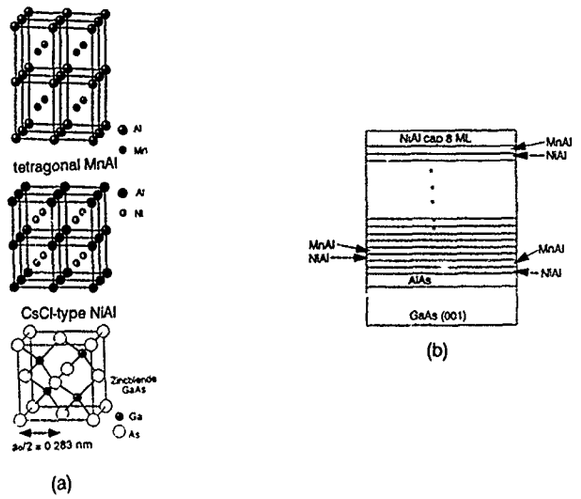

FIG. 1. Schematic of crystal structures of τMnAl, NiAl, and GaAs, and the multilayer structure of MnAl/NiAl grown on GaAs.

properties of ultrathin τMnAl/NiAl multilayers films. We describe these properties as a function of systematically increasing the NiAl film thickness within the multilayer structure. Furthermore, we compare the properties of the multilayer films with that of τMnAl, (Mn,Ni)Al, and MnGa/NiGa magnetic multilayers.

The crystal structure of τMnAl is an ordered CuAu-type tetragonal lattice with alternating planes of Mn and Al along the c axis as shown in Fig. 1(a). In bulk quenched films, the basal plane lattice parameter is a_0=0.277 nm and c_0=0.354 nm.[5] Stoichiometric NiAl is a nonmagnetic intermetallic with a cubic CsCl-type crystal structure with a lattice constant of a_0=0.289 nm. The basal plane lattice parameters for both NiAl and τMnAl are close to half of the lattice constant of GaAs (a_0=0.283 nm). Thus the lattice mismatch for NiAl on GaAs is +2.1% and τMnAl on GaAs is −2.1%. The measured lattice parameters for MBE grown epitaxial τMnAl on GaAs by x-ray diffraction show that a_0=0.283 nm and c_0=0.345 nm indicating that coherency between τMnAl and the underlying GaAs result in a reduced tetragonality compared to bulk crystals.[3]

In this study, a series of multilayer samples were grown with alternating Y monolayers of τMnAl and X monolayers of NiAl. A monolayer (ML) thickness of MnAl/NiAl is defined here as the Al–Al spacing in the ordered CuAu-type tetragonal structure (CsCl-type structure).[15] The number of τMnAl monolayers was held constant at Y=3 ML (1.05 nm) while the number of NiAl monolayers ranged from X=1–6 ML. This corresponds to a NiAl thickness of 0.35 to 2.1 nm. The τMnAl thickness was held constant because thicker layers would influence the magnetic properties. There were ten periods for all samples resulting in a total τMnAl thickness of 10.5 nm.

The MnAl/NiAl multilayers were grown using a conventional MBE equipped with Mn and Ni effusion cells. The multilayer structures were grown beginning with a semi-insulating (001) GaAs substrate as shown in the schematic in Fig. 1(b). Above the substrate, a 100-nm-thick undoped

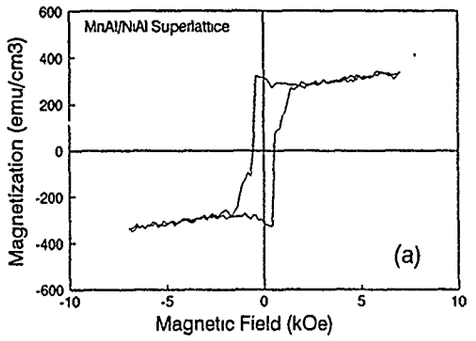
FIG. 2. Cross-sectional transmission electron microscopy taken from a MnAl(3 ML)/NiAl(3 ML) film with ten periods.

GaAs buffer layer and a 5-nm-thick AlAs layer were grown at 580 °C. Following the heterostructure growth, the substrate temperature was cooled to 250 °C and the arsenic flux eliminated. The multilayers were then grown at a substrate temperature of 250 °C in an arsenic-free ambient. The metal layers were grown using a template approach in which 1 ML of Ni was initially deposited on the AlAs surface and then Ni and Al at a 1:1 ratio were codeposited at a growth rate of 0.052 μm/h. Then, τMnAl was grown on the CsCl-type (001) NiAl surface by codeposition of Mn and Al at a growth rate of 0.061 μm/h. The Mn/Al ratio was 60/40 in order to ensure the formation of the ferromagnetic τ phase with good magnetic properties.[15] Alternating monolayers of τMnAl and NiAl were repeated to form a structure with the desired number of periods. Finally, a 8-ML-thick NiAl cap was grown on top and a postgrowth anneal of 350 °C for 2 min was performed. The time and temperature of the postgrowth anneal was optimized in order to produce the best magnetic properties. The anneal was found to be absolutely essential to the obtaining good magnetic properties.

Additional samples, with MnAl(6 ML)/NiAl(3 ML) with five periods and a $Mn_{30}Ni_{30}Al_{40}$ alloy were grown to determine the effect of thicker MnAl multilayers and comparable alloys on the magnetic properties.

The crystalline structure was verified using *in situ* reflection high-energy electron diffraction (RHEED) along the ⟨110⟩ azimuth during growth. Streaky RHEED patterns[15] were maintained throughout the growth of the multilayers indicating that monocrystalline multilayers with the desired epitaxial orientation of [110](001)MnAl/NiAl// [110](001)GaAs were maintained. After the tenth period, the RHEED pattern of the NiAl surface was a little less streaky than the τMnAl surface which showed very sharp streaks. This indicates that roughness on an atomic scale was present on the NiAl surface under the present growth conditions. The RHEED pattern did not change significantly after the postgrowth anneal. The sharp, streaky RHEED patterns were observed throughout most of the multilayer growth runs which indicates that they were all high-quality monocrystalline films with the proper epitaxial orientations. The RHEED patterns of the multilayers were better than those of τMnAl, which may be due to the reduction in strain between these layers.

Cross-sectional transmission electron microscopy (TEM) results for a MnAl(3 ML)/NiAl(3 ML) sample is shown in Fig. 2. The figure shows a ⟨110⟩ bright field image of the multilayer with ten periods grown on AlAs/GaAs. The image shows that the interfaces were very smooth and that compo-



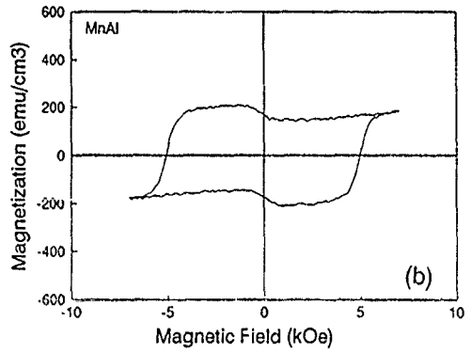


FIG. 3. Magnetization curves of (a) MnAl/NiAl multilayer and (b) τMnAl thin film.

sitional modulation was achieved in such a thin periodic structure. The extremely smooth interfaces indicated that there was little if any interfacial mixing between the τMnAl and the NiAl. Analysis of the diffraction pattern confirmed that the multilayers were stacked with the desired epitaxial orientations of [110](001)MnAl/NiAl//[110](001)GaAs and that the c axis of the tetragonal τMnAl was aligned normal to the substrate. The c_0 lattice parameter of the τMnAl layers was estimated to be 0.33–0.34 nm. This value was less than the 0.354-nm bulk value and slightly less than the 0.345 value for 10-nm-thick MBE grown τMnAl films.[16] This indicates that the τMnAl multilayers showed a significantly reduced tetragonality possibly due to elastic strain at the interface.

Measurements of the magnetic properties of the MnAl/NiAl multilayers were performed using vibrating sample magnetometer (VSM), magneto-optic Kerr effect (θ_k) measurements and the extraordinary Hall effect at room temperature. The multilayer samples were all measured by VSM in a magnetic field up to 10 kOe. Figure 3(a) shows a hysteresis loop from a MnAl(3 ML)/NiAl(3 ML) sample with a slightly different annealing condition. The nearly square hysteresis loop indicates perpendicular magnetization and the M_r and H_c measured 314 emu/cm^3 and 0.550 kOe, respectively. For comparison, the hysteresis loop of a τMnAl thin film is shown in Fig. 3(b). The figure shows that not only was the magnetization improved, but the H_c was also dramatically reduced.

The M_r and H_c values obtained for this multilayer film

TABLE I. Comparison of magnetic properties in MnAl(3 ML)/NiAl(3 ML), τMnAl, $Mn_{30}Ni_{30}Al_{40}$, and MnGa (6 ML)/NiGa(6 ML).

Sample	M_r (emu/cm^3)	H_c (kOe)	θ_k (degree)
MnAl(3 ML)/NiAl(3 ML)	314	0.550	0.1
MnAl	171	5.029	0.16
$Mn_{30}Ni_{30}Al_{40}$	57	1.215	···
MnGa(6 ML)/NiGa(6 ML)	302	2.29	···

were higher than those obtained for τMnAl, (Mn,Ni)Al films and MnGa/NiGa multilayers. Table I compares the M_r, H_c, and θ_k of these four structures. The M_r and H_c of a 10-nm-thick τMnAl film clearly differs from that of the MnAl(3 ML)/NiAl(3 ML) multilayer such that the M_r(171 emu/cm^3) was lower and the H_c was higher (5.029 kOe) than the multilayer. In addition, a similar thickness $Mn_{30}Ni_{30}Al_{40}$ alloy of comparable composition to the multilayer also showed a somewhat reduced M_r(57 emu/cm^3) and a higher H_c(1.215 kOe) than the multilayer. Also, multilayers of MnGa(6 ML)/NiGa(6 ML) showed a reduced M_r and higher H_c for even thicker magnetic (MnGa) layers.[14] Thus for applications that require integration of perpendicularly magnetized materials with underlying semiconductor electronics the higher magnetization and lower coercivity measured here for MnAl/NiAl multilayers seem quite desirable.

The effect of incorporating NiAl into a multilayer structure was studied with the series of samples with the same growth and annealing conditions. Figure 4 shows the effect of increasing the NiAl thickness on the M_r and H_c in the MnAl (3 ML)/NiAl(X ML) samples. As the NiAl thickness

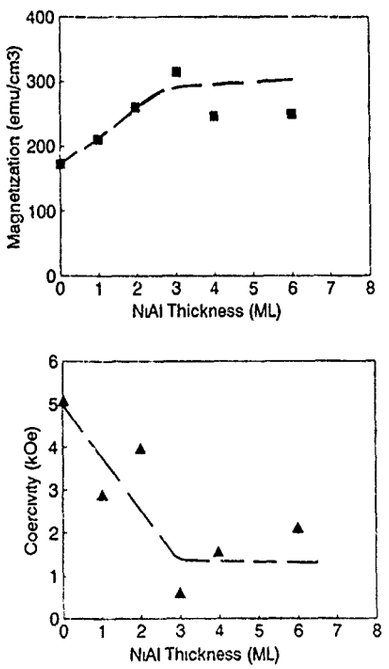

FIG. 4. Measurement of (a) remnant magnetization and (b) coercivity of MnAl(3 ML)/NiAl(X) with X=1–6 ML multilayers as a function of NiAl thickness.

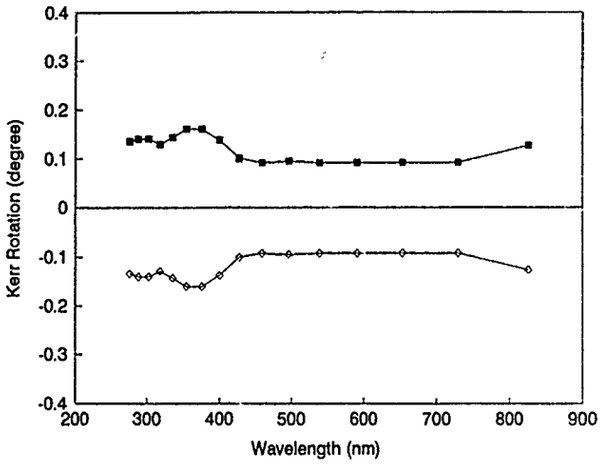

FIG. 5. Magneto-optic Kerr rotation of MnAl(3 ML)/NiAl(3 ML) as a function of wavelength.

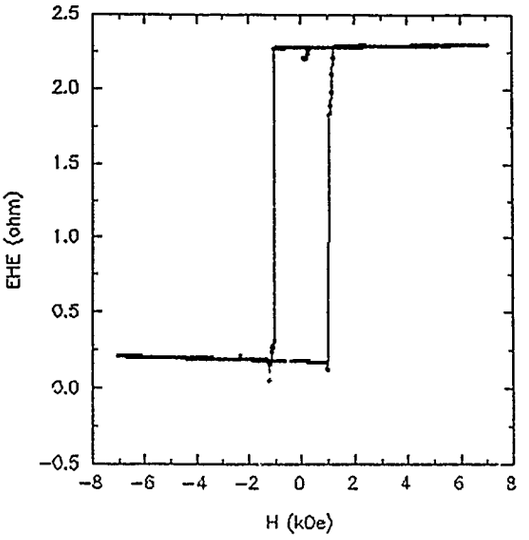

FIG. 6. Extraordinary Hall effect characteristics of a MnAl(3 ML)/NiAl(3 ML) multilayer measured at room temperature.

(X) increases, the M_r increases from 171 emu/cm^3 to as high as 314 emu/cm^3 for $X=3$ ML. Beyond 3 ML the M_r remained fairly constant. The figure also shows that the H_c decreases to a value of 0.55 kOe for $X=3$ ML. In all cases, the M_r of the multilayer structures was higher than the τMnAl, (Mn,Ni)Al, and MnGa/NiGa samples of similar thickness. As expected, the M_r increased if the thickness of the τMnAl was increased, as indicated by measurements of a MnAl (6 ML)/NiAl(3 ML) multilayer with a M_r of 342 emu/cm^3.

The magneto-optic Kerr rotation was measured on a MnAl (3 ML)/NiAl(3 ML) sample as a function of the wavelength from 830 to 270 nm. The rotation was measured after the samples had been poled either parallel or antiparallel to the film normal by exposure to a 8.0-kOe magnetic field. The Kerr rotation, shown in Fig. 5 was about 0.10° at 800 nm and remained fairly constant between 450 and 800 nm. The lower Kerr rotation measured for the multilayer compared to τMnAl may be attributed in part to 2.8-nm-thick nonmagnetic NiAl cap on the surface of the structure. Both rotation values are slightly lower than the 0.3° to 0.4° values reported for TbFeCo, but similar to 0.1°–0.2° reported for Co/Pt multilayers.[17] A reasonable value of the Kerr rotation is important particularly for applications such as magneto-optic recording or devices which utilize the rotation of polarization for the modulation of light.

The extraordinary Hall effect measurements performed on MnAl(3 ML)/NiAl(X ML) multilayers were all nearly square. The EHE is caused by the asymmetric scattering of electrons by magnetic species in a ferromagnetic material. A square shaped hysteresis loop therefore indicates a large component of magnetization perpendicular to the film plane and the Hall resistance is a measure of the film quality. Samples were fabricated into a Hall bar configuration by photolithography and chemical etching. Typically, a 100-μA dc current was applied to a 200-μm-wide Hall bar that was placed into a magnetic field oriented perpendicular to the film plane.

Figure 6 shows the results of a 200-μm Hall bar measurement in which a rectangular hysteresis loop was obtained. Switching of the magnetization direction occurred within an increment of 200–400 kOe. The switching field needed to reach saturation is believed to be due to a domain wall sweeping across the intersection of the Hall bar. The saturation values of the Hall resistance were in the range of 2.0–2.5 Ω, which are considered large enough for electrical readout.[15] Single step hysteresis loops were observed for all the measured samples. This differed from the multistepped EHE measured for MnGa/NiGa multilayers which may be applicable to multilevel signal recording.[14] The reason for these steps or lack of them is not clear, but may be due to less strain energy within the τMnAl multilayers than the MnGa multilayers.

The improved magnetization with thicker NiAl layers may in part be due to the reduced tetragonality observed in these structures compared to τMnAl. The c/a ratio decreased from 1.29 in the bulk, to 1.22 in epitaxial τMnAl to about 1.18 for MnAl (3 ML)/NiAl(3 ML) multilayers. This suggests a decrease in the tetragonality which appears to be coincident with a rise in remnant magnetization. Morisako[7] suggested that as both the c_0 and a_0 lattice constants decrease the magnetization of τMnAl should increase.[7] It was suggested that the elongated distortion of the tetragonal lattice weakens the exchange interaction between the electrons. Therefore, if the lattice constants are reduced, a higher magnetization would be obtained. In general, this may explain the improved magnetization within an optimized MnAl (3 ML)/NiAl(3 ML) multilayer. Hence, the role of strain on both magnetization and coercivity may be an important parameter that requires further investigation in order to exploit tunable magnetic properties within epitaxially designed magnetic thin films.

In summary, we have discussed the magnetic and magneto-optic properties of ultrathin ferromagnetic τMnAl and nonmagnetic NiAl multilayers grown by MBE on (Al,Ga) As heterostructures. These structures showed per-

pendicular magnetization, improved remnant magnetization and a lower coercivity compared to thin film τMnAl. Both the remnant magnetization and coercivity can be adjusted and further improved by incrementally increasing the monolayer thickness of the nonmagnetic NiAl layer. The magneto-optic and magnetic properties described here may be suitable for device applications which include magnetically controlled optoelectronics and nonvolatile memory elements.

Bi- and Al-doped DyIG(y Å)/Fe(x Å) (y=50 to 130 Å and x=5 to 15 Å) multilayer thin films were made by magnetron sputtering onto Si(111) substrates. Rapid thermal annealing was used to crystallize these garnet multilayers. The crystallized multilayer samples possess well-defined interfaces. Atomic force microscopy showed that the annealed samples had smooth surfaces, with small grain sizes (~30 to 80 nm). All of the samples had perpendicular magnetic anisotropy with very square hysteresis loops. The coercivity was found to vary from 600 Oe to 2 kOe, depending on Fe thickness and annealing conditions. The measured figure of merit $\sqrt{R(\theta_K^2+\epsilon_K^2)}$ at 420 nm was bigger than 0.4, suggesting that Bi- and Al-doped DyIG/Fe multilayers are promising candidates for blue light magneto-optical recording applications.

Bi-doped DyIG (garnet) thin films have moderate perpendicular magnetic anisotropy and large magneto-optical Faraday effect in the blue region of the spectrum. The magnetic parameters such as the coercivity H_c and the saturation magnetization M_s are easily varied through changes in the composition. These properties are the key for the materials to be used as a magneto-optical (MO) recording media at blue laser wavelengths.[1–5] Unfortunately, the garnets are polycrystalline with a large grain size and a rough surface, which will give a substantial media noise which is absent in the rare-earth-transition metal (RE-TM) amorphous MO recording media. Suzuki[5,6] demonstrated that by using rapid thermal annealing (RTA), where the heating ramp rate can exceed 50 °C/s, the grain size can be reduced to about 40 nm and the surface morphology can also be improved. Suzuki[6] also showed that the microstructure of the garnet films could be further improved through multilayering the garnet with Cr, Co, and SiO_2; this is because the space layer will interrupt the growth of garnet. In this paper, we will report the microstructure and the magneto-optical properties of thin films of Bi- and Al-doped DyIG multilayered with Fe.

$Dy_{1.6}Bi_{1.4}Fe_{1-x}Al_xO_{12}$ (x=0.6 to 1.0) and Fe multilayers were deposited on Si(111) and quartz room-temperature substrates by rf (for garnet) and dc (for Fe) magnetron sputtering in a pure Ar atmosphere. The Si was used for the purpose the RTA. Standard sintering techniques were used to make the ceramic garnet target. The individual garnet layer thickness was varied between 50 and 130 Å, while the Fe individual layer thickness was varied from 5 to 15 Å. We adjusted the total number of bilayers to keep the total sample thickness roughly at 1000 Å. As-deposited films are amorphous. The samples were then crystallized in air using a home-built rapid thermal annealing system consisting of a 1-kW halogen lamp with the light focused on the sample by an ellipsoidal mirror. The maximum heating ramp rate using this system was about 30 °C/s. The samples were typically annealed at 650 °C for 2 to 5 min. The microstructure and surface morphology of both as-deposited and annealed samples were investigated by atomic force microscopy (AFM). Both large- and small-angle x-ray diffraction were used to characterize the crystalline and multilayer structures. Kerr rotation measurements were carried out over the wavelength range 350–600 nm in magnetic fields up to 12 kOe.

After rapid thermal annealing, large-angle x-ray diffraction spectra shown that a single garnet phase was formed, with no trace of pure Fe diffraction peaks. The garnet grains are totally randomly oriented, with no preferred orientation in these multilayer thin films. Figure 1 shows the small-angle x-ray diffraction spectra both before and after annealing of a [BiAlDyIG(100 Å)/Fe(9 Å)]×10 sample. The two spectra both show six superlattice peaks, indicating that there are well-defined interfaces between the garnet and Fe layers even after a 650 °C RTA for 2 min. One surprising result is that the superlattice peaks of the annealed samples are slightly higher than those of the as-deposited samples, which suggests that the crystallization of the garnet improves the interface definition. However, more detailed studies are needed to fully understand this result. After crystallization, the positions of all the superlattice peaks shift toward larger angles, indicating that the crystallized garnet layers are

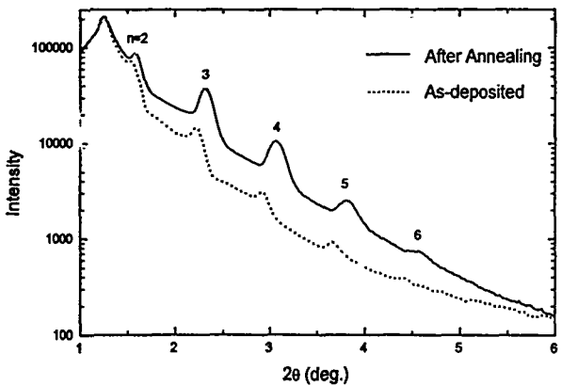

FIG. 1. Small-angle x-ray diffraction spectrum of [BiAlDyIG(100 Å)/Fe(9 Å)]×10 multilayers before (dashed line) and after (solid line) annealing.

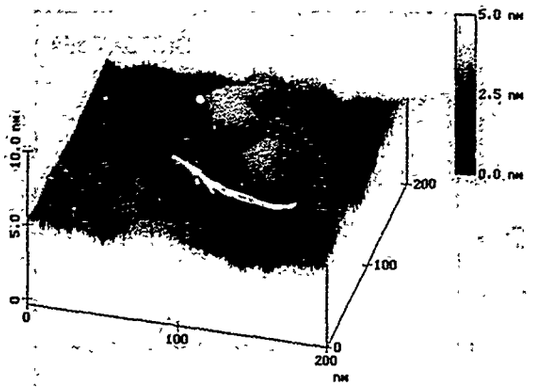

FIG. 3. AFM picture of [BiAlDyIG(100 Å)/Fe(9 Å)]×10 after 2-min rapid thermal annealing at 650 °C.

denser than the as-deposited amorphous layers.

We characterized the microstructure of our multilayer samples using atomic force microscopy. AFM pictures show that as-deposited amorphous multilayer films have little surface structure, with a surface roughness of ~1 nm. Figure 2 shows an AFM picture of [BiAlDyIG(100 Å)/Fe(11 Å)]×9 after 5 min RTA. From this picture we estimate the grain size to be roughly 80 nm, which is much smaller than the grain size of 1 μm typically obtained with oven-annealed single layer garnet films.[7] The surfaces of annealed samples are considerably rougher than those of the as-deposited films. An estimate of the peak-to-peak surface roughness for the sample of Fig. 2 is about 5 nm. Although the observed 80-nm grain size is much smaller than 1 μm, it is still far too large for magneto-optical recording applications. In order to further reduce the grain size and improve the surface smoothness, a shorter annealing time was used. Figures 3 and 4 show AFM pictures of a [BiAlDyIG(100 Å)/Fe(9 Å)]×10 multilayer film with different vertical scales. Assuming that the bumps observed in these figures are grains, we estimate the average grain size to be 20 to 30 nm. A 20 μm×20 μm scan (Fig. 4) shows the surface morphology of this same sample. Comparing Figs. 2 and 4, we can see clearly that shortening the annealing time is a very effective way of obtaining smooth surfaces. We estimate the peak-to-peak surface roughness to be 2 to 3 nm.

Although these results regarding the grain size must be confirmed by transmission electron microscopy (TEM) studies, we can safely conclude that rapid thermal annealing will reduce the grain size and multilayering the garnet with Fe (or other elements) will reduce the grain size further and substantially improve the surface morphology.

Figure 5 shows a Kerr hysteresis loop for a [BiAlDyIG(75 Å)/Fe(5 Å)]×13 sample which had been annealed at 650 °C for 5 min. The very square loop indicates that the sample has perpendicular magnetic anisotropy. Since our x-ray diffraction measurements show that the grains are randomly oriented, this perpendicular anisotropy must come from the stress.[8] The measured Kerr rotation is 1.2° at a wavelength of 410 nm and this value is independent of annealing time after more than 60-s annealing. This measured value is the combination of both Kerr and Faraday rotations, and it includes the effects of optical interference in the sample. The coercivity of this particular sample is ~1 kOe, and it sensitively depends on the annealing conditions and the individual garnet and Fe layer thicknesses. The figure of merit $\sqrt{R(\theta_K^2+\epsilon_K^2)}$ for [BiAlDIG(104 Å)/Fe(5 Å)]×14 with

Al reflect layer is 0.4 to 0.6 between the 400- and 500-nm region. In our experiments, we have found that if the individual Fe layer thickness is held fixed at 5 Å, the coercivity oscillates between 0.6 and 1.5 kOe as the individual garnet layer thickness is varied from 50 to 130 Å. This variation is not due to the shifting of the compensation temperature as the compensation temperature is about 170 K for most of our samples and is independent of the individual garnet layer thickness. These oscillations are difficult to understand and they need further investigation. A possible explanation might be related to thickness-dependent defects or inhomogeneities of our samples.

Figure 6 shows the dependence of the coercivity on the total number of bilayers for [BiAlDyIG(90 Å)/Fe(5 Å)]×N, where N is varied from 4 to 24. All these samples were annealed at 650 °C for 2 min with RTA technique. The coercivity decreases with increasing number of bilayers (that is the total thickness of the sample). It should be noted that the samples with N less than ten cannot be crystallized with the annealing condition mentioned above. To crystallize these thin samples either a higher annealing temperature or a longer annealing time is needed. The same situation was also noted for samples with individual garnet layer thicknesses less than 50 Å. This phenomenon is attributed to the increase of the surface-to-volume ratio or the surface tension of the garnet phase with decreasing particle size, as discussed by Cho *et al.*[9] The surface energy and surface stress usually tends to hinder the nucleation and growth of the garnet

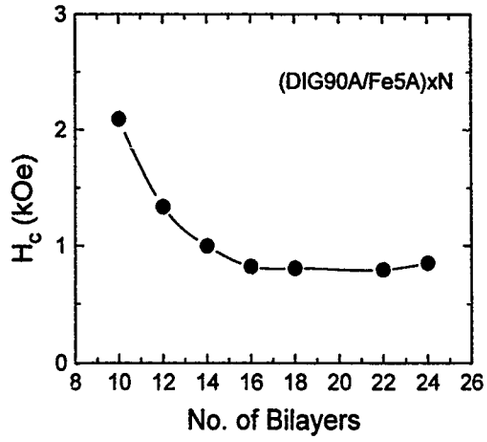

FIG. 6. Coercivity of [BiAlDyIG(90 Å)/Fe(5 Å)]×N as a function of the number of bilayers N after 650 °C 5-min annealing.

phase.[10] So the increase in H_c with decreasing number of bilayers may be due to either the smaller grain size or to a mixture of the crystalline and amorphous garnet phases in the thinner samples. The observed smaller saturation magnetization in these samples also support this assumption. Once again, a detailed TEM investigation will be needed to understand these results.

We have successfully made garnet/Fe multilayers with relatively sharp interfaces. Small grains (~30 nm) and smooth surfaces were realized by a rapid thermal annealing technique. The multilayers of garnet/Fe have square hysteresis loops with a large coercivity and large magneto-optic activity in the blue portion of the spectrum. These results show that the garnet/Fe multilayers are promising candidates for magneto-optic recording using blue lasers. Systematic studies of how the multilayers affect the magneto-optic behavior and the sample microstructure are underway.

We are thankful to Dr. Z. S. Shan and Dr. T. Suzuki for helpful discussions and to NSF and ARPA for financial support under Grants DMR-9222976, NSF-OSR-9255225, and MDA 972-93-1-009, respectively.

Inverted hysteresis in magnetic systems with interface exchange

M. J. O'Shea
Department of Physics, Cardwell Hall, Kansas State University, Manhattan, Kansas 66506-2601

A.-L. Al-Sharif
Department of Physics, Mu'tah University, Karak, Jordan

The effects of interface exchange on magnetic hysteresis are considered for a variety of situations in a two-phase model in which the phases are coupled antiferromagnetically. This work is motivated by studies of Co-CoO nanophase systems where inverted hysteresis loops, a phenomenon closely related to shifted hysteresis loops, are obtained. Some previous examples of systems with inverted hysteresis loops are reviewed and a two-phase model with uniaxial anisotropy and interface exchange is considered. It should be emphasized that this model cannot completely explain inverted hysteresis loops, but it does show that partially inverted loops can be obtained. Cases where H is not along an anisotropy axis are discussed; it was concluded that some alignment of H with the axis of the stronger anisotropy phase is necessary to obtain partially inverted hysteresis.

Interface exchange, identified over three decades ago,[1] can substantially influence magnetic hysteresis. These effects include (i) shifted hysteresis loops[1,2] where one magnetic phase provides a bias field to a second magnetic phase while not itself taking part in magnetic reversal and (ii) a more general case in which the biasing phase does take part in the magnetic reversal. In this work we shall briefly review experimental examples of inverted hysteresis loops, a phenomenon in which the forward and reverse branches are shifted in opposite directions so that they completely cross over. We believe that such loops are related to case (ii) above and will consider the extent to which interface exchange models are able to explain this type of hysteresis loop.

Figures 1(a) and 1(b), respectively, show examples of inverted hysteresis loops for a nominally amorphous $Zr_{40}Cu_{50}Mn_{10}$ amorphous alloy[3] prepared by rapid quenching and a layered material with a Co-based layer alternating with a Cu layer.[4] In this latter system the Co-based layer is made up of a dispersion of pure Co and CoO and the layer thickness is less than 10 nm.[4]

The similarity of inverted hysteresis loops to shifted loops suggests that interface exchange, and in particular an antiferromagnetic interface exchange, plays an important role. In order for interface exchange to be important, there must be a large interface area between two magnetic phases present in a system. To achieve this the system must be structured on a very fine scale, usually of the order of nanometers. In the case of the Co-O/Cu system we believe that it is the granular nature of the Co-O layer that is important.[4] In the case of the amorphous $Zr_{40}Cu_{50}Mn_{10}$ alloy,[3] we speculate that a fine grain structure exists here too. The structural correlation length calculated from the x ray for this alloy using the width of the broad amorphous maximum indicates short-range order on the scale of 2.5 nm. Note also that chemical short-range order could be present in this amorphous system as has been found in other amorphous systems.[5]

In this work we report on calculations of magnetic hysteresis in a model with two nonidentical phases, both having uniaxial anisotropy, as a function of (i) anisotropy strength, (ii) interface exchange strength, and (iii) angle between the anisotropy axes and applied field. We note that we do not expect this model (or any purely magnetic model) to produce completely inverted hysteresis behavior since the area of the loop will always be positive in such model solutions, but we will show that certain aspects of inverted hysteresis may be reproduced in this model. Calculations have been reported on a similar model and it is often assumed that the magnetization in each layer or phase may be described by a single vector M of constant magnitude. This rigid rotation assumption will be correct only in special cases. The strong ferromagnetic exchange in Co suggests that the rigid rotation assumption may have some validity here. Reference 6 has discussed the condition for the assumption of rigid rotation of the spins in a magnetic layer to be valid. We consider two phases, A and B, interacting through an interface exchange.

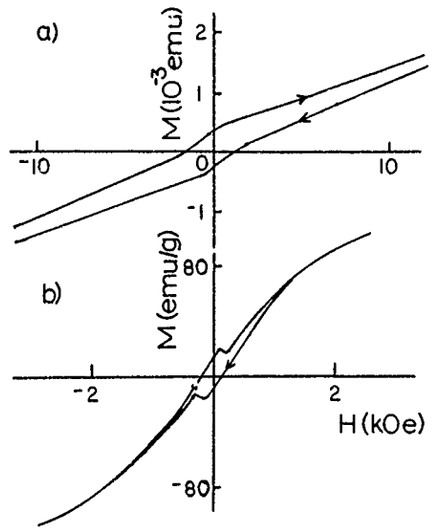

FIG. 1. Hysteresis loops for (a) amorphous $Zr_{40}Cu_{50}Mn_{10}$ (from Ref. 3), (b) a (Co-O)/Cu multilayer (from Ref. 4) with the applied field perpendicular to the film.

The macroscopic energy for this model is taken to be

$$E=-M_A H\cos\theta_A - M_B H\cos\theta_B - J\cos(\theta_B-\theta_A) + K_A\sin^2(\theta_A-\phi_A)+K_B\sin^2(\theta_B-\phi_B). \quad (1)$$

The first two terms represent Zeeman magnetic energies of the two phases of magnetizations M_A and M_B, the third term represents the interface exchange of strength J and the last two terms represent the anisotropy of each phase of strengths K_A and K_B. θ_A and θ_B are the angles that M_A and M_B, respectively make with the magnetic field direction. ϕ_A and ϕ_B are the angles that the uniaxial anisotropy axes of each phase makes with H. We have already discussed this model with reference to Co-O and associate the A phase with pure Co and the B phase with CoO.[4] Previous calculations assuming a rigid rotation of the magnetization[6-10] consider cases where H is along a high symmetry anisotropy direction for cubic or uniaxial anisotropy.

In our calculation we find that provided H is applied in a plane defined by the two anisotropy axes, then M_A and M_B remain in this plane for the range of parameters used in this work. Thus we can describe the directions of these magnetizations by one angle each (θ_A and θ_B, respectively) in Eq. (1). Values of θ_A and θ_B as a function of H are determined by following a local minimum in E of Eq. (1) by solving $\partial E/\partial\theta_A=0$ and $\partial E/\partial\theta_B=0$. The magnetization M is then calculated from

$$M=M_A\cos\theta_A+M_B\cos\theta_B. \quad (2)$$

We have shown previously that for selected values of the above parameters this model yields a magnetic hysteresis which produces partially inverted hysteresis. We show an example of a hysteresis loop for $M_A=2$, $M_B=1$, $K_A=1$, and $K_B=4$ with the anisotropy axes parallel to H ($\phi_A=\phi_B=0$) in Fig. 2. Only partially inverted behavior of hysteresis loops is found in this model. There is a large normal hysteresis at high fields that is not seen in experiments which accompanies the inverted behavior seen at smaller fields.

Figure 3 shows a complete magnetic phase diagram as a function of H (decreasing) and J using the above values of M and K for the case where the anisotropy axes are parallel to H. The insert in the figure shows the four possible collinear states and a canted state. A partially inverted hysteresis loop is generated if M_A reverses before H reaches zero when H is reduced from a high positive value, i.e., when state 2 (of the insert to Fig. 3) appears above the J axis. This occurs for J values of -1.6 to -7.1. Thus we find that if phase A has a somewhat larger M and smaller K than phase B then inverted behavior is present for a range of negative values of J.

Changing the angle between H and the anisotropy axes modifies the hysteresis loops. Figure 4 shows a series of magnetic hysteresis loops for a range of values of the anisotropy axes angles ϕ_A and ϕ_B with $J=-7$. As can be seen, the changes as a function of ϕ_A for a given value of ϕ_B are small. It appears that significant changes in the hysteresis occur when ϕ_B, the anisotropy axis angle for the more anisotropic phase, is varied. If ϕ_B is 90° then inverted behavior is not present. The small hysteresis observed for the loops corresponding to ϕ_A of 30° and 60° with $\phi_B=90°$ is normal

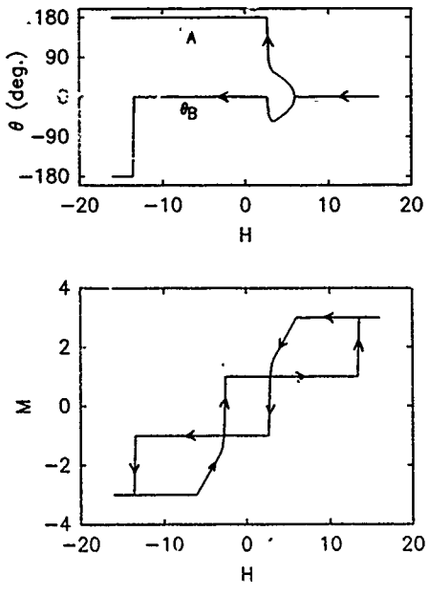

FIG. 2. Calculated magnetization (lower panel) from Eq. (2) and corresponding values of θ_A and θ_B (upper panel) determined from Eq. (1) as described in the text as a function of applied field for $M_A=2$, $M_B=1$, $K_A=1$, $K_B=4$ with $\phi_A=\phi_B=0$. Note that values of θ are only shown for half of the hysteresis cycle.

hysteresis as indicated by the arrows on the hysteresis loops. It is not surprising that inverted hysteresis vanishes in this limit since no metastable configuration exists for the strong anisotropy phase (phase B) when $\phi_B=90°$.

Relaxation of the rigid rotation assumption modifies the above results. A number of calculations have been reported on the magnetic hysteresis of a system where rigid rotation is not assumed to study the influence of interface exchange in various circumstances.[11-13] We find that allowing spins in phase A and B to deform, reduces the range of H over which inverted behavior is observed. This result is also not surprising since the inverted behavior corresponds to a rather high-

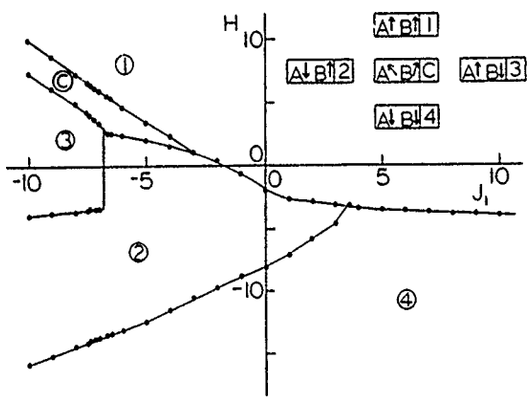

FIG. 3. Magnetic phase diagram for $M_A=2$, $M_B=1$, $K_A=1$, $K_B=4$ with $\phi_A=\phi_B=0°$ determined from Eqs. (1) and (2) as described in the text. The insert shows the four possible collinear magnetic states (numbers 1–4) and a canted state (labeled C). The range of J for which inverted hysteresis loops exist is given by the range of J for which state 2 is present above the J axis.

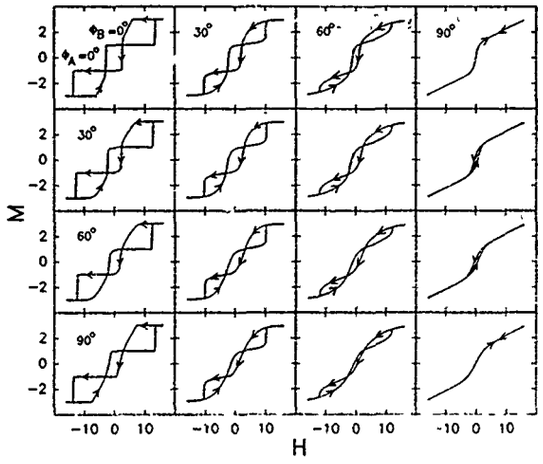

FIG. 4. Hysteresis loops for selected values of ϕ_A and ϕ_B using $M_A=2$, $M_B=1$, $K_A=1$, $K_B=4$, and $J=-7$. The values of ϕ_B and ϕ_A used are given in tabular form across the top and down the left of the diagram.

energy metastable state being occupied by M_A and M_B. Allowing the magnetization to deform allows the system to leave this metastable state for smaller reverse fields. We shall discuss these results in more detail elsewhere.[14]

A more complete model of inverted hysteresis should include a coupling of the magnetization to another property of the system which is able to store and release energy from the magnetic system. A possibility here is magnetoelastic effects which would have to store energy in strain fields in the material.

In summary we have shown within a simple model that partially inverted hysteresis loops may be obtained for selected values of anisotropy and selected negative (antiferromagnetic) values of interface exchange. If the assumption of rigid rotation is relaxed then the field range over which inverted behavior occurs is reduced. We are extending these calculations to include some magnetoelastic effects to determine if such effects can lead to completely inverted loops.

Central Research and Development, E. I. duPont, Wilmington, Delaware 19880-0356

The magnetic and structural properties of Co/CoO bilayers prepared by sputtering have been studied in films with Co thickness in the range of 65 to 250 Å. A two-phase structure consisting of hcp Co and fcc CoO was observed in the films. The coercivity was found to change inversely proportional to the Co thickness and to the sputtering rate. The highest H_c (9 kOe) was obtained in films exposed to ambient conditions for long periods of time. A shift in the hysteresis loop was found in field-cooled samples, indicating a strong exchange coupling between the Co and CoO phases.

Co/CoO films have been found to possess many novel properties, such as a perpendicular anisotropy, enhanced Kerr rotation, and exchange anisotropy.[1–5] These properties have potential applications in new perpendicular recording media. In previous studies, Co/CoO films were made by reactive sputtering in a mixture of Ar and O_2 gases[2–4] or by evaporation in O_2 gas.[1] These films had a microstructure consisting of hcp Co and fcc CoO fine particles in a columnar morphology perpendicular to the film plane. The magnetic and structural properties of the films were found to depend strongly on the partial pressure of oxygen during sputtering or evaporation. The unidirectional exchange anisotropy between Co and CoO particles is believed to play an important role in inducing the perpendicular magnetic anisotropy.[3]

In this study, the Co/CoO films are in the form of bilayers with the CoO formed by oxidizing the surface of the single Co films. In this morphology, the interaction is confined to the film's surface so that it is easier to study the exchange coupling between Co and CoO.

A dc sputtering apparatus was used to prepare the Co/CoO bilayers. The sputtering target was a 99.9% Co disk 2 in. in diameter and 0.053 in. in thickness. The distance between the target and the water-cooled substrate was 13.5 cm. The sputtering chamber was initially pumped down to $6–7\times10^{-8}$ Torr by a cryopump and then the Co film was deposited onto a kapton substrate by sputtering in a 5 mT Ar gas. The thickness range of the films was between 65 and 250 Å. Soon after the film was made, a small amount of air was introduced into the system under two different pressures (370 and 710 mTorr) to oxidize the surface of Co films for 2 h. The as-made Co/CoO films were also exposed to air for long periods of time (4 months) and the effect of additional oxidation was investigated.

The Co thickness was measured with Rutherford backscattering (RBS) and that of CoO by x-ray photoelectron spectroscopy (XPS). The crystal structure of bilayers was determined from selected area electron diffraction data and the microstructure was studied using a JEOL 100C transmission electron microscope (TEM). The magnetic properties were studied using a SQUID magnetometer.

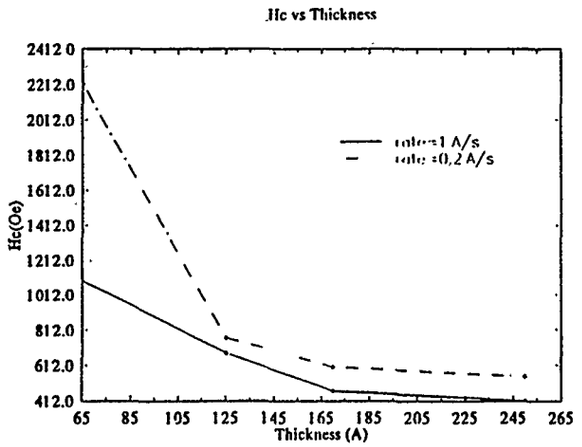

FIG. 3. Coercivity H_c vs Co thickness at 10 K for Co/CoO films.

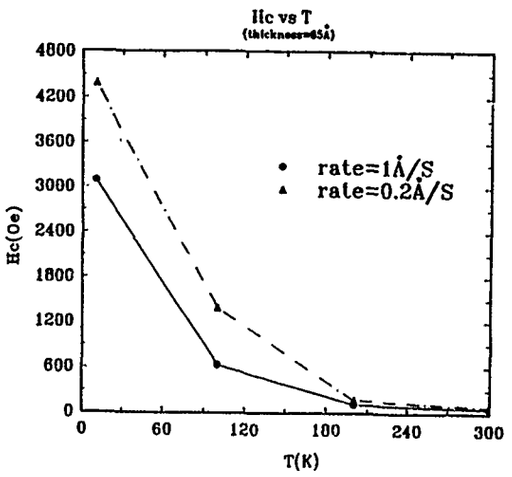

FIG. 4. Coercivity H_c vs temperature for Co/CoO films of thickness 65 Å prepared with sputtering at rates 1 Å/s and 0.2 Å/s.

The XPS data for the as-made and etched samples are shown in Fig. 1. The surface oxide layer was found to be CoO and its thickness varied from 26 Å in the 65 Å Co films to 64 Å in the 170 Å Co films. Selected area electron diffraction (Fig. 2) showed a mixture of hcp Co and fcc CoO phases. The grain size was found to increase with increasing film thickness from 45 to 70 Å for the 65 and 170 Å films, respectively. The bright field micrographs show that the distribution of Co particles is homogeneous.

The saturation magnetization M_s of Co/CoO bilayers exhibits a complex behavior with the Co thickness, the sputtering rate, and the oxidization conditions. The thin bilayers (<100 Å) showed a larger M_s when passivated at higher air pressures (710 mT). Co/CoO films exposed in air at ambient conditions for 4 months had a lower M_s.

The coercivity of the as-deposited films was found to increase with decreasing Co layer thickness as shown in Fig. 3. This behavior is also similar to the size dependence of H_c in Co powders.[6] Table I also shows that the coercivity changes inversely proportional to the sputtering rate. For larger sputtering rates, the quenching rates are higher and much finer particles (below the single domain particle size of 200 Å) are formed with a lower H_c. The thinner films (<100 Å) are also more sensitive to the sputtering rate than the thicker films. A larger H_c was obtained in the films passivated at the 370 mTorr air pressure than at 710 mTorr. It may be that the passivation is not complete at 370 mTorr, so when the samples are exposed to ambient conditions a stronger oxidation takes place resulting in thicker surface oxides. This explanation is consistent with the huge coercivity obtained in films exposed to air for long periods of time. The same argument can also be used to explain the magnetization dependence on passivation; films with proper passivation (710 mTorr) were less oxidized after exposing to ambient conditions than those with incomplete passivation (360 mTorr), and therefore they had a higher M_s. This behavior is similar to that of Fe fine particles[7] and indicates that the thickness of the surface oxide is critical to the hysteresis properties of the bilayers. As the temperature increased from 10 to 300 K, a steep drop in H_c to less than 100 Oe (Fig. 4) was observed.

The hysteresis loops of field-cooled samples were found to be shifted (Fig. 5), indicating the presence of an exchange anisotropy.[8–10] The change of coercivity between the zero-field-cooled and field-cooled samples, H_s, was used as a parameter to describe the exchange coupling between CoO and Co. Table II gives some results for H_s. For thin Co films, a larger H_s was observed, indicating a stronger influence of CoO.

No perpendicular anisotropy was observed in the films even with a Co thickness as low as 65 Å (see Fig. 6). This result is different from other studies[2–4] and it is probably due

to the formation of CoO films only on the surface of the films. It is well known that thin Co films have a perpendicular magnetic anisotropy, which arises from the magnetocrystalline anisotropy of hcp Co and the shape anisotropy of the columnar structure.[3] If the CoO is formed as a shell *around* the columnar Co, the exchange anisotropy between the ferromagnetic Co and antiferromagnetic CoO will enhance the Co perpendicular anisotropy;[3] but if the CoO is formed on the surface of the Co film, only the top Co particles are shelled by the CoO. In this case, the exchange anisotropy tends to turn the easy axis to the parallel direction and must compete with the magnetocrystalline and shape anisotropy. When a continuous CoO film is formed on the surface of the Co film, a large exchange anisotropy is expected to turn the easy axis parallel to the surface of the film. This is just what we found in the Co/CoO bilayers. The quantitative relation between the exchange anisotropy, magnetocrystalline, and shape anisotropy needs further investigation.

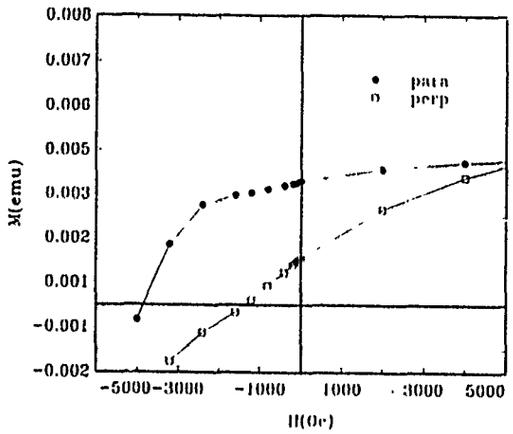

FIG. 6. Parallel and perpendicular hysteresis loops of a Co/CoO bilayer with Co thickness 65 Å at 10 K.

Co/CoO bilayers were made with dc sputtering by forming the Co films first and then oxidizing their surface. The bilayers were composed of hcp Co and fcc CoO. No perpendicular anisotropy was found in the bilayers and this is probably due to the exchange coupling between CoO and Co at the film's surface which exceeds the magnetocrystalline and shape anisotropy of inner Co particles. The large coercivity and the loop shift found in field-cooled thin films (with thickness of Co at 65 Å) are the result of a strong exchange interaction between Co and CoO.

The authors wish to thank Dr. C. Swann for the RBS measurements, and J. Yuan for the TEM pictures. This work is supported by NSF DMR-8917028.

Resistivity anomaly in nonmagnetic metals with ferromagnetic insulator proximity layers

G. M. Roesler, Jr., Y. U. Idzerda, P. R. Broussard, and M. S. Osofsky
Naval Research Laboratory, Code 6340, Washington, DC 20375-5343

Epitaxial bilayers and multilayers were prepared using the ferromagnetic insulator EuO and the metals V and Ag. For metal films of thickness 10 nm or less, there is a sharp change in the slope of the resistivity *versus* temperature, which occurs at 86 K for EuO/V specimens and at 50 K for EuO/Ag specimens. Soft x-ray magnetic circular dichroism measurements showed a clear dichroism for Eu but none for V. Therefore, the dR/dT discontinuity is attributed to a change in spin-dependent surface scattering at the insulator/metal interface caused by the magnetization of the surface layer of Eu^{++} ions. The difference in temperature between the dR/dT discontinuities between the two metals (and from the bulk EuO Curie temperature of 70 K) is tentatively attributed to the influence of the Ruderman–Kittel–Kasuya–Yosida (RKKY) mechanism.

Metallic multilayers involving magnetic materials are hosts to a rich variety of physical phenomena, including the recently observed giant magnetoresistance.[1] Among the physical variables affecting these phenomena may be the band structures and electron densities of the two component metals. Microscopically, the current carriers in such multilayers may experience spin-dependent scattering, specular or diffuse boundary scattering, and exchange at the interfaces, thus complicating the understanding of anomalous transport properties. Here, we report results on the transport behavior of single metals in contact with a ferromagnetic insulator. Such structures provide a physical system which is simpler than the all-metallic multilayer problem, as the magnetic moments are separate from the conduction sea (except at the interface), and the band structure of only one metal rather than two need be considered. We have observed a resistance anomaly in bilayers and multilayers of vanadium or silver in contact with the ferromagnetic insulator EuO. The anomaly may be caused by the magnetization of the layer of Eu^{++} ions at the interface. Furthermore, the Curie temperature of that layer may be affected by Ruderman–Kittel–Kasuya–Yosida (RKKY) coupling between Eu^{++} ions through the V or Ag conduction sea.

These metal/ferromagnetic insulator structures were prepared under conditions of heteroepitaxy. The V films were prepared by electron beam evaporation at typical pressures of 10^{-10} mbar, while the Ag films were prepared by thermal evaporation at typical pressures of 10^{-8} mbar. Sapphire or cubic zirconia substrates were used, and were held at 300–700 °C to obtain planar surfaces. The EuO layers were grown by thermal evaporation with the substrate held at 300 °C. Reflection high-energy electron diffraction (RHEED) from the film surface was used to monitor crystal structure and surface quality during growth of metal and insulator layers. RHEED patterns typically indicated two-dimensional films with a single crystal structure. Details of the film growth process will be published separately.[2] X-ray diffraction showed the presence of EuO and no other europium oxides. SQUID magnetometer studies indicated that the EuO layers became magnetic at the bulk Curie temperature (T_c) of 70 K, and the large Faraday rotation characteristic of EuO was observed.

Resistance was measured as a function of temperature using a four-terminal ac technique. A typical example of $R(T)$ for a EuO/V specimen is shown in Fig. 1. Note that the slope changes sharply at a temperature of 86 K, near but somewhat higher than the T_c of EuO. This feature occurred (always at 86 K) in the majority of EuO/V samples prepared. The feature did not appear to depend upon layer thickness of V between 1.6 and 10 nm, nor upon EuO layer thickness between 3 and 10 nm. A similar feature was observed in EuO/Ag bilayers, at 50 K rather than 86 K. In samples displaying this dR/dT discontinuity, there appeared to be no Kondo effect, as dR/dT remained positive down to the lowest temperature of measurement (4.2 K). By contrast, a minority of samples displayed Kondo-like behavior, that is, showed a resistance minimum between 20 and 50 K.

Whether a particular EuO/V sample would show the dR/dT discontinuity or Kondo behavior (which appear to be mutually exclusive) may depend sensitively on the atomic ordering at the metal/insulator interface. During some growths, the RHEED pattern did not change immediately when overlayer growth commenced, but changed to the new structure gradually over several atomic layers. Such struc-

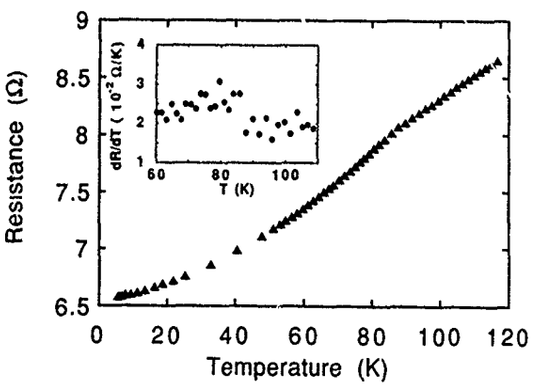

FIG. 1. The resistance of a vanadium-europium oxide multilayer as a function of temperature. The sample had the structure EuO/V/EuO/V/EuO, with 3-nm EuO layers and 2.7-nm V layers. Inset shows the temperature behavior of dR/dT. Bilayer samples show the same feature at 86 K as the multilayer samples.

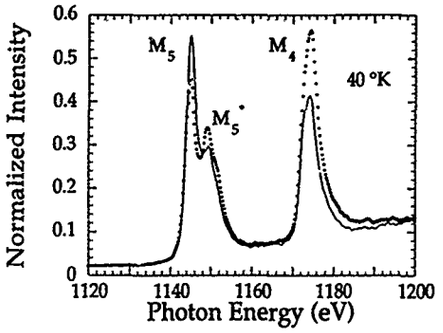

FIG. 2. XAS spectra of the M_5 and M_4 peaks of Eu in an EuO/V multilayer. The solid curve is the spectrum for negative helicity photons, and the dotted curve is for positive helicity. Pure EuO films had identical behavior.

tures displayed the dR/dT discontinuity. During other growths, the RHEED pattern disappeared immediately and a new one reappeared after several atomic overlayers were deposited. Some of the latter structures showed Kondo-like behavior.

We have considered two microscopic mechanisms by which the magnetization of the EuO might cause the observed dR/dT discontinuities. Magnetization could affect the band structure of the metal, and it could affect spin-dependent scattering at the metal/insulator interface. The band structure effect model is motivated by the similarity of the discontinuity in dR/dT to that observed in ferromagnetic metals, e.g., Ni. The effect of magnetization in producing a resistivity slope change in Ni is successfully explained by the model of Mott.[3] This model requires that a large fraction of the scattering events in a metal be interband scattering events involving an unfilled d band at the Fermi energy. This picture is appropriate in V but may not apply to Ag. In the EuO/metal system, the d band of the metal must become polarized through exchange with the localized Eu f states. When the Eu^{++} ions become magnetized, the d band splits by the exchange Zeeman energy, reducing the d states available for s-d scattering. The second model explains the dR/dT discontinuity in terms of a reduction of spin-dependent surface scattering rather than a reduction of interband scattering. Here, the magnetization of the surface layer of Eu^{++} ions is supposed to greatly increase the energy required for an (inelastic) spin-flip scattering event, thus presumably reducing the resistivity below the magnetic ordering temperature.

In an effort to detect magnetization of V, which would be required in the s-d scattering picure, soft x-ray magnetic circular dichroism (SXMCD) measurements were made on a EuO/V multilayer as well as on single-layer EuO films. SXMCD is the difference between the x-ray absorption of positive and negative helicity (left-and right-circularly polarized) photons at the $3d$ metal L_3 and L_2 absorption white lines, or at the M_5 and M_4 absorption white lines of a $4f$ metal. This technique is used for element-specific determination of the presence of ferromagnetism in heteromagnetic samples.[4] The ferromagnetism of the EuO layers is observed in the SXMCD of the Eu spectrum. Figure 2 shows a strong dichroism between the x-ray absorption spectroscopy (XAS)

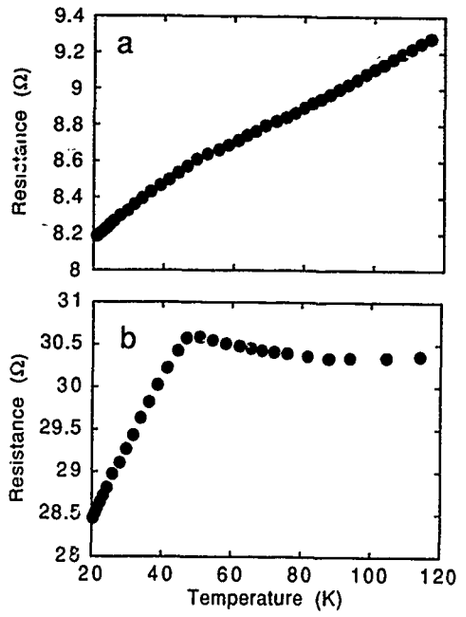

FIG. 3. The resistance of two EuO/Ag bilayers as a function of temperature. Ag thicknesses were (a) 7.6 nm and (b) 3.6 nm. EuO thickness was 10 nm.

spectra for negative-helicity (solid) and positive-helicity (dots) photons at the Eu M_5 and M_4 absorption edges. A strong and unexpected temperature dependence in the difference of these spectra, that is, in the SXMCD signal, was observed in both multilayer samples and pure EuO films.[5] However, no dichroism was observed between the L_3 and L_2 spectra of V upon cooling below the dR/dT discontinuity.

The lack of SXMCD for V with an EuO proximity layer is difficult to reconcile with the s-d scattering model. Another difficulty with that picture is the presence of a dR/dT discontinuity in bilayers containing Ag rather than V. The resistance *versus* temperature of two such bilayers may be seen in Fig. 3. Since Ag has filled d bands, the Mott s-d scattering mechanism is not implicated. We surmised that measuring the Hall effect in the EuO/V system would help clarify the scattering mechanism. If spin-dependent scattering is occurring, one might expect to see anomalous Hall behavior. However, both above and below the dR/dT discontinuity, the measured Hall coefficient was the same in sign and magnitude as that measured[6] in bulk V. Because the Eu^{++} ions are in an S state, however, the absence of anomalous Hall scattering might not be unusual. High-field magnetoresistance measurements are planned to help resolve the scattering mechanism question.

There is a qualitative difference in the scattering behavior near the dR/dT discontinuity between specimens with Ag and those with V. There is little thickness dependence to the absolute magnitude of the discontinuity in samples containing V; however, as seen in Fig. 3, the feature at 50 K in samples with Ag becomes much more dramatic as thickness is decreased. Furthermore, the slope dR/dT remains essentially constant above the 86-K feature in V specimens; however, in the Ag specimens, the slope decreases significantly as the 50-K feature is approached, even becoming negative

in the thinnest samples, as may be seen in Fig. 3(b). Similar behavior is predicted[7] for critical behavior of the resistivity near magnetic transitions, assuming ferromagnetic behavior at the V/EuO interface and antiferromagnetic behavior at the Ag/EuO interface. The upward (downward) displacement of the resistivity features from the bulk EuO Curie temperature of 70 K at an interface with V(Ag) is consistent with a ferromagnetic (antiferromagnetic) interaction at the interface. A possible model of this interaction is the RKKY coupling of the *surface layer* of Eu^{++} ions through the conduction sea of V or Ag. A calculation to determine whether the RKKY mechanism is plausible would consider ions on the surface of a *semi-infinite* conduction sea rather than the usual infinite one. The tendency of the surface layer of V to magnetize[8] may also be germane. The novel transport phenomenon described here is yet another example of the richness of the physics involved when magnetic atoms and conduction electrons interact.

The magnetization processes of two series of sandwiches of compositions Sm-Co/Co/Sm-Co′ and Sm-Co/Gd-Co/Sm-Co′ prepared by dc bias sputtering are presented. The layers of Sm-Co and Sm-Co′ have different compositions each with a different coercive field. The central layer consists of a soft magnetic material with a thickness varying from 500 to 5000 Å. In these systems, it is possible to stabilize a magnetic configuration with the magnetic moments of the external layers having opposite directions. Due to the magnetic coupling between the layers associated with the strong exchange interactions between cobalt atoms throughout the whole sample, a large planar Bloch wall is formed in the central layer. The width of this wall depends on the intrinsic properties of this central layer, but the magnetization processes vary with the relative magnitude of the wall width to the thickness of this layer. For a large thickness of the central layer, the Bloch wall is very mobile under applied field leading to a very large susceptibility.

Magnetic multilayers made from rare-earth and transition metal alloys may exhibit a wide variety of magnetic properties. Indeed, considering the numerous possibilities of chemical composition and thickness of each constituting layer, their magnetic moment, anisotropy, and coercivity can be fitted to yield specific and original magnetic properties of the sample.

Recently, Alameda *et al.*[1] reported on the magnetic properties of a (Sm-Co)/(Zr-Co)/(Sm-Co)′ system: They showed that it is possible to stabilize a peculiar magnetization state with the magnetic moments in the two Sm-Co layers pointing into opposite directions and a domain wall existing in the central layer. This wall, very mobile in this amorphous material, leads to an almost reversible magnetization process, in contrast to the irreversible process observed in a single Co-Zr layer.

We have undertaken the study of such a behavior in two series of sandwiches of compositions A: (Sm-Co)/(Gd-Co)/(Sm-Co)′ and B: (Sm-Co)/Co/(Sm-Co)′. All these samples are characterized by a central layer consisting of a relatively soft magnetic material (Co or Gd-Co) sandwiched between two hard magnetic Sm-Co layers with different coercivities. In Sm-Co intermetallic compounds, the Sm and Co moments are ferromagnetically coupled, while in Gd-Co compounds, the Gd and Co moments are coupled antiferromagnetically, with the Gd moment dominating the Co one for the composition used. The Co–Co exchange interactions, which are the strongest, lead in zero field to a macroscopic ferrimagnetic arrangement for the system A (the magnetization direction alternates in adjacent layers) and to a ferromagnetic one for the system B. In the ferrimagnetic Gd-Co system, a saturated state is induced under applied field, with the formation of a Bloch wall in the Co sublattice at each interface. The transition field and the creation or annihilation of such Bloch walls have been studied in more detail in (Y-Co)/(Gd-Co)/(Y-Co) sandwiches.[1–4]

In this paper we discuss a variety of original magnetization processes of a series of sandwich systems in which the layer moments, layer coercivities, and layer thicknesses are different.

The sandwiches (Sm-Co)/Co/(Sm-Co)′, (Sm-Co)/(Gd-Co)/ (Sm-Co)′ have been prepared at the IBM Research Center in San José from targets of Sm, Co, and $Gd_{0.37}Co_{0.63}$ by dc bias sputtering under a residual Ar pressure of 3 mTorr, the initial vacuum being 10^{-7} Torr. The Sm-Co layers are in fact multilayers obtained by alternate deposition of very thin Co and Sm films [respectively, $(Sm_{5\ Å}Co_{10\ Å})_{30}$ and $(Sm_{5\ Å}Co_{20\ Å})_{20}$], giving a different coercive field for each layer.

A quartz oscillator was used to control the thicknesses of ~500 Å for the external layers and between 500 and 5000 Å for the central layers. Except for the crystalline films obtained from pure Co, the materials are amorphous.

An easy direction magnetization was induced by placing a permanent magnet next to the silicon substrates and thus applying a field parallel to the film surface during deposition.

Magnetization experiments were performed using a SQUID magnetometer at 4.2 K and a vibrating-sample magnometer at 20 and 300 K. The magnetic field was applied in the easy direction of magnetization. The magnetization curves for the different samples are shown in Figs. 1–5.

The magnetization curves of all the samples are characterized by three or two steps, when the magnetic field sweeps in the same direction. These transitions are associated with the reversal of the magnetic moment of a layer at a field value that depends on the coercivity of the layer as well as on its magnetic coupling with adjacent layers. Indeed, the strong exchange interactions between cobalt moments lead to the existence of Bloch walls in some of the magnetization states. For example, in the saturated state of the samples with Gd-Co as central layer, the Sm-Co layer moment and the Gd moments are aligned in the direction of the field, while the Co moments of the Gd-Co layer point in the opposite direction. Consequently, in the saturated state, a large planar

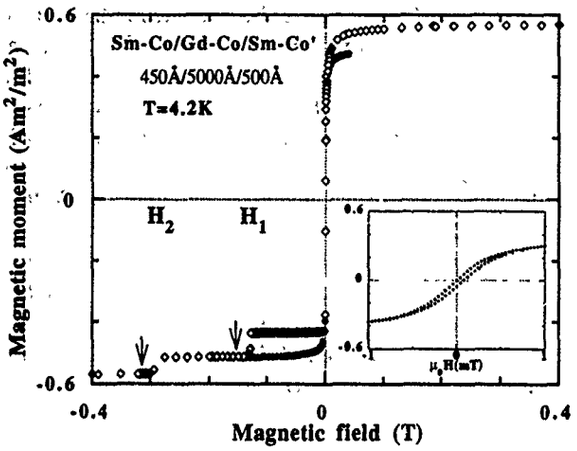

FIG. 1. Magnetization curve at 4.2 K with the applied field in the easy direction for the Sm-Co/5000 Å Gd-Co/Sm-Co′ sample. The insert shows the magnetization process after application of a field between H_1 and H_2, with a different scale.

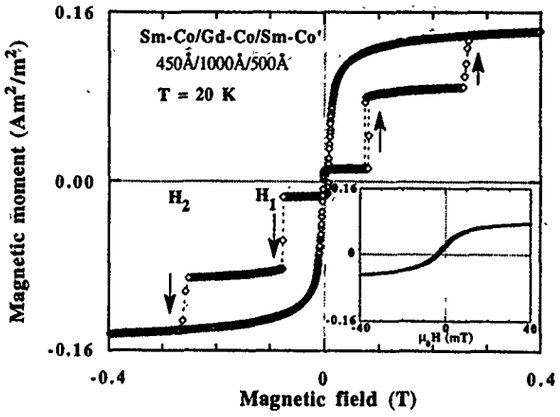

FIG. 3. Magnetization curve at 20 K with the applied field in the easy direction for the Sm-Co/1000 Å Gd-Co/Sm-Co′ sample. The insert shows the magnetization process after application of a field between H_1 and H_2. Arrows indicate irreversible magnetization process.

Bloch wall lies in the vicinity of each interface, while there is none in zero field. When decreasing the field from the saturated state on, the existence of these Bloch walls explains the curvature observed at low field in the magnetization curves of the samples (Gd-Co 5000 Å) (Fig. 1) and (Gd-Co 1000 Å) (Fig. 3), as well as the transition taking place in a small positive field (H_0). In zero field, all the Co moments are aligned throughout the whole sample after suppression of the Bloch walls, minimizing the total exchange energy, in absence of Zeeman energy. At room temperature (Fig. 2), this transition appears in a larger field (~20 mT) than at 4.2 K (<1 mT) (Fig. 1) in agreement with the much smaller value of the magnetic moment of the central layer (3). For the same reason, a larger transition field (~5 mT) is observed for the sample with the thinner central layer (Gd-Co 1000 Å) than in the (Gd-Co 5000 Å) sample, corresponding to the reversal of a smaller magnetic moment.

The subsequent application of a magnetic field in the opposite direction does not change the value of the total magnetic moment which indicates a single domain configuration in each layer. Increasing the field further in this negative direction induces a second transition at H_1 (130 mT in Gd-Co samples). This transition corresponds to magnetization reversal in the less coercive Sm-Co layer, accompanied by the creation of a Bloch wall in the Gd-Co layer minimizing the large Co-Co exchange interactions throughout the whole sandwich. Finally, a last transition occurs at a field H_2 [~280 mT in (Gd-Co 5000 Å) and (Gd-Co 1000 Å)], when the second layer of Sm-Co with the larger coercive field reverses with the creation of a second Bloch wall in Gd-Co at the second interface.

The observed behavior is somewhat different in the sandwiches with cobalt in the central layer (Co 1000 Å, Fig. 4 and Co 500 Å, Fig. 5): in the saturated state all the Co moments are aligned in the direction of the field and no Bloch wall exists. Decreasing the field down to zero keeps

this state with a quite constant total magnetic moment, which is the signature of single domain configuration for each layer. Applying a field in the negative direction decreases the total magnetic moment in the (Co 1000 Å) sample (Fig. 4) but not in the thinner (Co 500 Å) sample (Fig. 5). Indeed, the decrease of the total magnetic moment necessitates to reverse some magnetic moments of cobalt and then to create at least two Bloch walls in the cobalt layer. Considering the relative thickness of the wall in comparison with the thickness of the cobalt layer, this situation is possible in the thicker layer but not in the thinner one, at least for a field smaller than the field at which the less coercive Sm-Co layer reverses its magnetization. In fact, in these two samples, the magnetic moment of the Co central layer and that of Sm-Co reverse together (H_0 and H_1 are identical) under creation of one Bloch wall, the transition being particularly sharp for the thinner sample. The next transition occurs in a nearby applied field (H_2), because it corresponds to the reversal of the second Sm-Co layer with the concurrent annihilation of the existing Bloch wall.

We now have a closer look at the magnetic state, in which the two Sm-Co layers have their magnetization in opposite directions, with a Bloch wall inside the central layer of Gd-Co or Co. This state is obtained, after saturation of the sample, by applying a magnetic field in the opposite direction, with a value between H_1 and H_2 and releasing the field afterwards. A nearly completely reversible magnetization process is obtained as reported in Fig. 1 for the (Gd-Co 5000 Å) sample. The insert in Fig. 1 shows that 1 mT is enough to reverse the major part of the magnetization of the Gd-Co layer. Around zero field, it corresponds to a susceptibility of ~2300 SI (or ~20 emu/g Oe to be compared to the value of 2.3 emu/g Oe obtained in the ZrCo system of Ref. 1). This large susceptibility is associated with a very mobile wall in the thick layer of Gd-Co. Such a behavior is also obtained for the (Gd-Co 1000 Å) sample, but with a much smaller susceptibility (insert on Fig. 3). In that case, the wall width has the same order of magnitude as the entire Gd-Co layer thickness and the wall doesn't have the same mobility.

A different behavior occurs in samples with cobalt in the central layer (Figs. 4 and 5). After application of a field ($H_1<H<H_2$) creating the configuration with a Bloch wall in the Co layer, the decrease of the magnitude of the applied field leads to a transition (at H_3) towards the saturated state. This transition corresponds to the reversal of the magnetization of the less coercive Sm-Co layer simultaneously with the Co layer but it happens in a very small positive field ($H_3 \ll H_1$) in the (Co 1000 Å) sample, while the transition occurs in a negative field in the Co 500 Å layer. This transition is then associated with the suppression of the Bloch wall inside the cobalt layer and happens in a lower field than the coercive field of the noncoupled layer.

The reversible part, with a small susceptibility, is reduced to a small field region between H_1 and H_3. The susceptibility is smaller for the thinner Co layer, because the wall occupies a large part of the layer width and then the magnetic moment of the layer is small. It is also possible that this Bloch wall, which has been created at the interface with the more coercive Sm-Co layer, is trapped at this interface and needs a larger field to be unpinned. A similar behavior is observed in the (GdCo 5000 Å) sample at room temperature (Fig. 2), in which the magnetic moment of the Gd-Co is small.

In conclusion, we have presented complex and original magnetization processes observed in sandwiches consisting of three layers, made of different materials and exchange coupled together. Particularly, it has been possible to stabilize a magnetic state with a large susceptibility, associated with the motion of a Bloch wall. Quantitative analyses are in progress in order to have a better understanding of the observed properties.

The authors wish to acknowledge V. S. Speriosu and D. R. Wilhoit for their kind help during the preparation of the samples.

Magnetic properties of antiferromagnetic superlattices

Shufeng Zhang
Department of Physics, New York University, New York, New York 10003

Guihua Zhang
Courant Institute of Mathematical Sciences, New York University, New York, New York 10012

The temperature dependence of the magnetic properties of magnetic superlattices by using the Bethe approximation to the inhomogeneous Ising model is studied. A self-consistent equation which determines the variation of the magnetic moment for any layer thicknesses is derived. In particular, the crossover from bulk-dominated behavior for large thicknesses of layers to interface-dominated behavior for small thicknesses is discussed. The results both qualitatively and quantitatively differ from mean-field theory; the experimental observation for FeF_2/CoF_2 and CoO/NiO superlattices is explained.

Magnetic superlattices are new materials whose magnetic properties are readily distinguishable from those of bulk materials. For example, the specific heat of an FeF_2/CoF_2[1] superlattice cannot be obtained by the superposition of the individual bulk specific heats of FeF_2 and CoF_2 due to interfacial interaction. Many theoretical investigations[2,3] on magnetic superlattices have been put forward with different models and approximations. While most of the attention was focused on low-temperature properties, Diep[4] has recently studied the magnetic transition temperature of a Heisenberg model of antiferromagnetic superlattices by using a Green's function method. To explain the experimental data[1] on thermal expansion coefficient which is proportional to magnetic contribution of specific heat, a mean-field theory[5,6] has also been developed. With this theory, one can qualitatively estimate a critical thickness of the layers above which the specific heat displays two maxima with respect to temperature. The peak at the higher temperature corresponds to the phase transition in the superlattice while the other at the lower temperature is due to the rapid increase of the moments of the material with lower bulk Néel temperature. This latter maximum may be suppressed by interfacial interaction when the layer thicknesses are reduced. Although the mean-field theory successfully describes some properties of the superlattices, it fails to explain the long magnetic coherence length observed experimentally. Borchers *et al.*[7] have shown that for certain temperature ranges, e.g., above 400 K, the center of the CoO layers (Néel temperature of bulk CoO is 291 K) has vanishingly small moments while the magnetic coherence length is still much larger than the bilayer thickness of NiO/CoO superlattices.

We study the temperature dependence of the magnetic properties of magnetic superlattices by using the Bethe–Peierls approximation. This approximation[8] is a useful tool for studying spin-glass systems in which both the magnitude and the sign of the interactions between neighboring magnetic spins are random.[9] Although both the Bethe approximation and the mean-field theory give the same critical exponents near the transition temperatures, the key difference is that the former takes into account the short-range correlation which is essential in understanding the *temperature dependence* of the magnetic properties. It turns out that experimental data on the magnetization, the coherence length, and the specific heat can be well explained.

The interaction we consider is of the nearest-neighbor Ising type in which a spin in the nth layer parallel to the interfaces only couples with spins in nearest layers:

$$H=-\sum_{n,i} H_n^i s_n^i-\sum_{n,\langle i,j\rangle} J_{n,n+1} s_n^i s_{n+1}^j, \tag{1}$$

where s_n^i is the spin at site i in the nth layer, and H_n^i is the local external magnetic field. Here we have neglected coupling of the spins within the same layers.[10] We now apply the Bethe approximation to the above Hamiltonian for spin-half, i.e., $s_n^i=\pm 1$; extension to the higher order spins will be given elsewhere.

The Bethe approximation to an Ising spin system on a regular lattice can also be taken as an exact solution of the system on a Bethe lattice.[11] This lattice is simply connected, i.e., for any two sites there is a unique path to connect them; each site connects with independent branches. The interaction from all branches to a given site can be represented by effective fields h_n^l, where integer l runs from 1 to the coordination number 2μ. For layered structures, translational invariance in planes parallel to the interfaces simplifies these effective fields to A_n and B_n which are the contributions from the branches connecting nth layer to $(n+1)$-th and $(n-1)$-th layers, respectively. Therefore, the thermodynamic average of the spin s_n^i can be written as[9]

$$s_n\equiv\langle s_n^i\rangle=\tanh(\beta H_n+\beta\mu A_n+\beta\mu B_n), \tag{2}$$

where $\beta=1/kT$ and we have used uniform external fields in planes parallel to interfaces, i.e., $H_n=H_n^i$.

To find these effective fields, we focus on one branch from a site in the nth layer to one in the $(n+1)$-th layer. For this one branch system, one can easily arrive at

$$\frac{e^{\beta A_n}}{e^{-\beta A_n}}=\frac{e^{\beta(J_{n,n+1}+h'_{n+1})}+e^{\beta(-J_{n,n+1}-h'_{n+1})}}{e^{\beta(-J_{n,n+1}+h'_{n+1})}+e^{\beta(J_{n,n+1}-h'_{n+1})}}, \tag{3}$$

where $h'_{n+1}\equiv H_{n+1}+(\mu-1)A_{n+1}+\mu B_{n+1}$. A simple algebra leads to

 0021-8979/94/75(10)/6685/3/$6.00 © 1994 American Institute of Physics

$$\tanh(\beta A_n)=\tanh(\beta J_{n,n+1})\tanh[\beta H_{n+1}+\beta(\mu-1)A_{n+1}+\beta\mu B_{n+1}]. \quad (4)$$

Similarly,

$$\tanh(\beta B_n)=\tanh(\beta J_{n-1,n})\tanh[\beta H_{n-1}+\beta(\mu-1)B_{n-1}+\beta\mu A_{n-1}]. \quad (5)$$

The above equations, Eqs. (4) and (5), with the periodic boundary conditions form a complete set of self-consistent equations for $\{A_n\}$ and $\{B_n\}$ that can be solved numerically; so can all the derivatives. Once we solve these recursion equations, the magnetization in each layer for the superlattice can be obtained by using Eq. (2). The other thermodynamic quantities can also be found numerically.

The internal energy is

$$U=-\sum_n H_n s_n-\sum_{n,\langle i,j\rangle} J_{n,n+1}\langle s_n^i s_{n+1}^j\rangle \quad (6)$$

and specific heat is $c_v=dU/dT$. To calculate these quantities, we need to find the correlation function $\langle s_n^i s_m^j\rangle$. In general, this can be done by first calculating the local susceptibility and then by using the fluctuation-dissipation relation. For a particular case where $m=n+1$, we find the correlation between two neighboring spins is

$$\langle s_n^i s_{n+1}^j\rangle=q_{n,n+1}\pm(q_{n,n+1}^2-2q_{n,n+1}s_n s_{n+1}+s_n^2+s_{n+1}^2-1)^{1/2}, \quad (7)$$

where $q_{n,n+1}=\coth(2\beta J_{n,n+1})$, and $+(-)$ corresponds to $J>0$ ($J<0$). It is clearly seen that above the transition temperature, in which all $s_n=0$, the correlation does not vanishes, in contrast to the mean-field theory.

We now consider an infinite antiferromagnetic superlattice which consists of material A with exchange constant $J_A<0$ and layer thickness N_A (in units of monolayers), and material B with exchange constant $-J_B>-J_A$ and layer thickness N_B. We choose J_A and J_B such that they give the correct Néel temperatures T_A and T_B for bulk samples of A and B within the Bethe–Peierls approximation, i.e., $J_{A(B)}=0.5kT_{A(B)}\exp[(2\mu-2)/2\mu]$.[12] The only unknown parameter is the exchange constant at an interface J_s which characterizes the coupling between materials A and B. A reasonable value for J_s is an average of J_A and J_B for an ideal superlattice. The magnetic unit cell of the superlattice is $P=N_A+N_B$ if it is even and $P=2(N_A+N_B)$ if N_A+N_B is odd. To solve Eqs. (4) and (5) efficiently, we expand their right sides in terms of $\tanh\beta A_n$ and $\tan\beta B_n$. Rather than solve for A_n and B_n, we determine $\tanh\beta A_n$ and $\tanh\beta B_n$ because these functions are bounded between -1 to 1 and are well-behaved numerically. By giving initial random values of $\tanh\beta A_n$ and $\tanh\beta B_n$ ($n=1,2\ldots P$) and by using periodic boundary conditions (e.g., $\tanh\beta A_{P+1}=\tanh\beta A_1$), one can easily achieve solutions for any given temperatures. In all the ranges of temperature we considered, the number of iterations required for convergence is typically smaller than 10^4, even near the transition temperature.

The temperature variation of the moments in the superlattice is depicted in Fig. 1 where we show the moments of the layers from the center of the material A to the center of the material B. When the temperature is lowered to the transition temperature, the ordering occurs in the entire superlattice simultaneously; this can be seen by nonzero values of moments for all layers below the transition temperature. When the moments are built up for layers of B, they act as an "external field" and induce moments in A layers. However, the moments in the center of A remain small until the temperature is lowered close to the bulk Néel temperature T_A—a signature of bulk feature that the moments increase rapidly near T_A. The magnetization curves in Fig. 1 are in good agreement with the neutron scattering experiment.[7]

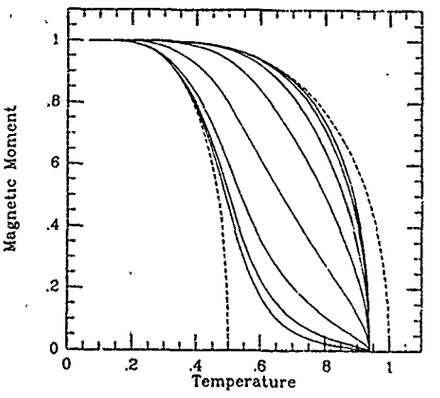

FIG. 1. Temperature dependence of the moments in a superlattice. We have chosen $N_A=N_B=8$, $J_B=2J_A$ $J_s=1.5J_A$, and $2\mu=8$. Temperature is normalized to the bulk Néel temperature T_B. The dashed curves represent the moments of bulk materials of A (lower curve) and B (upper curve). The eight moments from the center of the A layers to the center of B layers are represented by the eight solid curves (from lowest to highest).

Although mean-field theory gives the similar behavior to Fig. 1, there are significant differences in understanding other magnetic properties. Let us suppose the superlattice is divided into pieces; each piece consists of material B with thickness N_B sandwiched by A with thickness of $N_A/2$ on both sides. Since the mean-field theory neglects local correlations, these pieces are coupled through average moments of the boundaries of each piece (same as the moments in the center of A layers, see Fig. 1). These moments are quite small when the temperature is close to T_B, e.g., $T>0.8T_B$. Therefore, the mean-field theory predicts that these pieces defined above are magnetically uncoupled for temperature $T>0.8T_B$. Equivalently, the magnetic correlation length must be smaller than bilayer thickness at these temperatures; this is in contradiction with the experimental observations by Borchers *et al.*[7] They have shown that the magnetic coherence length of the NiO/CoO superlattice is several times larger than the bilayer thickness at $T=400$ K while the moments of the center of the CoO layers are practically zero. Our formulation overcomes this apparent shortcoming of the mean-field theory, because we have taken into account the short-range correlations. From Eq. (7), the correlation function is sizable even if s_n is zero. The energy, Eq. (6), depends on these correlation function and, therefore, one cannot freely flip all the spins in one piece mentioned above without changing the spins in other parts. To describe the magnetic

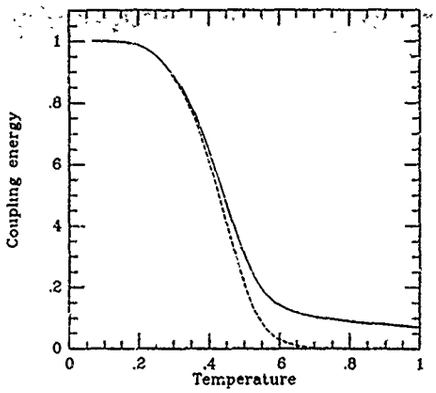

FIG. 2. Temperature dependence of the coupling energy for the same superlattice with Fig. 1. Solid and dashed curves are from our calculation and the mean-field theory, respectively.

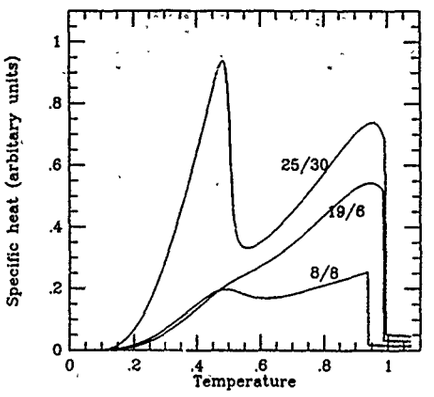

FIG. 3. Temperature dependence of specific heats per superlattice period. The three curves labeled as 25/30, 19/6, and 8/8 are for three samples with different layer thickness N_B/N_A.

coupling in the antiferromagnetic superlattice we define the coupling energy to be the change of energy by flipping all the spins in one piece while leaving all others unchanged. This definition of the coupling energy is similar to that for ferromagnetic superlattices, e.g., Fe/Cr.[13] We show in Fig. 2, the coupling energy as a function of temperature. For comparison, we also show the corresponding curve from the mean-field theory. The salient feature is that the coupling energy, which is proportional to the correlation function, is considerably larger than that of mean-field theory when the temperature is above T_A. Therefore, we are able to explain why the superlattice of NiO/CoO is coherent while the moments in the center of CoO layers are vanishingly small.

To compare with experimental results on the thermal expansion of FeF_2/CoF_2 which is proportional to the specific heat, we calculate the specific heats for three samples with different combinations of layer thicknesses. For thick samples $N_A=30$ and $N_B=25$, there are two peaks shown in Fig. 3. The first peak near T_B characterizes the phase transition, while the second peak comes from rapid changes of the moments in the material A (CoF_2) near T_A. Although the second peak (to be called as quasitransition peak) does not represent a true phase transition, it reflects the bulk property of CoF_2. When the CoF_2 layer is thin as for the sample of $N_A=6$ and $N_B=19$, however, the quasitransition is completely suppressed by interfacial interactions. The presence or absence of the quasitransition peak, as well as the shape of the specific curves for FeF_2/CoF_2 superlattices, are in excellent agreement with the experimental results.[1]

We should point out that the specific heats we show in Fig. 3 are different from that coming from the mean-field calculation. Since the mean-field theory sets zero correlation, the influence of the material B to the material A is underestimated. The quasitransition peaks in specific heats which characterize one of the bulk properties for material A are much higher than ours. Therefore, in order to explain the on-set of the suppression of the quasitransition peak in thin layers one must choose much larger interfacial interaction constant in the mean-field theory than in our approximation. In addition, we find the specific heat is nonzero when the temperature is higher than the transition temperature, (see Fig. 3), in contrast to the mean-field theory.

Ferromagnetic resonance, SQUID magnetometry, and x-ray diffraction have been used to characterize a set of $[Fe_3O_4(68\ Å)/NiO(17\ Å)]_N$ superlattices (SL) with $N=3$, 10, 30, and 100, as well as a 1.5-μm-thick Fe_3O_4 film. For this NiO thickness, Fe_3O_4 layers are strongly coupled and the in-plane anisotropy is much less than the 330-Oe ferromagnetic resonance (FMR) linewidth at 35 GHz. Both in-plane and perpendicular FMR at 9.5 and 35 GHz have been used, with the 9.5-GHz data showing significant hysteresis associated with the sample magnetization. X-ray diffraction indicates that both the film and SL's are nearly cubic single-crystalline structures with long-range coherence. The 300 K magnetization data indicate the presence of small cubic anisotropy in the SL's, although bulklike Fe_3O_4 magnetic ordering in the thick single film. When the Fe_3O_4 film is cooled below the Verwey transition in a 10 kOe field (aligned along ⟨100⟩), the FMR shows that the sample develops a large uniaxial ($K_u=1.8$ kOe) in-plane anisotropy with its easy axis along the field direction. Decreased microwave loss also occurs abruptly at the film T_V.

The near-lattice-matched structures of Fe_3O_4, NiO, and MgO permit one to grow superlattices (SL) of Fe_3O_4/NiO on MgO(001) substrates. Recent work shows that the interplay of the interlayer exchange, the bulk and strain-induced anisotropy, and alternating ferrimagnetic and antiferromagnetic structures lead to unusual magnetic properties in this system.[1,2] In this paper, we extend the coordinated ferromagnetic resonance (FMR), magnetometry, and x-ray diffraction study carried out earlier[3] to examine the effect of temperature, field cooling and the number of bilayers on the magnetic properties of Fe_3O_4/NiO superlattices and Fe_3O_4 films.

A Fe_3O_4 sample 1.5 μm thick and a series of $(Fe_3O_4/NiO)_N$ superlattice samples were grown on thin MgO(001) substrates by oxygen-plasma-assisted molecular beam epitaxy using the methods described previously.[4] For the superlattices used in the present study, the Fe_3O_4 layer thickness was held fixed at 68 Å (eight magnetic unit cells) and the NiO thickness at 17 Å (four magnetic unit cells). Samples were prepared with $N=3$, 10, 30, and 100 to probe the effect of the bilayer repetition number on the magnetic behavior.

Ferromagnetic resonance measurements were carried out at 35 and 9.5 GHz at various temperatures in the range 100–300 K. Both magnetic field in-plane and perpendicular data were obtained. SQUID magnetometry data were acquired on all samples in fields up to 55 kOe either parallel or normal to the thin film. The θ-2θ x-ray diffraction patterns measured for each of these samples permitted the SL period and the in-plane and perpendicular coherence to be established. The more intense modulation satellites could be seen easily even for the $N=3$ superlattice while for the $N=100$ sample at least nine high-angle satellites were measurable. Analysis of the peak positions and linewidths of the x-ray spectra established the presence of a nearly cubic single-crystal lattice with long-range (>2000 Å) coherence in the Fe_3O_4 film, and SL's with a nearly 1% in-plane lattice distortion and coherence length that scales with the total SL thickness. X-ray spectra of similar superlattices have been reported previously.[1,4]

When the temperature of bulk Fe_3O_4 is cooled below the so-called Verwey transition, the conductivity abruptly decreases, caused by the atomic ordering of the Fe^{2+} ions, and the lattice distorts.[5] Based on this behavior, the film FMR was examined as a function of temperature, and Fig. 1 shows the FMR spectra at 35 GHz after the sample has been cooled through the Verwey temperature T_V with a field of 14 kOe applied along [100].

Note that the previously equivalent [100] and [010] spectra are very distinct after the field cooling. Most of the film gives rise to the broad FMR lines near 5.6 kOe for $\vec{H}\|[100]$ and 10.9 kOe for $\vec{H}\|[010]$. A small fraction of the film which did not distort produces the narrower FMR lines near 9.4 kOe in both orientations. Alternatively, one can cool with $\vec{H}\|[010]$ and the roles of [100] and [010] are reversed. This indicates that the application of a large field along a given ⟨100⟩ during cooling selects that direction as the magnetically easy direction for all (or almost all) of the sample.

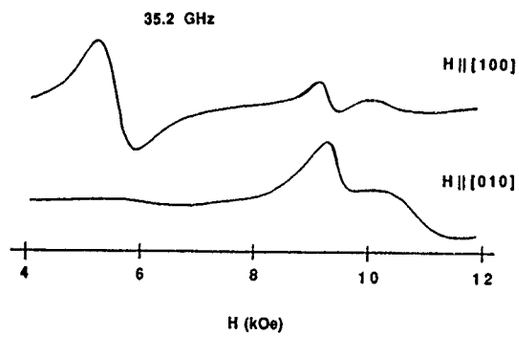

FIG. 1. Effect of cooling a Fe_3O_4 film through the Verwey transition with a field of 14 kOe along the in-plane [100]. The subsequent in-plane 35.2-GHz FMR spectra are shown for $\vec{H}\|[100]$ and $\vec{H}\|[010]$. At room temperature, a single narrow FMR line at 10.3 kOe is found for both these field directions.

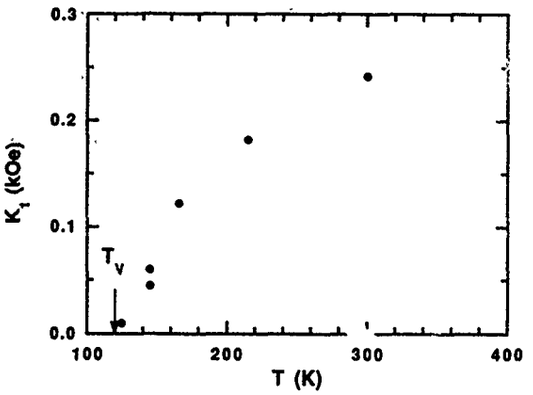

FIG. 2. Temperature dependence of the cubic anisotropy parameter K_1 for a 1.5-μm-thick Fe_3O_4 film.

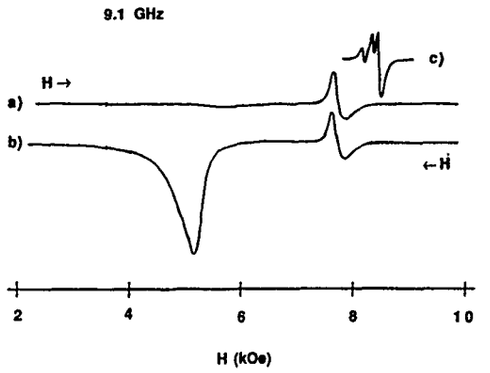

FIG. 3. Note the marked hysteresis in the 9.1-GHz FMR spectrum of a Fe_3O_4 film field-cooled with $\vec{H}$ (and $\vec{H}_{cool}$) along the [001] film normal for (a) increasing and (b) decreasing field scans. Trace (c) shows the corresponding spectrum at 300 K.

We found that cooling in zero field leaves the two in-plane ⟨100⟩ directions equivalent and the spectrum a superposition of the two field-cooled cases, indicating that the film breaks up into different regions with their local distortion axes (and, hence, easy directions) along one or the other ⟨100⟩.

The in-plane angular dependence of the spectra in the distorted Verwey state can be fit fairly well with the following parameters: $4\pi M' = 7.5$ kG, $K_u/M = -1.8$ kOe, and $K_1 = 0$. Here, $K_u \cos^2 \alpha$ is a uniaxial aniotropy which favors $\vec{M} \| \vec{H}_{cool}$, α is the angle between $\vec{H}_{cool}$ and M, and K_1 is the usual fourth-order cubic anisotropy. The strain introduced as the film distorts introduces a significant change in the effective magnetization $4\pi M' = 4\pi M + 2K_\perp/M$.

We found that a large (cold) field applied 90° away from the field-cooled direction causes a decrease in intensity of the field-cooled signal. Furthermore, as the sample warms toward T_V, the field-cooled signal also decreases while the previously weak signal due to undistorted Fe_3O_4 (near 9.4 kOe in Fig. 1) increases and narrows rapidly. After the abrupt decrease in microwave cavity Q (indicating the increase in sample conductivity at T_V) occurs, only the undistorted signal remains. The temperature variation of the cubic anisotropy of the film for $T > T_V$ is shown in Fig. 2. It appears that K_1, which decreases as the temperature is lowered below 200 K, vanishes at T_V.

Finally, we note that when one carries out similar experiments at 9.1 GHz with a 14-kOe field normal to the film during cooling below T_V, the marked hysteresis shown in Fig. 3 is found. The intense signal near 5.2 kOe (found only when H is decreasing) occurs just as the sample magnetization direction starts to deviate from being parallel to $\vec{H}$. It is not clear why only a very weak version of this signal is observed for H increasing. Note also the decrease in $4\pi M'$ (shown by the drop in the resonance field, see trace c) when $T < T_V$. This is due to a decreased $4\pi M'$ induced by the Fe_3O_4 distortion favoring $\vec{M}$ normal to the film when $\vec{H}_{cool}$ is along the normal. The low-field satellites seen in Fig. 3(c) are spin waves as indicated by explicit calculations.

We call attention to the fact that the FMR behavior described above is similar to that found[6] for bulk Fe_3O_4. This shows that the substrate-induced distortion (≈0.3% for this sample) does not have any major qualitative effect on the magnetic properties of the film

The most significant magnetic aspect of the behavior of Fe_3O_4/NiO superlattices is the difficulty in saturating the magnetization even when the magnetic field is applied in plane.[1,2] For example, our present measurements show that the magnetization of a $[Fe_3O_4(68\ Å)/NiO(17\ Å)]_{100}$ SL [shown in Fig. 4(a)] is only 65% of saturation at 20 kOe and is still not saturated at 50 kOe. The magnetization profiles of the $N = 30$ and 10 SL's are qualitatively the same as the $N = 100$ SL, when the total moment is normalized to the Fe_3O_4 volume, with sigmoidal hysteresis and difficulty of saturation. The profile for $[Fe_3O_4(68\ Å)/NiO(17\ Å)]_3$ [Fig.

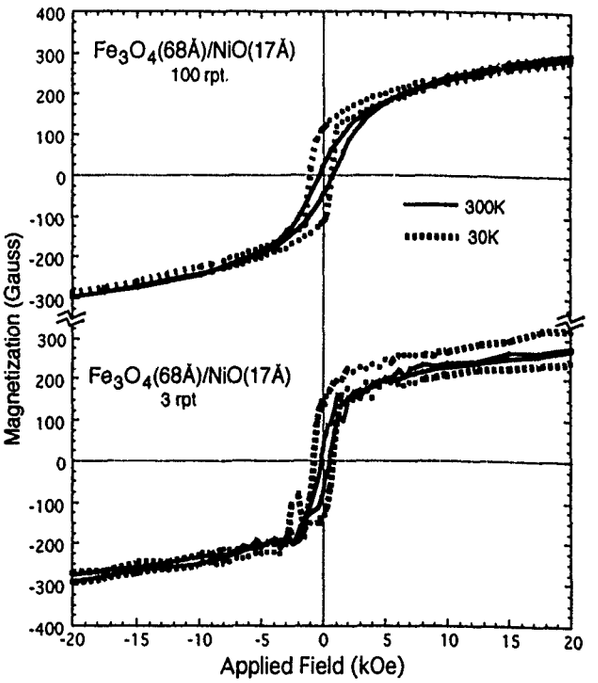

FIG. 4. Magnetization vs magnetic field behavior for two $[Fe_3O_4(68\ Å)/NiO(17\ Å)]_N$ superlattices with $\vec{H} \| [100]$; (a) $N = 100$ and (b) $N = 3$.

TABLE I. FMR Parameters of $(Fe_3O_4/NiO)_N$ superlattices. Based on 35-GHz data at 300 K, $g=2.12$ assumed.

N	$4\pi M'$ (kG)	δH (kOe)	$W_\parallel$ (kOe)	$W_\perp$ (kOe)
100	2.34	0.08	0.33	0.47
30	2.12	0.08	0.33	0.44
10	2.14	0.075	0.32	0.37
3	2.34	0.06	0.34	0.44

4(b)] is somewhat narrower and squarer with a low-field shoulder and nearly linear high-field slope.

We consider this lack of saturation most likely to be due to a frustrated magnetic state in which different Fe_3O_4 regions of the SL sample have their net magnetic moments aligned in opposite directions (in zero field). This "frustration" is thought to arise from local errors in the nominal Fe_3O_4 or NiO thickness which lead to some adjacent 68-Å Fe_3O_4 layers being exchange coupled antiparallel rather than parallel as would be the case for a perfect superlattice.

Assuming this is the origin of the effect, the question arises as to whether this variation is mostly a bilayer-to-bilayer effect or if the errors are distributed randomly across the film plane. Since the likelihood of the occurrence of a layer-to-layer fluctuation increases with the number of Fe_3O_4/NiO repeats, one would expect to see corresponding changes in the M vs H and FMR behavior with N if layer-to-layer effects were dominant.

The relevant FMR data are summarized in Table I for the superlattices studied. The effective magnetizations $4\pi M'$ determined from $\vec{H}$ in-plane or $\vec{H}$ perpendicular data are in good agreement and only the average value is given. The quantity δH represents the maximum variation in the FMR field position as the direction of $\vec{H}$ is varied in-plane. As can be seen from Table I, this anisotropy variation is never more than a small fraction of the parallel or perpendicular linewidths W. We also note that the FMR positions do not show full fourfold symmetry as $\vec{H}$ is rotated in plane although weak inequivalent minima were observed at the two $\langle 100 \rangle$ directions.

The most important information in Table I, however, is the observation that none of the parameters listed show any large or systematic variation with N even though N is varied by more than a factor of 30. From this and the magnetization data of Fig. 4, we conclude that any region-to-region coupling-sign variation must be distributed primarily among areas within individual superlattice bilayers rather than mainly through the SL thickness.

Single crystal superlattices of Fe_3O_4 and NiO, grown on MgO(100), provide a means to study the competition between interfacial exchange coupling effects and epitaxial strain induced by these closely, but not perfectly, lattice matched materials. Both induce profound macroscopic magnetic effects in the superlattices, especially for films with very thin (<80 Å) modulation thicknesses. The Fe_3O_4 Verwey conductivity transition in the bulk (~120 K) is highly sensitive to both the exact stoichiometry of the iron oxide and the presence of strain and is accompanied by a structural and magnetic anisotropy change. X-ray diffraction measurements show that these superlattices are tetragonally distorted (up to 1%), with the increased strain associated with superlattices composed of thin bilayers. By tracking the magnetic evidence of this phase transition using SQUID magnetometry techniques, we observe attenuation of the effect in superlattice films as the iron oxide layers grow thinner and the nickel oxide layers are thickened, which suggests that the presence of strain in the iron oxide layers is highly important. The small structural distortion is observable in neutron diffraction measurements of a Fe_3O_4 film. Studies of the diffuse and critical scattering associated with this transition in strained iron oxide films and Fe_3O_4/NiO superlattices and a comparison to previous work on bulk Fe_3O_4 single crystals will be discussed.

Neutron diffraction measurements reveal the nature of the magnetic structure in Fe_3O_4/NiO superlattices grown by molecular beam epitaxy. By taking advantage of differences between the spinel and rocksalt crystalline symmetries, we have separated the magnetic order parameters of the Fe_3O_4 and NiO bilayer components. The NiO antiferromagnetic order develops at temperatures 10–150 K greater than $T_{Néel}$ for bulk (520 K) due to exchange coupling of the Ni spins to the Fe_3O_4 (T_{Curie}=858 K) at the superlattice interfaces. The resultant scaling of the NiO transition temperature with the bilayer composition is consistent with expectations from mean-field treatments for a modulated magnetic material. In addition, the NiO spin order propagates coherently through several superlattice bilayers, while the magnetic coherence of the Fe_3O_4 is limited by a random stacking of the spinel unit cell at the interfaces when the NiO interlayers are thicker than ≈15 Å. A model for the diffraction data, based upon a Hendricks–Teller description of the interfacial disorder, demonstrates that the observed broadening of selected crystalline and magnetic reflections originates directly from these stacking faults. Combining the high angle diffraction results with those from polarized-beam reflectivity analysis, we extract specific information about the moment distribution in these superlattices and qualitatively explain the evolution of the magnetic structure with temperature.

After a general introduction describing the mechanisms of the current perpendicular to the layer plane magnetoresistance (CPP-MR), a microscopic model based on the Boltzmann equation is presented and a general expression of the magnetoresistance is derived in which the spin diffusion length appears as the unique scaling length of the problem. In the limit where the spin diffusion lengths are much larger than the layer thicknesses, the expression of the CPP-MR becomes very simple and similar to that already used at Michigan State University for the analysis of experimental results. Out of this limit, the model predicts a dramatic reduction of the CPP-MR if the spin diffusion lengths are shortened sufficiently by paramagnetic impurities or spin-orbit scatterers. Finally, a calculation is presented of the spin-dependent interface resistances involved in the model and related to interface potential steps, and experimental data are compared.

I. INTRODUCTION

The giant magnetoresistance (GMR) of the magnetic multilayers[1,2] was first observed and studied in the so-called CIP (current-in-plane) geometry. Then, in 1991, Pratt *et al.*[3] at Michigan State University could also measure GMR effects in the CPP (current perpendicular to the layer plane) geometry. We refer to Pratt *et al.*[4] and to the invited paper of Bass *et al.* at this conference[5] for a review of the extensive results obtained at Michigan State University on multilayer structures based on the Co/Cu and Co/Ag systems. More recently, Gijs, Lenczowski, and Giesbert[6] have also been able to measure CPP-GMR effects on mesoscopic structures prepared by lithography (which allows them measurements at room temperature).

The several models developed for the CIP-GMR (Ref. 7 and 8) are very generally based on the different conduction properties of the spin ↑ (majority) and spin ↓ (minority) electrons in ferromagnetic metals.[9] Although the CPP-MR can be also attributed to spin-dependent conduction, there are important fundamental differences between the mechanisms of the CPP- and CIP-MR. The main difference actually comes from the spin accumulation and spin relaxation effects occurring in the CPP geometry.

An illustration of the spin accumulation and relaxation effects at an interface is presented in Fig. 1. A plane boundary separates two semi-infinite ferromagnetic materials having opposite magnetizations (one can imagine a very thin nonmagnetic layer separating the two regions). We suppose that the conductivity of the majority spin channel is larger. Therefore, far from the boundary on the left-hand side, the spin + electrons (those which are majority electrons in this region) carry a larger part of the current than the spin−electrons. On the contrary, at the right-hand side, the spin + (now minority electrons) carry a smaller part of the current. Consequently, for electrons flowing from the left- to the right-hand side, the incoming flux of spin + (spin −) electrons from the left-hand side is larger (smaller) than their outgoing flux to the right-hand side, which gives rise to accumulation (depression) of spin + (spin −). This means an out-of-equilibrium polarization and an increase (for spin +) or decrease (for spin −) of the chemical potential around the boundary. In a stationary regime, the out-of-equilibrium polarization is balanced by spin relaxation processes. However, because the spin relaxation time is very long (compared to the momentum relaxation time), the spin + accumulation (or spin − depression) diffuses far from the interface. The equations of this problem have already been written down by Johnson and Silsbee[10] or van Son, van Kempen, and Wyder.[11] In the case of Fig. 1, with, in addition, symmetric spin ↑ and spin ↓ bands differing only by their scattering rates, one obtains an exponential variation of the spin polarization, that is, an exponential increase (decrease) of the chemical potentials of the spin + (spin −) electrons, $\Delta\mu_{+(-)}=\pm\Delta\mu$ with $\Delta\mu\sim\exp(z/l_{sf})$ on the left-hand side and $\Delta\mu\sim\exp(-z/l_{sf})$ on the right-hand side; l_{sf} is the spin diffusion length (SDL) that we define precisely below. $\Delta\mu$ is represented in Fig. 1(a). The variation with z of the spin-dependent chemical potentials gives rise to spin-dependent forces (pseudoelectric fields) that slow down (accelerate) the spin + (spin −) electrons at distances of the order of l_{sf} on both sides of the boundary. Consequently the currents, see Fig. 1(b), and also the electric field, see Fig. 1(c), are affected in a broad range, $-l_{sf}\lesssim z\lesssim+l_{sf}$, around the interface.

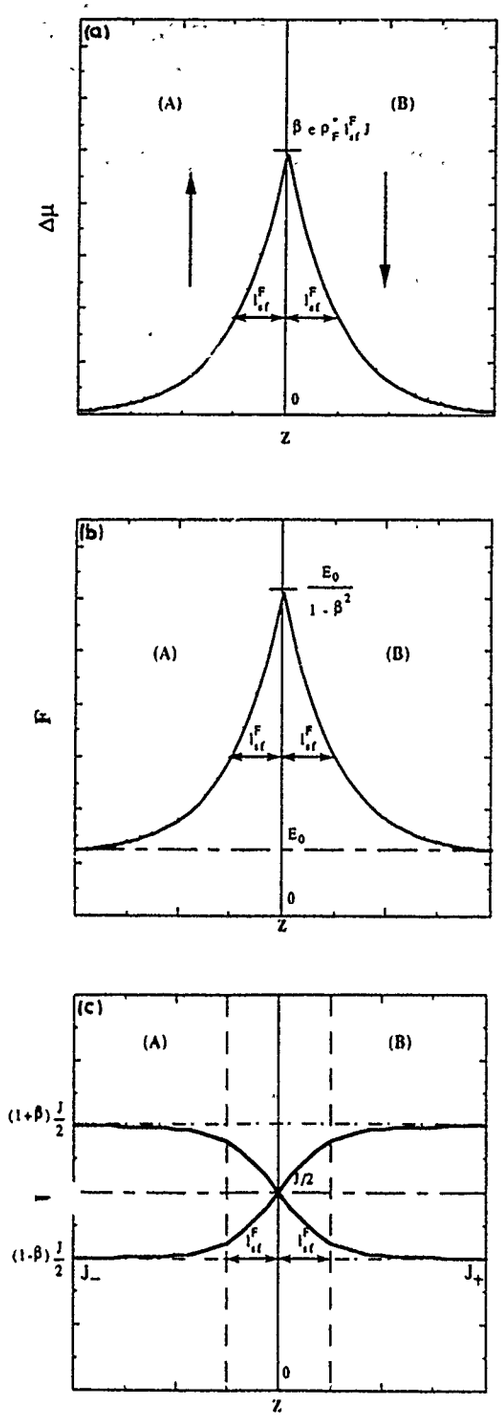

FIG. 1. Illustration of spin accumulation effects at the interface $z=0$ between two semi-infinite ferromagnetic regions with opposite magnetizations. The arrows indicate the majority spin direction in each region. The electrons flow from left- to right-hand side, and the spin + electrons are supposed to be weakly scattered at the left-hand side and strongly at the right-hand side. The change $\Delta\mu$ of the chemical potential of the spin + electrons (proportional to the out of equilibrium spin polarization), the absolute values of the current densities for spin + and spin − electrons, J_+ and J_-, respectively, and the absolute values of the electric field E are plotted vs z. See also Refs. 14 and 15.

In contrast, in the CIP geometry, the perturbation by an interface does not extend farther than the resistivity mean free path (MFP) λ. This is an important difference since, in systems such as Co/Cu or Co/Ag, l_{sf} is estimated at a few thousand Å and is larger than λ by one order of magnitude.[12,13]

This fundamental difference between CIP and CPP appears clearly also in the theoretical models: the MFP λ is the scaling length of CIP-MR,[7,8] whereas, as shown in Sec. II, the spin diffusion length (SDL) l_{sf} becomes the unique scaling length of the CPP problem. More practically, this also means, for example, that the CIP-MR vanishes when the thicknesses exceed λ, and the CPP-MR only when they exceed l_{sf} (see Sec. IV). Another important consequence is that, with values of l_{sf} of a few thousands of Å, most experiments of CPP-MR have been performed in multilayers with individual thicknesses much shorter than l_{sf}. In this limit, the expression of the CPP-MR becomes very simple,[12,16] in agreement with the phenomenological picture developed at Michigan State University.[4,5] In CIP-MR, a similar simple limit is expected for individual thicknesses much shorter than the MFP λ, but this thickness range is hard to reach and never very extended.

How do these questions of spin accumulation, spin relaxation and spin diffusion length appear in the theoretical models develop for the CPP-MR up to now?

Johnson and Silsbee[10] and van Son and co-workers[11] have treated the problem of spin accumulation at interfaces with macroscopic equations, and Johnson[14] has applied the same approach to the problem of the CPP MR. The model of Valet and Fert,[12,16] that we summarize in the first part of this article, is a microscopic model of the spin accumulation effects in CPP MR, based on the Boltzmann equation. The first result of this model is that the macroscopic equations of Johnson and Silsbee[10] or van Son and co-workers[11] are justified if the MFP λ is much shorter than the SDL l_{sf} (in addition, in this limit, l_{sf} becomes the unique scaling length of the problem). Then, in the application of the CPP MR of the multilayers, our calculation departs from that of Johnson.[14] We show that it is important to treat the interplay between spin accumulation at successive interfaces and we find a general expression[12] of the CPP MR quite different from Johnson's expression.[14] In the limit of very long spin diffusion lengths (much longer than the individual thicknesses) our expression of the GMR becomes very simple and is equivalent to the expressions that Pratt *et al.*[4,5] have found in a simple "two-channel model" and used for the interpretation of their experiments.

Besides the approach of Johnson[14] or Valet and Fert[12,16] taking into account the spin accumulation effects and their balance by spin-flip processes, several other models by Zhang, Levy, and Camblong,[17] Bauer,[18], or Inoue, Itoh, and Maekawa[19] are based on the assumption that the current is conserved in each spin channel (no spin flip). This assumption that the electrons of a given absolute spin direction carry the same proportion of the total current in the layers where they are spin ↑ (majority) and, say, weakly scattered, as well as in the layers where they are spin ↓ and strongly scattered, is not so odd as it could appear at first view. As a matter of fact, in the limit of very long SDL in our model, the spin-dependent forces arising from spin accumulation accelerate and slow down the electrons in such a way that, in first approximation, the current proportion in each channel does not change when the magnetization flips. Thus, the existence

of spin accumulation effects, with the additional hypothesis of infinite SDL, is the hidden basis of the models with conserved current for each spin direction. It is therefore probable that there are many common features with the predictions of these models[17–19] and what we predict in the long SDL limit of our calculation (in spite of the use of different formalisms, Kubo, Landauer, or Boltzmann).

II. MODEL (REFS. 14 AND 15)

We present shortly the model which is described in detail in Ref. 12. The starting point is a Boltzmann-like equation in which we introduce the following distribution function for the electrons of spin s (note that, throughout the article, we refer to + or − for the absolute spin directions of the conduction electrons, and to ↑ or ↓ for the majority and minority spin directions in the magnetic layers),

$$f_s(z,\mathbf{v})=f^0(v)+\frac{\partial f^0}{\partial \epsilon}\{[\mu^0-\mu_s(z)]+g_s(z,\mathbf{v})\}. \tag{1}$$

The term $g_s(z,\mathbf{v})$ express the displacement of the distribution in the presence of current and the term $\mu_s(z)$ accounts for the z dependence of the chemical potential related to spin accumulation effects [$f^0(v)$ is the Fermi–Dirac distribution]. We obtain for the linearized Boltzmann equation

$$v_z\frac{\partial g_s}{\partial z}(z,\mathbf{v})+\left(\frac{1}{\tau_s}+\frac{1}{\tau_{sf}}\right)g_s(z,\mathbf{v})=\left(v_z\frac{\partial \tilde{\mu}_s}{\partial z}(z)+\frac{\tilde{\mu}_s(z)-\tilde{\mu}_{-s}(z)}{\tau_{sf}}\right), \tag{2}$$

where $\tilde{\mu}_s(z)=\mu_s(z)-eV(z)$ is the electrochemical potential for spin s, and $(\tau_{sf}^{-1}+\tau_s^{-1})=(\tau_s')^{-1}$ and τ_{sf}^{-1} are the relaxation rates for the momentum in each channel and for the spin polarization, respectively. In the low-temperature limit, we neglect the momentum transfer between the two channels by coherent electron magnon scattering, that is, in the usual notation, the spin mixing term $(\tau_{\uparrow\downarrow}^{-1}\sim\rho_{\uparrow\downarrow})$.[9] Since τ_{sf}, related to spin-flip scattering, is generally, much longer than the momentum relaxation time τ_s involved in the resistivity, τ_s'/τ_{sf} is a small number. At the lowest order in τ_s'/τ_{sf}, one obtains[12] the macroscopic equations already derived by Johnson and Silsbee[10] or van Son and co-workers,[11]

$$J_s=\frac{\sigma_s}{e}\frac{\partial \tilde{\mu}_s}{\partial z}, \tag{3}$$

$$\frac{e}{\sigma_s}\frac{\partial J_s}{\partial z}=\frac{(\tilde{\mu}_s-\tilde{\mu}_{-s})}{l_s^2}, \tag{4}$$

where J_s is the current density for spin, s, $\sigma_s=n_s e^2\tau_s'/m$ is the conductivity for the spin s channel, l_s is the SDL for spin s defined by

$$l_s=v_F[\tau_{sf}(\tau_{sf}^{-1}+\tau_s^{-1})^{-1}/3]^{1/2}\approx v_F(\tau_{sf}\tau_s/3)^{1/2}. \tag{5}$$

Equation (3) is a sort of Ohm law and Eq. (4) expresses the balance between spin accumulation by the current divergence and the spin relaxation by spin flip. These equations lead to a diffusion-type equation for $\Delta\mu=(\mu_+-\mu_-)/2$,

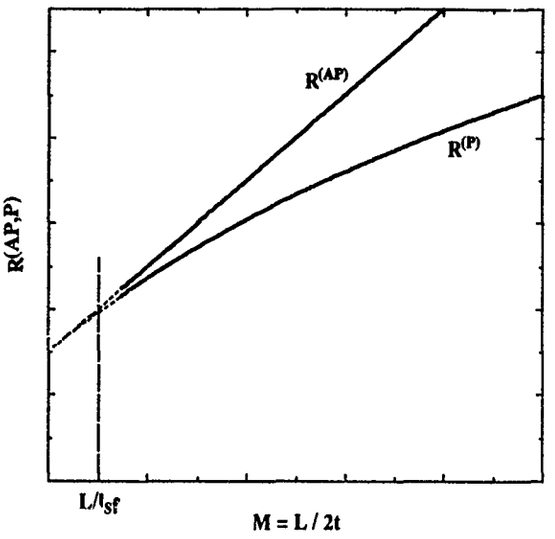

FIG. 2. Predicted variation of the CPP resistance of a multilayer as a function of the number of bilayers M for a fixed total thickness L and the same individual thickness for the ferromagnetic and normal layers, $t_F=t_N=t=L/(2M)$. The calculation is performed for interface spin dependent scattering only ($\beta=0$).

$$\frac{\partial^2\Delta\mu}{\partial z^2}=\frac{\Delta\mu}{l_{sf}^2}, \tag{6}$$

where $l_{sf}^{-2}=l_\uparrow^{-2}+l_\downarrow^{-2}$ and to variations as $\exp(\pm z/l_{sf})$ for $\Delta\mu$, for the currents $J+$ and $J-$ and for the electric field $F=(2e)^{-1}\partial(\tilde{\mu}_++\tilde{\mu}_-)/\partial z$. We have shown in Fig. 1 the variation of $\Delta\mu$, $J\pm$, and F for an isolated interface. In multilayers, the interference between successive interfaces gives rise to combinations of $\exp(\pm z/l_{sf})$ and to oscillations with the period of the multilayered structure. Examples are given in Fig. 2 of Ref. 12. In the limit w ere the SDL l_{sf} is much longer than the layer thicknesses t, the amplitude of the oscillations of $(J_+-J_-)/(J_++J_-)$ vanishes as $(t/l_{sf})^2$, which shows that the assumption of conserved currents in each channel is justified in this limit.

The above model has been used to calculated the CPP resistance and the CPP MR of multilayers. The notation is the following. The resistivity for the spin ↑ or spin ↓ electrons in the ferromagnetic layers is written as

$$\rho_{\uparrow(\downarrow)}=\frac{1}{\sigma_{\uparrow(\downarrow)}}=2\rho_F^*[1-(+)\beta]. \tag{7}$$

The interface resistance due to diffuse or specular scattering at interfaces (see Sec. V) and involved in the boundary conditions for $\tilde{\mu}(z)$ [i.e., $\tilde{\mu}(0^+)-\tilde{\mu}(0^-)=r_sJ_s(0)/e$] is written as

$$r_{\uparrow(\downarrow)}=2r_b^*[1-(+)\gamma]. \tag{8}$$

The notation in Eqs. (7) and (8) is the same as in Refs. 4 and 12: $2\rho_{\uparrow(\downarrow)}(2r_b^*)$ is the mean value of the spin ↑ and spin ↓ resistivities (interface resistances); β and γ are the spin asymmetry parameters which give rise to the GMR. The interface resistances[4,12] are introduced to express the enhanced scattering in an interfacial zone that is supposed to be infinitesimally thin and include also a Landauer-type condition induced by specular reflections (Ref. 20; see also Sec. IV).

For a unit area multilayer composed of M bilayers, the following resistance is finally obtained for parallel (P) and antiparallel (AP) arrangements of the magnetization in successive layers:

$$R^{(P,AP)}=M(r_0+2r_{SI}^{P,AP}) \quad \text{with} \quad r_0=(1-\beta)^2\rho_F^* t_F+\rho_N^* t_N+2(1-\gamma^2)r_b^*, \tag{9}$$

$$r_{SI}^{(P)}=\frac{\dfrac{(\beta-\gamma)^2}{\rho_N^* l_{sf}^{(N)}}\coth\left(\frac{t_N}{2l_{sf}^{(N)}}\right)+\dfrac{\gamma^2}{\rho_F^* l_{sf}^{(F)}}\coth\left(\frac{t_F}{2l_{sf}^{(F)}}\right)+\dfrac{\beta^2}{r_b^*}}{\dfrac{1}{\rho_N^* l_{sf}^{(N)}}\coth\left(\frac{t_N}{2l_{sf}^{(N)}}\right)\dfrac{1}{\rho_F^* l_{sf}^{(F)}}\coth\left(\frac{t_F}{2l_{sf}^{(F)}}\right)+\dfrac{1}{r_b^*}\left[\dfrac{1}{\rho_N^* l_{sf}^{(N)}}\coth\left(\frac{t_N}{2l_{sf}^{(N)}}\right)+\dfrac{1}{\rho_F^* l_{sf}^{(F)}}\coth\left(\frac{t_F}{2l_{sf}^{(F)}}\right)\right]}, \tag{10}$$

$$r_{SI}^{(AP)}=\frac{\dfrac{(\beta-\gamma)^2}{\rho_N^* l_{sf}^{(N)}}\tanh\left(\frac{t_N}{2l_{sf}^{(N)}}\right)+\dfrac{\gamma^2}{\rho_F^* l_{sf}^{(F)}}\coth\left(\frac{t_F}{2l_{sf}^{(F)}}\right)+\dfrac{\beta^2}{r_b^*}}{\dfrac{1}{\rho_N^* \rho_{sf}^{(F)} l_{sf}^{(N)}}\tanh\left(\frac{t_N}{2l_{sf}^{(N)}}\right)\dfrac{1}{\rho_F^* l_{sf}^{(F)}}\coth\left(\frac{t_F}{2l_{sf}^{(F)}}\right)+\dfrac{1}{r_b^*}\left[\dfrac{1}{\rho_N^* l_{sf}^{(N)}}\tanh\left(\frac{t_N}{2l_{sf}^{(N)}}\right)+\dfrac{1}{\rho_F^* l_{sf}^{(F)}}\coth\left(\frac{t_F}{2l_{sf}^{(F)}}\right)\right]}. \tag{11}$$

t_F (t_N) ($l_{sf}^{(N)}$) are the thicknesses and SDL of the magnetic (nonmagnetic) layers. Before discussing the general behavior expected from Eqs. (9)–(11) in Sec. IV, we begin by considering the long SDL limit in Sec. III.

III. LONG SPIN DIFFUSION LENGTH LIMIT

In the limit $l_{sf}^{(F)} \gg t_F, l_{sf}^{(N)} \gg t_N$, Eqs. (9)–(11) lead to simple expressions equivalent to those derived by Pratt *et al.*[4,5] to account for most of their experimental data on Co/Ag and Co/Cu multilayers,

$$R^{(AP)}=M(\rho_F^* t_F+\rho_N^* t_N+2r_b^*), \tag{12}$$

$$\frac{1}{R^{(P)}}=\frac{1}{M}\left(\frac{1}{2\rho_F^*(1-\beta)t_F+2\rho_N^* t_N+4r_b^*(1-\gamma)}+\frac{1}{2\rho_F^*(1+\beta)t_F+2\rho_N^* t_N+4r_b^*(1+\gamma)}\right) \tag{13}$$

$$\sqrt{(R^{(AP)}-R^{(P)})R^{(AP)}}=\beta\frac{t_F}{t_F+t_N}\rho_F^* L+2\gamma r_b^* M, \tag{14}$$

where L is the tota. thickness [$L=M(t_F+t_N)$]. Alternatively these expressions are also obtained in a two-channel scheme where the resistance of each channel (+,−) is a series sum of the resistivity times the layer thickness of the F and N metals plus the sum of the $2M$ interface resistances, as ill ...rated by Fig. 3 in Ref. 12 and also described in Refs. 4 and 5.

In Figs. 2 and 3, we show examples of the predicted variations of the resistance or MR with M for a fixed total length L. In Fig. 2, for $t_F=t_N=L/2M$ and with only interfacial spin-dependent scattering (i.e., $\beta=0$), $R^{(AP)}$ is a linear function of M; on the other hand $R^{(P)}$ is not strictly linear but its departure from a linear variation is significant only when the contribution from interfaces is much smaller than from scattering inside the layers. This behavior has been clearly characterized in extensive measurements.[4,5] In Fig. 3, $[(R^{(AP)}-R^{(P)})R^{(AP)}]^{1/2}$ is plotted versus M, again for a fixed total thickness L and $t_F=t_N=L/2M$. Such a plot, extensively used in the analysis of experimental results,[4,5] is quite interesting since the intercept of the linear variation with the vertical axis yields the bulk asymmetry parameter β, while its slope gives the interface asymmetry parameter γ (γ turns out to be larger than β in Co/Ag and Co/Cu). All these linear variations with M are predicted only in the long SDL limit, that is, for $M \gg L/l_{sf}$, and for finite SDL deviations are expected at the left-hand side of the dashed vertical line in Fig. 3. In the following section we see what is predicted for shorter SDL, that is, when the dashed vertical line comes into the experimental range of M.

IV. CPR-MR FOR FINITE SPIN DIFFUSION LENGTHS

When the SDL is not much larger than the individual layer thicknesses, the simple expressions of Sec. III, Eqs. (12)–(14), are no longer valid and we must come back to the general expression of Sec. II, Eqs. (9)–(11).

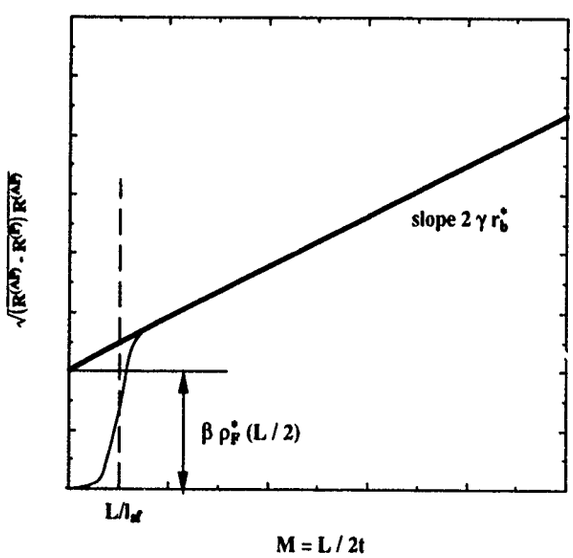

FIG. 3. $\sqrt{(R^{(AP)}-R^{(P)})R^{(AP)}}$ is plotted as a function of the number of bilayers M for a fixed total thickness L and the same individual thickness for the ferromagnetic and normal layer, $t_F=t_N=t=L/(2M)$. The solid line is the linear variation expected from Eq. (14) for the limit $t \ll l_{sf}$ or $M \ll L/l_{sf}$. For $M<L/l_{sf}$, Eq. (14) is no longer valid and $\sqrt{(R^{(AP)}-R^{(P)})R^{(AP)}}$ drops as $\exp(-t/4l_{sf}) \sim \exp(-L/2Ml_{sf})$ (see thin solid line).

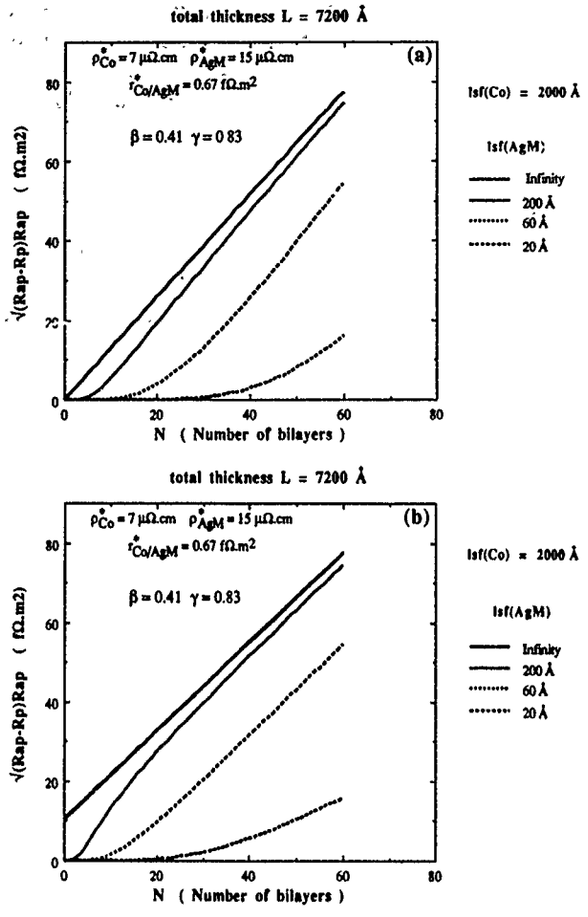

FIG. 4. $\sqrt{(R^{(AP)}-R^{(P)})R^{(AP)}}$ is plotted as a function of the number of bilayers M for several values of the SDL $l_{sf}^{(N)}$ [see values of l_{sf} (AgMn) indicated in the figure] and a constant value of $l_{sf}^{(F)}$ [l_{sf}(Co)=2000 Å]. The total thickness L is fixed: (a) t_F=60 Å, $t_N=L/M-t_F$; (b) $t_F=t_N=L/2M$. The parameters of the calculations are those derived from Co/AgMn (Ref. 5), i.e., ρ_N^*=15 μΩ cm, ρ_F^*=7 μΩ cm, r_b^*=0.67 fΩ m², β=0.41, γ=0.83. For comparison with experimental results, see Bass *et al.* (Ref. 5).

In Fig. 4, for a multilayer with a fixed total thickness L, we show the curves of $[(R^{(AP)}-R^{(P)})R^{(AP)}]^{1/2}$ versus the number of bilayers M calculated for several values of $l_{sf}^{(N)}$. Figure 4(a) is for t_F=60 Å, $t_N=L/M-t_F$, and Fig. 4(b) for $t_F=t_N=L/2M$. For the calculation from Eqs. (9)–(11), we have used the parameters ρ_N^*, ρ_F^*, r_b^*, β, γ derived by Bass *et al.*[5] from the analysis of experimental results on Co/AgMn.

For $l_{sf}^{(N)}=\infty$, we observe the linear variation expected for this limit from Eq. (14) and already represented in Fig. 3. When $l_{sf}^{(N)}$ is shortened, the CPP-MR is dramatically reduced and departs strongly from a linear variation with M. As expected, the MR is practically reduced to zero at small values of M, that is for $t_N \gg l_{sf}^{(N)}$. It can be shown from Eqs. (9)–(11) that $[(R^{(AP)}-R^{(P)})^{(AP)}]^{1/2}$ starts at small values of M as $\exp(-L/Ml_{sf}^{(N)})$ in Fig. 4(a) and as $\exp(-L/2Ml_{sf}^{(N)})$ in Fig. 4(b), and catches up with the linear variation of the long spin diffusion length limit for $M \gg L/l_{sf}^{(N)}$ (i.e., $t_N \ll l_{sf}^{(N)}$).

There are several ways to shorten the SDL in the nonmagnetic layers and test the theory [as seen easily from Eqs. (9)–(11), the SDL in the magnetic layers has less important effects and we consider only the problem of the SDL in the normal layers]. The simplest situation is when impurities with strong spin-orbit coupling are introduced in the layers. Very efficient impurities should be $5d$ (or even $4d$) elements as, (i) their d states are strongly mixed with the conduction states, (ii) the spin orbit is strong for $5d$ states. The contribution to the spin-flip relaxation rate of the conduction electrons can be written as[21]

$$(\tau_{sf}^{-1})_{so}=N_I v_F \sigma_{sf}^{so},$$
$$\sigma_{sf}^{so}=40\pi(\lambda_d/\Delta)^2 \sin^2(\pi Z_d/10)/k_F^2, \tag{15}$$

where N_I is the impurity concentration, λ_d the spin-orbit constant of the d states, Δ the width of the d virtual bound state, and Z_d the number of d electrons on the impurity. We have estimated[5] that 6% of Pt in Ag should reduce the SDL to about 30 Å.

Another possibility is to induce spin relaxation by adding some paramagnetic impurities.

By adding Mn impurities in the nonmagnetic layers of Co/Ag and Co/Cu multilayers to shorten $l_{sf}^{(N)}$, Bass *et al.*[5] have been able to observe clearly the reduction of the CPP-MR and the departure from a linear variation with the number of bilayers. We refer to Figs. 4 in Ref. 5 for a fit of our theoretical expressions with experimental data. The shortening of the SDL by Mn impurities has been calculated by one of us (A.F.).[5] It turns out that a few at % of Mn are predicted to shorten the SDL significantly, in agreement with the experimental results.

V. SPIN-DEPENDENT INTERFACE RESISTANCES

The spin-dependent interface resistances involved in our model, see Eq. (8), can be due, either to specular reflections and refractions by perfect interfaces or, in addition, to diffuse scattering by the roughness (disorder) of the interfaces. It would be of great interest to know the relative importance of these two contributions to the interfaces resistances and also their respective spin dependencies. In addition, it happens that the specular reflections do not contribute directly to the CIP-MR,[22,23] so that a predominant contribution from specular reflections to the CPP-MR would mean that CIP- and CPP-MR have different microscopic origins.

Two of us (J.B. and A.F.) have calculated the interface resistances induced by the electron reflection and refraction at spin-dependent potential steps (perfect interfaces) between layers.[24] The potential steps are of the form

$$U_\sigma(x)=\begin{cases}0 & \text{for } x<0 \quad \text{(nonmagnetic layer)},\\ U_\sigma & \text{for } x>0 \quad \text{(magnetic layer)},\end{cases}$$

where U_σ ($\sigma=\uparrow,\downarrow$) are constants. The electrons are free electrons, and their Fermi energy is E_F for $x<0$ and E_F-U_σ for $x>0$ and spin σ. The reflection and refraction coefficients are calculated by using the expressions given, for example, by Hood and Falicov[23] and the interfaces resistances are calculated in the Landauer formalism.[20] This leads[24] to an expression of the interface resistance that we do not reproduce here. A plot of r_σ as a function of U_σ/E_F for $U_\sigma>0$ is shown in Fig. 5. As expected r_σ starts from zero for $U_\sigma=0$ and diverges as U_σ tends to E_F. The experimental data

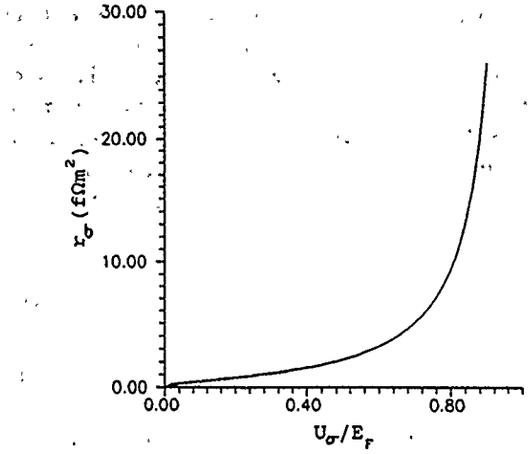

FIG. 5. Interface resistance r_σ vs U_σ/E_F [from Barnas and Fert (Ref. 22)].

found in Refs. 4 and 5 are $r_\downarrow=2.08$ fΩ m^2 and $r_\uparrow=0.17$ fΩ m^2 for Co/Ag, and $r_\downarrow=1.76$ fΩ cm^2 and $r_\uparrow=0.24$ fΩ m^2 for Co/Cu multilayers. As can be seen from Fig. 5, the higher resistances, $r_\downarrow=2.08$ fΩ m^2 in Co/Ag and $r_\downarrow=1.76$ fΩ m^2 in Co/Cu, can be accounted for by assuming reasonable values of $U_\downarrow/E_F$ around 0.4 (in a free-electron model for s electrons in Co, Cu, and Ag, $U_\downarrow/E_F=0.4$ could be obtained, for example, by assuming 0.5 s electrons per atom and spin direction in Cu or Ag and 0.23 minority spin s in Co). The smaller values for $r_\uparrow$ correspond to values of $U_\downarrow/E_F$ of the order of only 0.03, i.e., to a not very different number of s electrons in Co, Cu, and Ag for this spin direction. Qualitatively, the high value of the ratio $r_\downarrow/r_\uparrow$ can be supposed to follow from the contrast between a good fit of the s bands of Co, Cu, and Ag for one spin direction and bad mismatch of the bands for the other spin direction.

An additional contribution to the interface resistance can arise from diffusive scattering by interface disorder. Can this contribution be important? Let us consider a disordered interfacial layer of thickness 4 Å with the typical high resistivity of an amorphous alloy of 4 μΩ m in each spin channel (2 μΩ m is a typical value of the resistivity for amorphous alloys containing transition metals, which gives 4 μΩ m for each spin channel). Writing $r_\sigma=\rho_\sigma l$ with $l=4\times10^{-10}$ m and $\rho_\sigma=4$ μΩ m one obtains $r_\sigma=1.6$ fΩ m^2. We thus find that scattering by interface roughness can also contribute significantly to the interface resistance.

VI. CONCLUSIONS

We have reviewed some of the main problems raised by CPP-MR experiments: the specific role of the spin accumulation and relaxation effects in the CPP geometry, the importance of the spin diffusion length as the scaling length of the problem, and the origin of the spin-dependent interface resistances. Up to now, most experiments have been performed in the long spin diffusion length limit, with the great advantage of a simple and fruitful analysis of the experimental results.[3–5] The experiments on multilayers doped by Mn reported by Bass *et al.*[5] at this conference represent certainly a new interesting direction for the investigation of spin relaxation processes. Measurements as a function of temperature, which have been performed so far only by Gijs and co-workers[6] should also raise interesting problems related to the scattering by spin fluctuations.

How to isolate effects of spin-flip scattering on giant magnetoresistance in magnetic multilayers (invited)

J. Bass, Q. Yang, S. F. Lee, P. Holody, R. Loloee, P. A. Schroeder, and W. P. Pratt, Jr.
Department of Physics and Astronomy and Center for Fundamental Materials Research, Michigan State University, East Lansing, Michigan 48824-1116

A technique is described for isolating effects of finite spin diffusion lengths on the magnetoresistance (MR) of magnetic multilayers at low temperatures by measuring the MR with the current perpendicular to the layer planes. Applying this technique to relatively concentrated Co/AgMn and Co/CuMn multilayers yields large effects, generally consistent with expectations from a theory by Valet and Fert [Phys. Rev. B **48**, 7099 (1993)]. However, some complicating issues still need to be resolved.

I. INTRODUCTION

Several magnetic multilayers composed of alternating thin layers of ferromagnetic (F) and nonmagnetic (N) metals display large decreases in electrical resistance with increasing magnetic field H.[1–3] This phenomenon, called giant magnetoresistance (GMR), is of both scientific and technological interest.[4] To fully understand GMR, we must understand how it depends upon all of the different kinds of scattering that electrons experience in bulk F and N metals and at F/N interfaces.[5–7] In this article, we focus upon spin-flip scattering in the N metal at low temperatures.

At low temperatures, electron scattering in magnetic multilayers is dominated by elastic scattering at the F/N interfaces and from impurities in the F and N metals. The direction of an electron's spin then usually stays fixed as the electron traverses the multilayer. This means that the quantity of interest in the present paper, the electron spin diffusion length l_{sf}, is much longer than the structural lengths of the multilayer: F-layer thickness t_F; N-layer thickness t_N; and bilayer thickness, $\Lambda=t_F+t_N$.

Most GMR analyses to date have neglected spin-flip scattering. This assumption is valid at low temperatures for pure-metal-based multilayers, but becomes less valid as the temperature rises, because electron-magnon scattering, which flips spins, grows with increasing temperature. Since most technological applications of GMR will occur at room temperature, it seems clear that we need to understand effects of spin-flip scattering to fully understand GMR.

Observed T^2 variations of both the traditional MR with current flow in the layer planes (CIP MR)[8] and the MR with current flow perpendicular to the layer planes (CPP MR)[3] have been taken as evidence for scattering (including spin-flip scattering) of electrons by thermally excited magnons. However, the temperature dependence of GMR is a complex phenomenon,[9] from which it is difficult to extract information about spin-flip scattering.

This difficulty stimulated us to look for effects of spin flip scattering on the GMR at low temperatures. We first briefly explain why we use the CPP MR instead of the more traditional CIP MR.

The CIP MR has the advantage of being much easier to measure, since the typical CIP resistance is $\approx 1\ \Omega$. But the CIP MR contains several unknown parameters,[10] and its behavior at low temperatures is dominated by the (elastic) mean-free-path for momentum transfer, λ_{el},[6] which is not what we wish to investigate here. The dominant effect on the CIP MR of adding impurities that flip spins is to change λ_{el}, making it difficult to isolate any effects due to spin flip scattering alone. In addition, the CIP MR is affected only by those spin-flip scattering events that transfer momentum between spin up and spin down electrons, and these events are negligible at low temperatures. The particular quantity of present interest, l_{sf}, measures the relaxation of spin accumulation at interfaces, which occurs in the CPP-MR,[11–15] but not in the CIP MR. Thus, l_{sf} does not play a role in the CIP MR and cannot be isolated by measuring the CIP MR.

The CPP MR, in contrast, is harder to measure, with either very small resistances $\approx 10^{-7}\ \Omega$, or the need to make very small samples by lithographic patterning.[3] But it has the advantage that when l_{sf} is large, λ_{el} is not a characteristic length in the CPP MR. The only characteristic length is l_{sf}.[14,15] The expressions for the CPP MR then become simple, as we and others have shown.[11,13,14] In this paper we show how combining a particular set of measured quantities associated with the CPP MR lets us isolate just those effects due specifically to the reduction of l_{sf}. We could reduce l_{sf} either by adding a strong spin orbit interaction via a very heavy impurity such as Au or Pt, or by adding a strong spin-spin interaction via an impurity with a local moment, such as Mn. In this paper we examine data for both Co/AgMn and Co/CuMn.

II. SAMPLES

Each of our CPP MR samples consists of a sputtered multilayer of interest sandwiched between two $\approx$1.1-mm-wide crossed-superconducting Nb strips with area of overlap $A \approx 1.2\ \text{mm}^2$. A known current is fed into one Nb strip and taken out of the other, and the resulting potential difference between the two Nb strips is determined. Details of our techniques for preparing samples, characterizing them, and simultaneously measuring the CPP MR and the CIP MR are given elsewhere.[2] We assume that our samples are best described as multilayers, although it has been suggested that sputtered metal-metal multilayers such as ours are better characterized as anisotropic inhomogeneous alloys.[16]

For brevity, we limit ourselves to: (a) the CPP MR; (b) samples with fixed total thickness $t_T=N\Lambda$ as close as pos-

 0021-8979/94/75(10)/6699/5/$6.00 © 1994 American Institute of Physics

sible to 720 nm (N is the number of bilayers in a sample); and (c) samples with fixed t_F ($=t_{Co}$)=6 nm. To avoid proximity effects with the superconducting Nb current and potential leads, Co layers were sputtered on both sides of the new AgMn and CuMn multilayers, which thus consisted of N bilayers plus one extra Co layer. To avoid complications due to oscillating interactions between F layers as t_N changes, we only examine samples with $t_N \geq 6$ nm, which is beyond the range of oscillating MRs,[1] and large enough so that exchange interactions between F layers should be small. Mn was chosen because we had appropriate targets available, and experience in sputtering both AgMn and CuMn for studies of finite size effects in spin glasses.[17] Fairly large Mn concentrations were chosen to maximize the chance of seeing an effect since, as we see below, the estimates for l_{sf}^N are uncertain.

III. TWO-CHANNEL MODELS

A. $l_{sf}^N \sim$ Infinity

We[13] and others[11,14] have argued that when $l_{sf} \gg l_{el}, \Lambda$ (i.e., spin-flip scattering is negligible), the total CPP resistance times sample area AR_T can be well described by a model in which electrons are divided into two channels, up (+) and down (−) relative to the direction of the applied field H, which carry current independently. The AR_T in each channel (+,−) is simply a series sum of the resistivities times total layer thicknesses of the F and N metals plus the sum of the area times interface resistances of the F/N interfaces. Schematically, we thus have for each channel an expression of the form

$$AR^{(+,-)} = 2AR_{S/F} + (N+1)\rho_F^{(+,-)} t_F + N\rho_N t_N + 2NAR_{F/N}^{(+,-)}, \quad (1)$$

where the term $2AR_{S/F}$ accounts for the interface resistances between the superconducting (S) Nb current leads and the (F) Co boundaries at the two ends of the samples.[18] We assume that this additional term is spin independent. For ease of presentation, we neglect the difference between N and $N+1$ in equations that follow.

In the standard models for the CIP MR and CPP MR of magnetic multilayers, the largest resistance occurs when the magnetizations M_i of neighboring F layers are oriented antiparallel (AP) to each other, and the smallest when they are oriented parallel (P). We thus focus upon these two limiting cases.

We define $\rho\uparrow = 2\rho_F/(1+\beta)$ to be the resistivity of a F layer when the electron spin and the local M_i are parallel to each other, and $\rho\downarrow = 2\rho_F/(1-\beta)$ to be the resistivity when they are antiparallel. Here ρ_F is the F resistivity measured on independent thin F films or sandwiches.[18] Similarly, we take $R\uparrow = (2R_{F/N})/(1+\gamma)$ and $R\downarrow = (2R_{F/N})/(1-\gamma)$.

In the AP state ($M=0$) we expect, by symmetry, that $AR^{(+)} = AR^{(-)}$. Since the resistances of the (+) and (−) channels add in parallel, AR_T should be just one-half of these equal values. Continuing to neglect differences between N and $N+1$, we find[13]

$$AR_T(\mathrm{AP}) = 2AR_{S/F} + N[(\rho_F^* t_F) + \rho_N t_N + 2AR_{F/N}^*], \quad (2a)$$

where $\rho_F^* = \rho_F/(1-\beta^2)$ and $R_{F/N}^* = R_{F/N}/(1-\gamma^2)$.

For fixed t_T and t_F, we use the relation $t_T = Nt_F + Nt_N$ to eliminate t_N from Eq. (2a),

$$AR_T(\mathrm{AP}) = 2AR_{S/F} + \rho_N t_T + N[(\rho_F^* - \rho_N)t_F + 2AR_{F/N}^*]. \quad (2b)$$

Plotting AR_T(AP) vs N should thus give a straight line with ordinate intercept $2AR_{S/F} + \rho_N t_N$ and slope $(\rho_F^* - \rho_N)t_F + 2AR_{F/N}^*$. $2AR_{Nb/Co}$ has been separately measured to be $\approx 6f\Omega$ m^2,[18] and ρ_N can be calculated for a known impurity concentration[19] and also directly measured on 300–500-nm-thick sputtered films. The intercept can thus be independently determined, and the only unknowns in Eq. (2b) are ρ_F^* and $R_{F/N}^*$. These two quantities can be determined by also measuring AR_T(AF) for a series of samples with fixed t_T and $t_F = t_N$. We have published such measurements for Co/Ag, Co/AgSn, and Co/Cu.[12,13,20]

In the (P) state ($H \geq H_s$, $M = M_s$), in contrast, spin + and spin − electrons behave differently. Here, we showed[13] that adding their resistances in parallel and rearranging gives

$$AR_T(\mathrm{P}) = AR_T(\mathrm{AP}) - N^2(\beta\rho_F^* t_F + 2\gamma AR_{F/N}^*)^2/[AR_T(\mathrm{AP})]. \quad (3)$$

Equation (3) can be rewritten to yield the important linear relationship[13]

$$A\sqrt{R_T(\mathrm{AP})[R_T(\mathrm{AP}) - R_T(\mathrm{P})]} = N[\beta\rho_F^* t_F + 2\gamma AR_{F/N}^*]. \quad (4)$$

The right-hand side of Eq. (4) is independent of ρ_N and also of t_T (except through N). For samples with fixed t_F, a plot of the experimentally determined left-hand-side of Eq. (4) versus N should yield a straight line through the origin. For samples with $t_F = t_N$, a similar plot should yield a straight line with slope proportional to γ and ordinate intercept proportional to β. Equation (4) thus allows independent determinations of γ and β, once ρ_F^* and $R_{F/N}^*$ have been found from Eq. (2).

For fixed t_F, if we modify ρ_N by adding only a few percent impurities to the N metal, so that the parameters on the right-hand side of Eq. (4) do not change, then the slope of the line passing through the origin should also not change. This property makes Eq. (4) ideal for testing for effects of finite l_{sf}, since simply adding elastic scattering impurities to the N metal should not move data points off this line. Reducing l_{sf}, in contrast, should decrease the difference between AR_T(AP) and AR_T(P), via spin relaxation,[21] spin mixing,[15] or both. The signature of a finite l_{sf} will be data that fall farther below the line from Eq. (4) as N decreases (i.e., t_N increases).

B. Finite l_{sf}^N

Formal equations for AR(AP) and AR(P) for finite l_{sf} were recently derived by Valet and Fert,[14] and are repeated as Eqs. (9)–(11) in the preceding paper by Fert and co-workers in the present volume.[21] Strictly, these equations contain two different spin-dependent diffusion lengths, l_{sf}^N and l_{sf}^F, for the N and F metals; but, inserting typical values for the various parameters shows that the data are insensitive to l_{sf}^F—i.e., l_{sf}^F must be ≤ 1 nm to measurably change Eq. (4). It is thus l_{sf}^N that is of primary interest, and that we try to reduce in these experiments.

TABLE I. Estimated parameters for Co/AgMn and Co/CuMn.

Alloy	Co/AgMn (9 at. %)	Co/CuMn (7 at. %)
λ_{el} (nm)[a]	5.6	2.1
λ_{sf} (nm)[b]	≈90	≈24
$l_{sf}^{N}=\sqrt{(\lambda_{el}\lambda_{sf})/6}$	≈9	≈3

[a]The estimates for λ_{el} were obtained by combining the free-electron equations (Ref. 25), $\lambda_{el}=836\ \text{nm}/\rho(\text{n}\Omega\ \text{m})$ for Ag and $\lambda_{el}=656\ \text{nm}/\rho(\text{n}\Omega\ \text{m})$ for Cu, with values for the alloy residual resistivities estimated from the intended impurity concentrations and the resistivities per at. % impurity given in Ref. 19. Independent measurements of the residual resistivities of sputtered 300- or 500-nm-thick films are consistent with these estimates for AgSn, AgMn, and CuMn.

[b]The estimates of the spin-flip mean free path λ_{sf} for AgMn and CuMn are based on calculations by Fert (Ref. 22) using available information about exchange coupling in these alloys. Interactions between the Mn impurities might lead to actual values for λ_{sf} and l_{sf} larger than these estimates.

As noted above, we chose to test our procedure by using the magnetic impurity Mn. Estimates of l_{sf}^{N} for scattering from noninteracting Mn impurities in AgMn and CuMn require a complex analysis, which was kindly performed by Fert.[22] The actual values of l_{sf}^{N} for our AgMn and CuMn alloys could be larger than these estimates because, at the low temperature (4.2 K) where our measurements are made, interactions between the dilute magnetic Mn ions yield a complex coherent state called a spin glass (SG). Below its "spin-freezing temperature," this coherent state may well cause less spin-flip sputtering than for noninteracting impurities. Unfortunately, we do not understand the SG state well enough to predict how much l_{sf}^{N} might increase. The bulk spin-freezing temperatures in our samples are about 38 K for 7 at. % Mn in Cu and 28 K for 9 at. % Mn in Ag. Even corrected for finite size effects,[17] the temperatures for our thinnest SG layers (t_N=6 nm) are still well above 4.2 K.

Finally, we note that the Valet and Fert equations are strictly valid only when $l_{sf}\gg l_{el}$, whereas in our samples $l_{sf}\approx l_{el}$ (Table I). We thus do not expect detailed quantitative agreement with our AgMn and CuMn data, which would require, among other things, including an extra term,[14] the magnitude of which has not yet been estimated.

IV. DATA AND ANALYSIS

We begin by showing that adding Mn does not qualitatively change the H dependence of our data. Figure 1 shows the field dependencies of $AR_T(H)-AR_T(H_s)$ for (6 nm/6 nm) multilayers of Co/Ag, Co/AgMn, and Co/AgSn, all measured in our standard CPP system, which goes only up to $H=1$ kOe. The three data sets are similar in form: the CPP MR is largest in the initially prepared state—designated H_0—decreases until H_s is reached, and then cycles through the curves shown, with maximum values at the peak field H_p. The values of H_p are also not much different for the three samples, suggesting similar magnetic couplings (or absence thereof) between F layers. Since the AF state is naturally associated with the largest value of $AR_T(H)$, we limited our previous analyses of Co/Ag, Co/AgSn, and Co/Cu to H_0;[13,20] for similar reasons we limit ourselves here to H_0,

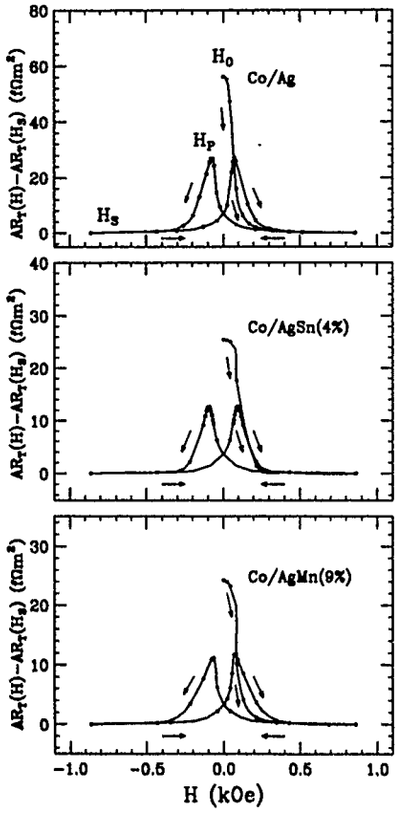

FIG. 1. $AR_T(H)-AR_T(H_s)$ vs H for (6 nm/6 nm) Co/Ag, Co/AgSn, and Co/AgMn multilayers with similar values of H_p. Values of H_p for nominally identical multilayers can vary by ~50%. The curves through the data are simply computer drawn guides to the eye.

also. Using H_p, instead, does not change any of the conclusions we reach, but there are quantitative differences that we will discuss elsewhere.[23]

We examine next whether the values of $AR_T(H_0)$ for different impurities are consistent with Eq. (2b). In Fig. 2 we plot $AR_T(H_0)$ and $AR_T(H_s)$ versus the number of bilayers N for our three Ag-based multilayers for fixed t_{Co}=6 nm. The $AR_T(H_0)$ data for Co/Ag and Co/AgSn fall close to straight lines, as predicted by Eq. (2b). Within their ≈10% scatter, the $AR_T(H_0)$ data for Co/AgMn are consistent either with the straight-line prediction in Eq. (2b) or with the slight curvature predicted by Eq. (10) from Ref. 21 (upper dashed curve in Fig. 2). With either linear or curved extrapolations, the ordinate intercepts for these and the Cu-based multilayers are all consistent to within experimental uncertainties with independently measured values of $2AR_{Nb/Co}+\rho_N t_T$.[23] As expected, the values of $AR_T(H_s)$ fall below those for $AR_T(H_0)$. As also expected, the fits to the Co/AgMn data are not as good as those to the Co/Ag and Co/AgSn data. It is not obvious from Fig. 2 alone which, if any, of the data sets involved reduced l_{sf}^{N}.

To isolate effects of reduced l_{sf}^{N}, we examine the square-root quantity of Eq. (4). As a reference against which to compare our data, Fig. 3 shows the predictions for this square root from the Valet and Fert equations for a range of values of l_{sf}^{N}. In Fig. 3 we have used the parameters for Co/Ag,[20] except that we have taken ρ_N=15 μΩ cm, appro-

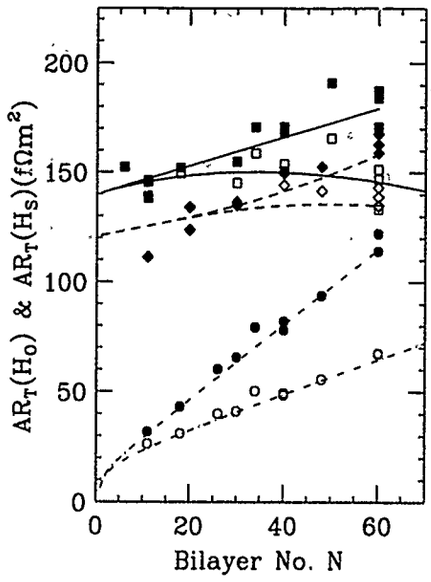

FIG. 2. $AR_T(H_0)$ (solid symbols) and $AR_T(H_s)$ (open symbols) vs bilayer number N for Co/Ag (circles), Co/AgSn (squares), and Co/AgMn (diamonds) multilayers with fixed t_{Co}=6 nm and t_T~720 nm. The broken Co/Ag curves and solid Co/AgSn curves are fits to Eqs. (2b) and (3); the downward curvature at small N for Co/Ag comes from corrections because these samples did not have a covering Co layer under the top Nb strip. The dashed Co/AgMn curves are fits to Eqs. (9)–(11) of Ref. 21. We do not expect the Co/AgMn fits to be as good as those for Co/Ag and Co/AgSn.

priate to our Ag-Mn-alloy multilayers. The fit is not sensitive to the Co/Ag parameters; an alternative set for Co/AgSn (Ref. 20) yields nearly indistinguishable predictions [e.g., compare Fig. 3 with Fig. 4(a) of Ref. 21]. Smaller values of ρ_N lead to larger deviations from the straight lines, and larger

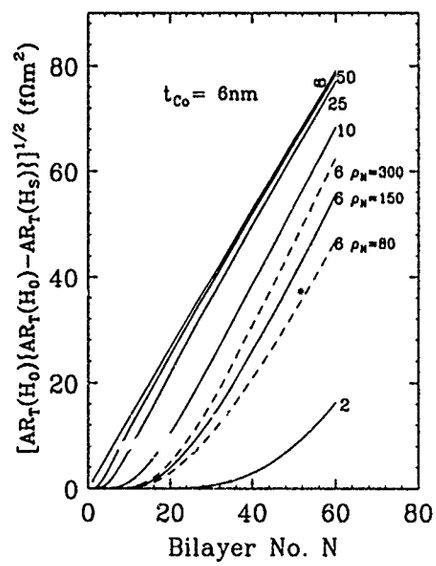

FIG. 3. $\sqrt{AR_T(H_0)[AR_T(H_0)-AR_T(H_s)]}$ vs bilayer number N calculated using Eqs. (9)–(11) from Ref. 21. The line labeled ∞ indicates the fit to Eq. (4) with the parameters for Co/Ag. The solid curves were calculated for the indicated values of l_{sf}^N using these same parameters and assuming ρ_N=150 nΩ m. To show the effect of varying ρ_N, the dashed curves for l_{sf}^N=6 nm were calculated for ρ_N=80 and 300 nΩ m as indicated.

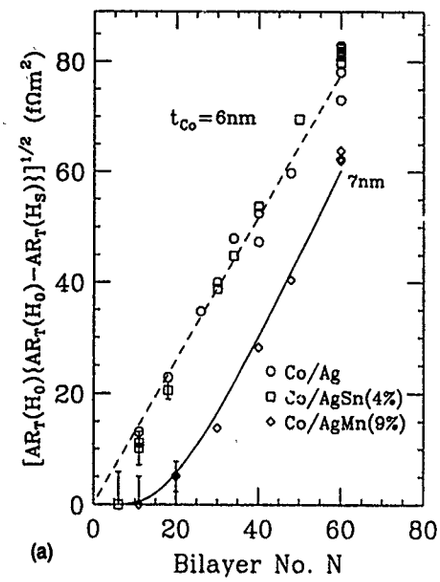

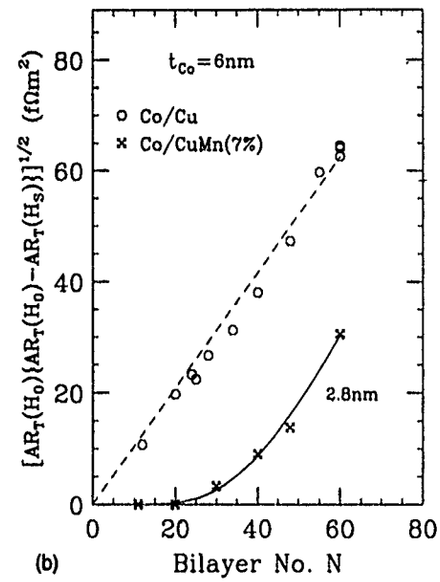

FIG. 4. (a) $\sqrt{AR_T(H_0)[AR_T(H_0)-AR_T(H_s)]}$ vs N for the data of Fig. 2. The curve through the AgMn data is for l_{sf}^N=7 nm. Some important error bars are shown; for larger values of the square root the uncertainties are dominated by geometric uncertainties that are ~±4% of the ordinate value. (b) $\sqrt{AR_T(H_0)[AR_T(H_0)-AR_T(H_s)]}$ vs N for Co/Cu and Co/CuMn. The curve through the CuMn data is for l_{sf}^N=2.8 nm.

values to somewhat smaller deviations; but, as illustrated by the alternative curves for l_{sf}^N=6 nm, these differences are modest, so that the curves in Fig. 3 fairly describe what we expect for our samples. If the true values of l_{sf}^N for AgMn and CuMn lie near the estimated lower bounds for l_{sf}^N given in Table I, then we expect the Co/AgMn and Co/CuMn data to fall well below the respective Co/Ag or Co/Cu lines.

Figure 4(a) shows the data for our three Ag-based multilayer sets plotted in the form of Eq. (4). As shown previously,[13,20] to within experimental uncertainties and variations among samples from different sputtering runs, the Co/Ag and Co/AgSn data are consistent with a single straight line through the origin. The Co/AgMn data, in contrast, fall

well below the line, and display the expected larger fractional deviations from the line as $N \rightarrow 0$. Figure 4(b) shows similar data for Co/Cu and Co/CuMn. Again, the Co/Cu data fall on a straight line,[20] and the Co/CuMn data fall well below this line, deviating more from the line as $N \rightarrow 0$. The curves through the Co/AgMn and Co/CuMn data are calculated using the Fert and Valet equations with the values of l_{sf}^{N} indicated on the graphs. Given that our data do not satisfy the validity condition $l_{sf} \gg \lambda_{el}$ for these equations, these values are surprisingly close to the estimates of Table I.

The data in Figs. 4(a) and 4(b) for Co/AgMn and Co/CuMn are consistent with the predictions from the equations of Valet and Fert with reasonable values for l_{sf}^{N}. We conclude by briefly examining whether these behaviors could be due to other causes.

One possibility is that the couplings between F layers might be more ferromagnetic with SG interlayers, leading to reduced values of the square root in Eq. (4). If so, we would expect to see differences in the hysteresis curves for multilayers with the different N metals. To check this possibility, we measured the saturation magnetizations and the coercive fields H_c for Co/Ag, Co/AgSn, and Co/AgMn. The results were very similar to each other.[23] This agreement for H_c was presaged by the closeness of the values of H_p in Fig. 1, since we have shown elsewhere that $H_p \approx H_c$.[2]

Another possibility is that the magnetic character of the SG layers causes the saturation field H_s for the CPP MR to be larger than the maximum field of 1 kOe in our standard CPP measuring system. To check this possibility, we measured selected samples in a higher field system, up to 10 kOe, limited by the H_{c2} of our Nb strips. No evidence of a higher saturation field was found for Co/Ag, Co/Cu, Co/AgSn, or Co/CuMn. However, the values of $AR_T(H)$ for Co/AgMn samples continued to decrease approximately linearly with increasing field up to 10 kOe.[23] Assuming H_s to be 10 kOe would cause the data points for AgMn in Fig. 4(a) to rise only part of the way toward the straight line for no spin-flip scattering; however, it is possible that the data continue to decrease to still higher fields. Since it is known that SGs alone can have substantial negative linear MRs at high magnetic fields,[24] we made some S/SG/S sandwiches of both AgMn and CuMn and measured their CPP MRs. We did not find negative MRs large enough to explain the high-field behaviors of the Co/AgMn multilayers;[23] there is thus still some question about the right explanation for the Co/AgMn data in Fig. 4(a).

V. SUMMARY

To summarize, we have shown how to isolate effects of a finite spin diffusion length l_{sf}^{N}, using the CPP MR of magnetic multilayers, and we have looked for such effects in multilayers containing alloys of Ag and Cu with the magnetic impurity Mn. For both Co/AgMn and Co/CuMn, the data of Fig. 4 deviate from straight-line behavior in the way expected, and the sizes of the deviations are comparable to predictions from a theory by Valet and Fert, even though the data do not satisfy the validity condition ($l_{sf} \gg \lambda_{el}$) of this theory. The interpretation of the AgMn data is further complicated by the presence of a negative linear MR above $H_s = 1$ kOe, the significance of which is not yet understood. To complete the case for our proposed technique, we plan to measure the CPP MR for smaller concentrations of Mn in Cu and Ag to check that the data scale with impurity concentration as predicted, and to extend measurements to the nonmagnetic alloys Co/AgPt and Co/CuPt, where spin-orbit effects should shorten l_{sf}^{N} enough to give significant effects.

ACKNOWLEDGMENTS

This research was supported in part by the US NSF under Grant No. DMR 91-22614, by the MSU Center for Fundamental Materials Research, and by the Ford Motor Co. We are pleased to thank A. Fert for helpful advice for providing the estimates of l_{sf}^{N} for AgMn and CuMn and for clarifying for us the nature of l_{sf} and why it plays no role in the CIP-MR. Our collaboration with him was supported by the US NSF under Grant No. INT-92-16909 and by the companion grant AI0693 from the French CNRS. We also thank P. M. Levy and M. B. Stearns for helpful conversations and suggestions.

Electronic transport in metallic multilayers is discussed in the language of the Landauer–Büttiker scattering formalism. The semiclassical conductance through a disordered interface can be unambiguously separated into specular and diffuse scattering contributions. Analytical results are derived for the perpendicular conductance of multiple disordered interfaces. Predictions for the transport properties of interfaces with dilute but strongly scattering defects should be accessible to verification by experiments. First results of first-principles calculations of ballistic transport in magnetic multilayers are presented.

I. INTRODUCTION

The giant magnetoresistance or spin-valve effect found in antiferromagnetically coupled metallic multilayers[1] has recently been studied in the so-called CPP (current perpendicular to the interface plane) geometry, both experimentally[2,3] and theoretically.[4–14] One of the many advantages of this configuration compared to the more conventional CIP (current in plane) geometry is its high symmetry, which simplifies the physics and allows more insight into the electronic transport through heterointerfaces. The importance of interface scattering in many areas of metal and semiconductor physics is reflected by numerous articles since the seminal work by Fuchs,[15] which are mainly concerned with transport parallel to an impenetrable rough interface, e.g., in the two-dimensional electron gas.[16] In the present article interface scattering is discussed for metallic transport normal to the interfaces on the basis of the Landauer–Büttiker formalism.[17] We show that in a semiclassical approximation the diffuse scattering is unequivocally connected to the impurity scattering correction to the electric field vertex. Our approach gives a simple relation between the specular and diffuse part of the transmitted wave. The conductance of a multilayer is found by a semiclassical concatenation of single interfaces. The theory can be applied to find the magnetoconductance in magnetic multilayers, where spin-dependent interface scattering is generally believed to be responsible for the spin-valve effect.

In Sec. II the Landauer–Büttiker formalism is introduced with emphasis on its relation to the conventional linear response theory. In Sec. III we review our previous results for disordered interface scattering in the semiclassical and effective mass approximations.[6,12,13] A critical assessment of the validity of our results is given in Sec. IV, where evidence is presented for the importance of quantum interference and band-structure effects beyond the semiclassical approximation.

II. LANDAUER–BÜTTIKER FORMALISM

The Landauer conductance formula[17] can be derived directly from the Kubo formula for the two-terminal configuration as sketched in Fig. 1.[18] It is required that (i) the sample is connected to the contacts via two low-impedance leads and (ii) the contacts are at thermodynamic equilibrium with a small electrochemical potential difference $\Delta\mu=\mu_1-\mu_2$. According to the Kubo linear response formalism the current can be calculated in terms of a nonlocal conductivity tensor $\underline{\sigma}(\mathbf{r},\mathbf{r}')$ and the local electric field $\mathbf{E}_{\rm loc}(\mathbf{r})$. The total current passing through an arbitrary plane S with normal $\hat{\mathbf{n}}_S$ is given as

$$J_S=\int_S d\mathbf{r}\,\hat{n}_S(\mathbf{r})\cdot\mathbf{j}(\mathbf{r})=\int_S d\mathbf{r}\int_\Omega d\mathbf{r}'\;\hat{\mathbf{n}}_S\underline{\sigma}(\mathbf{r},\mathbf{r}')\mathbf{E}_{\rm loc}(\mathbf{r}'). \tag{1}$$

We may choose S to cut through one of the leads and to be part of the surface defining the total volume Ω which encloses the sample (see Fig. 1). The local electric field is the gradient of the electrochemical potential $\mathbf{E}_{\rm loc}(\mathbf{r})=\nabla\mu(\mathbf{r})/e$ which vanishes in the leads according to our assumption (i). The chemical potentials in the leads are supposed to be identical to the ones in the contacts [assumption (ii)]. The divergence theorem and the condition of local charge conserva-

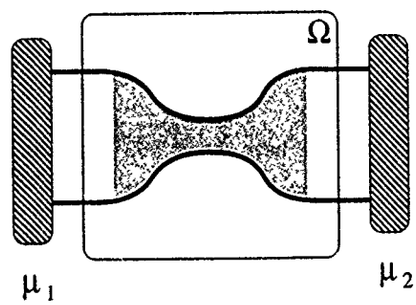

FIG. 1. Transport experiment described by Landauer's formula in the two-terminal configuration. A current flows through the sample due to an electrochemical potential difference $\mu_1-\mu_2$ between the contacts which are indicated by heavy shading. Ω is the volume encircled by the thin line, which includes the shaded sample region and part of the low-impedance leads to the equilibrated contacts.

tion, $\nabla \cdot \mathbf{j}(\mathbf{r})=0$, can then be employed to transform the volume integral in Eq. (1) into a surface integral,

$$J_2=-J_1=G\Delta\mu/e, \tag{2}$$

where J_1 and J_2 are the currents through the two leads and G is the conductance,

$$G=\int d\mathbf{r}\int d\mathbf{r}'\ \hat{\mathbf{n}}_1(\mathbf{r})\underline{\sigma}(\mathbf{r},\mathbf{r}')\hat{\mathbf{n}}_2(\mathbf{r}'). \tag{3}$$

This result shows that the current through the sample depends only on the *total* potential drop over the sample and it is not necessary to know the *local* current and electric-field distribution to obtain the transport properties. It can then be shown[18] that the conductance is proportional to the sum of the transmission probabilities $|t_{m,n}|^2$ between the different modes m and n at the Fermi energy in the left- and right-hand side leads (spin-degeneracy assumed),

$$G=\frac{2e^2}{h}\sum_{m,n}|t_{m,n}|^2. \tag{4}$$

The transmission amplitude $t_{m,n}$ can be calculated via the Schrödinger equation.[13,19]

In many experiments it is not possible to cleanly separate "contacts," "leads," and the "sample." However, the Landauer–Büttiker formalism can be applied also when the conductance is limited by a well-defined narrow sample region as sketched in Fig. 1, where the contribution of the contact/lead region, and inaccuracies of its theoretical treatment, can be safely disregarded. In macroscopic samples the effects of the contacts may be neglected anyway. One might also wonder if the formalism may be applied to the spin-valve effect. It is well known that a ferromagnetic layer causes a nonequilibrium spin polarization of the outgoing current.[20,21] On the other hand, the equilibrated contacts are an essential ingredient in the derivation of Landauer's formula. However, this problem is of no concern as long as the spin-flip relaxation length is sufficiently longer than the length of the narrow sample section which limits the conductance. If the spin flip takes place in a wide sample section or in the contacts itself, it will not significantly contribute to the conductance. The spin-flip-induced degradation of the giant magnetoresistance with increasing temperature[8,22] cannot be treated by our theory, however.

III. DISORDERED INTERFACE SCATTERING

We consider the configuration in Fig. 2(a), i.e., a relatively narrow pillar of metallic material which limits the current in the circuit, as fabricated by Gijs *et al.*,[3] although macroscopic devices as investigated by Pratt *et al.*[2] can be treated as well. The de Broglie wavelength in high-density metals is only a few Å and quantum effects due to lateral confinement can be neglected for pillars wider than, say, 0.01 μm. In this regime the sample boundaries also have a negligible effect. Let us first consider scattering at a single interface. The interface roughness is modeled by short-range scatterers that are randomly distributed over the interface. The incoming and outgoing electron states are in this section approximated by plane waves with an effective parabolic dispersion. The wave function at an energy E is determined by the Schrödinger equation,

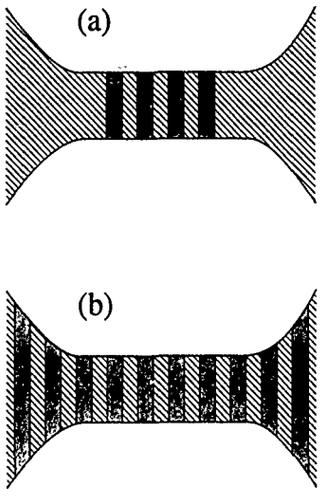

FIG. 2. (a) Sample geometry considered in the first part of the article, where the leads are made from a bulk metal, and the conductance is limited by the narrow region containing a heterostructure. (b) Pillar made from a superlattice, a configuration which is accessible to band-structure calculations.

$$\left(-\frac{\hbar^2}{2}\nabla\frac{1}{m^*(x)}\nabla+U_C(x)+V(x,y,z)\right)\psi(x,y,z)$$
$$=E\psi(x,y,z). \tag{5}$$

The conduction-band profile, $U_C(x)$, and the effective mass of the electron $m^*(x)$, are approximated by step functions at $x=0$. The interface roughness is represented by the potential $V(x,y,z)$. Landauer's conductance formula for this situation reads (spin degeneracy assumed)

$$G=\frac{2e^2}{h}\sum_{\mathbf{k}_\parallel,\mathbf{k}_\parallel'}^{\text{prop}}|t_{\mathbf{k}_\parallel,\mathbf{k}_\parallel'}|^2. \tag{6}$$

$\mathbf{k}_\parallel$ and $k_\perp$ are the transverse and longitudinal components of the wave vectors related by

$$k_\perp^L=[(2m_L^*/\hbar^2)(E_F-U_L)-k_\parallel^2]^{1/2},$$
$$k_\perp^R=[(2m_R^*)/\hbar^2)(E_F-U_R)-k_\parallel^2]^{1/2}.$$

The transmission (reflection) coefficient from state $\mathbf{k}_\parallel'$ to state $\mathbf{k}_\parallel$ is $t_{\mathbf{k}_\parallel,\mathbf{k}_\parallel'}(r_{\mathbf{k}_\parallel,\mathbf{k}_\parallel'})$ and the summation is over propagating modes. In the following we set $\Delta U_C=0$ and $\Delta m^*=0$, which considerably simplifies the analytical treatment (see Ref. 13 for generalizations of the following equations). Current conservation and the continuity of the wave function relate the transmission probabilities and the transmission coefficients by an optical theorem,[23]

$$\sum_{\mathbf{k}_\parallel}^{\text{prop.}}|t_{\mathbf{k}_\parallel,\mathbf{k}_\parallel'}|^2=\text{Re}(t_{\mathbf{k}_\parallel',\mathbf{k}_\parallel'}). \tag{7}$$

The diagrams contributing to the transmission probability can be classified as crossing or non-crossing. The crossing

diagrams[13] describe phase coherence phenomena like weak (Anderson) localization of the wave function.[24] Neglecting crossing diagrams, i.e., phase coherent scattering between different defects, it is possible to find the transmission probability in terms of the irreducible self-energy Σ (Ref. 13),

$$\langle |t_{k_\parallel,k'_\parallel}|^2\rangle = \delta_{k_\parallel,k'_\parallel}\frac{k_\perp^2}{\left|k_\perp + i\frac{m^*}{\hbar^2}\Sigma\right|^2} + \frac{k_\perp}{\left|k_\perp + i\frac{m^*}{\hbar^2}\Sigma\right|^2} \times \frac{\frac{-m^*}{\hbar^2}\,\mathrm{Im}(\Sigma)}{\Sigma^{\text{prop.}}_{k''_\parallel}\frac{k''_\perp}{\left|k''_\parallel + i\frac{m^*}{\hbar^2}\Sigma\right|^2}} \frac{k'_\perp}{\left|k'_\perp + i\frac{m^*}{\hbar^2}\Sigma\right|^2}. \quad (8)$$

Our approximation is called semiclassical and valid for $|\Sigma|/E_F \ll 1$. Otherwise it breaks down when the distance between dephasing inelastic collisions becomes larger than the average separation between scatterers. Electrons are scattered specularly at the interface if the transverse component of the wave vector is conserved, which is the first term on the right-hand side of Eq. (8). The second term clearly represents the diffuse scattering contribution, which vanishes if the vertex correction is not taken into account.

To lowest order in the self-energy $m^*\Sigma/(\hbar^2 k_F)$ the conductance is independent of the real part of the self-energy,

$$G = G^0(1 - 4\eta_{IR} + 2\eta_{IR}), \quad (9)$$

where $\eta_{IR} = -m^*\,\mathrm{Im}(\Sigma)/(\hbar^2 k_F)$. $G^0 = (2e^2/h)(Ak_F^2)/(4\pi)$ is the Sharvin conductance which is proportional to the sample cross section A. The second term reduces the conductance due to specular scattering. The third, diffuse term *increases* the conductance by opening additional channels for electron transport.

We will now study the situation where all scatterers have equal magnitude of strength $\pm\gamma$ with an average $\bar{\gamma}$ which does not have to vanish. The self-energy is calculated in the single-site approximation, i.e., using the exact cross section for isolated defects, but neglecting crossed diagrams,

$$\Sigma^S = \frac{\eta_{IR}\bar{\gamma} - in_{IR}(m^*/\hbar^2)\gamma^2(k_F/2\pi)(1 - i\sqrt{\alpha^2 - 1})}{1 + [(m^*\gamma/\hbar^2)(k_F/2\pi)]^2(1 - i\sqrt{\alpha^2 - 1})^2}. \quad (10)$$

This result reduces to the Born result in the weak scattering limit $[m^*\gamma k_F/(\hbar^2\pi) \ll 1]$. For strong scattering $[m^*\gamma k_F/(\hbar^2\pi) \gg 1]$, but to lowest order in η_{IR}, we obtain the interesting result that

$$G = \frac{2e^2}{h}\left(\frac{Ak_F^2}{4\pi} - \frac{N_{IR}}{\alpha^2}\right), \quad (11)$$

where a high-momentum cutoff αk_F characterizes the spatial range of the scattering potentials. The conductance is reduced by a factor proportional to the number of defects $N_{IR} = An_{IR}$. Each scatterer effectively blocks one channel and the conductance becomes independent of the scattering strength. This blocking is somewhat reduced by a factor $1/\alpha^2$ via a "leak" of evanescent states. An experiment is proposed to test this expression: Insert a layer (or a multilayer, see below) with strong short-range scatterers between two low-impedance leads. Such a structure could be realized by the technique of δ-doping, which is routinely employed in semiconductor technology. By measuring the conductance and the number of impurities the theory can be checked and the leaking factor α can be determined which provides information about the range of the scattering potential. Note that a nonzero average of scatterers has no effect on the conductance in this limit.

Results for a single interface can be generalized to N interfaces, taking both interface scattering and bulk impurity scattering into account. Semiclassical concatenation of transmission probabilities[19] is consistent with the neglect of crossing diagrams in the single-interface scattering. The transmission properties do not change with the distance between the interfaces in this approximation. By allowing the interfaces to be infinitesimally close to each other, one can convince oneself that the relation between the transmission probabilities and the transmission coefficients, Eq. (7), still holds for the N-interface configuration. The conductance for a multilayer is

$$\frac{G^{(N)}}{G^0} = 1 - 2x_N + 2x_N^2 \ln\left(1 + \frac{1}{x_N}\right), \quad (12)$$

where $x_N = N/(2\bar{N}) = L/(2l)$. $\bar{N} = l/L_p = [2\eta_{IR} + L_p/l_{BI}]^{-1}$ is the mean free number of traversed interfaces, where L is the total sample length, $L_p = L/N$, l is the global mean free path and l_{BI} is the mean free path due to bulk impurity scattering. This relation agrees with Eq. (11) in Ref. 6 for $\Delta U_C = 0$. The two-dimensional equivalent of this expression is of interest in quasiballistic transport in semiconductor nanostructures,[25,26]

$$\frac{G_{2D}^{(N)}}{G_{2D}^0} = 1 - \frac{x_N\pi}{2} + \begin{cases} \dfrac{x_N^2}{\sqrt{1-x_N^2}}\ln\left(\dfrac{1+\sqrt{1-x_N^2}}{x_N}\right) & \text{for } x_N < 1, \\ \dfrac{x_N^2}{\sqrt{x_N^2-1}}\arccos\dfrac{1}{x_N} & \text{for } x_N > 1, \end{cases} \quad (13)$$

where $G_{2D}^0 = (2e^2/h)(Wk_F/\pi)$ is the two-dimensional Sharvin conductance, proportional to the channel width W. For disordered homogeneous samples these expressions are similar but not identical to de Jong's solution for the Boltzmann equation.[26] The reason for the differences can be traced to the complete backscattering of electrons with grazing incidence in the present formalism, which in the Boltzmann approach are transmitted with probability of one-half.[26] In the large N limit a Drude-like (Ohm's law) expression is obtained for the conductivities,

$$\sigma_\infty = \begin{cases} \lim_{N\to\infty} \dfrac{NL_p G^{(N)}}{A} = \dfrac{2e^2}{h}\,\dfrac{k_F^2}{3\pi}\,l & \text{in three dimensions,} \\ \lim_{N\to\infty} \dfrac{NL_p G_{2r}^{N}}{W} = \dfrac{2e^2}{h}\,\dfrac{k_F}{2}\,l & \text{in two dimensions.} \end{cases} \tag{14}$$

For three-dimensional superlattices this limit has been treated before by Zhang and Levy.[4]

For a magnetic multilayer it is now straightforward to find the conductance by including spin-dependent interface and bulk scattering. The difference in the mean free number of traversed interfaces between both spin channels is $\Delta\tilde{N}$ and the spin-averaged results is $\tilde{N}$. The magnetoconductance of an antiparallel coupled multilayer is $\Delta G = G^P - G^{AP}$. The magnetoconductance depends on the parameters $\Delta\tilde{N}$, $\tilde{N}$, and the number of interfaces N. The spin-valve effect increases with the number of bilayers and saturates at the Drude limit for $N \gg \tilde{N}$ (Ref. 4). In the limit of a magnetic superlattice the relative magnetoconductance is

$$[\Delta G/G^P]^{\text{Drude}} = (\Delta\tilde{N}/2\tilde{N})^2.$$

IV. VALIDITY OF SEMICLASSICAL AND EFFECTIVE-MASS THEORY

It is important to assess the accuracy of the semiclassical and the effective-mass approximations for transition-metal multilayers, which are the most interesting class of compounds for applications of the present theory. The semiclassical approximation discards quantum interference effects which are known to be important for several other properties. The oscillatory coupling of magnetic layers is a genuine quantum interference effect since it depends on the thickness of the non-magnetic layer.[27] Size-quantized states have been observed by inverse photoemission and claimed to mediate the magnetic coupling.[28] It is therefore not clear from the outset that semiclassical approximations can be used to describe transport properties. A combined theory for coupling and transport proposed in Ref. 29 is still in a formal stage. In a numerical study on disordered multilayers Asano and co-workers[9,10] provide evidence that quantum size effects can be very important for the transport properties. They proceed from a tight-binding approximation for the d electrons, which corresponds to a small bandwidth and large effects for a given potential discontinuity. The effect of the potential step is much smaller, however, when s electrons at the Fermi energy are considered to be responsible for the transport, especially in Cu/transition-metal multilayers. Zhang and Levy[14] also found rather small quantum effects of miniband formation for the small potential step sizes seen by s electrons. In reality, free electrons and d electrons are strongly hybridized. This problem cannot be solved satisfactorily within an effective-mass approximation, revealing the need for a transport theory which takes the correct band structure of the transition metal into account. s-d hybridization has been investigated in a tight-binding approximation by Itoh, Inoue, and Maekawa[30] to investigate the scattering potential of a rough Cu/Ni surface. Coehoorn[31] correlates magnetotransport with the spin-dependent occupation number differences of d orbitals at heterointerfaces obtained from first-principles band-structure calculations. Oguchi[32] employ band-structure calculations of superlattices to calculate the average Fermi velocities, i.e., the gradient of the energy dispersion at the Fermi surface, parallel and perpendicular to the interfaces. The strong anisotropies are due to quantum size effects similar to those found by Asano and co-workers.[9,10] However, transport and band structures are connected heuristically by introducing a phenomenological transport scattering time.

Here we want to emphasize that the Landauer–Büttiker formalism lends itself very well to go beyond the effective-mass and semiclassical approximations, taking into account band-structure effects rigorously. The Landauer conductance formula is easily rewritten for the case of a complicated band-structure by labeling the in- and outgoing electron states at the Fermi energy by the parallel crystal momentum $\mathbf{q}_\parallel$ inside the first Brillouin zone and band index ν (spin degeneracy assumed),

$$G = \frac{2e^2}{h} \sum_{\mathbf{q}_\parallel \nu, \mathbf{q}'_\parallel \nu'} |t_{\mathbf{q}_\parallel \nu, \mathbf{q}'_\parallel \nu'}|^2. \tag{15}$$

The calculation of the transmission probabilities is of course more difficult. In order to get a feeling for the interrelation between electronic structure and transport, we propose considering the perfectly ballistic regime of a microstructure or point contact. This regime might be realized in future devices since atomically perfect interfaces are already obtainable by molecular-beam-epitaxy crystal growth techniques. Furthermore, Asano and co-workers[9,10] pointed out that the projected density of states of unperturbed systems is strongly correlated with the conductance affected by interface roughness scattering. The finite (Sharvin) conductance is proportional to the finite cross section A and the contact conductances in the narrow sample region due to heteroinsertions.[6] The configuration in Fig. 2(a) is not directly accessible to band-structure calculations, however. We therefore concentrate on the configuration in Fig. 2(b), for which the Sharvin conductance comes down to the sum of the projections S of the Fermi surfaces for the different bands on the plane normal to the transport direction $\hat{\mathbf{n}}$,[33]

$$\begin{aligned} G_{\hat{\mathbf{n}}} &= \frac{2e^2}{h}\,\frac{A}{4\pi^2}\,\frac{1}{2} \sum_\nu S_\nu(\hat{\mathbf{n}}) \\ &= \frac{2e^2}{h}\,\frac{A}{4\pi^2}\,\frac{1}{2} \sum_\nu \int d\mathbf{q} |\hat{\mathbf{n}}\cdot\nabla_{\mathbf{q}}\epsilon_\nu(\mathbf{q})|\,\delta[\epsilon_\nu(\mathbf{q}) - E_F], \end{aligned} \tag{16}$$

which can be calculated given the band-structure energies $\epsilon_\nu(\mathbf{q})$ on a sufficiently fine mesh of wave vectors in the first Brillouin zone. In Fig. 3 we plot the number of conduction channels for Cu, which is proportional to the ballistic conductance through a constriction with cross section A, as calculated using first-principles band structures obtained by the linear muffin-tin orbital method (see Ref. 33 for details). To indicate the contributions from different bands the Fermi energy is varied, keeping the Cu band structure unmodified.

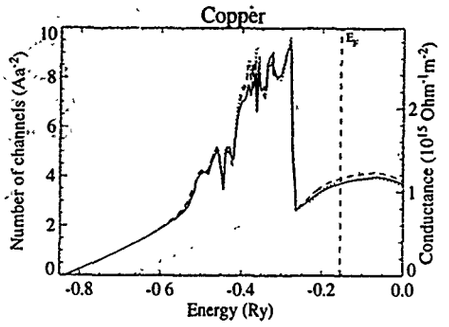

FIG. 3. Number of conducting channels in a constriction of copper with cross section A and oriented along the main crystal axes ⟨100⟩ (solid line), ⟨110⟩ (dashed line), and ⟨111⟩ (dotted line) (a=3.61 Å). The Fermi energy is varied for the (fixed) energy band structure calculated for Cu. The dashed straight line is the free-electron result.

Note that $G_{\hat{\mathbf{n}}}$ is anisotropic even for cubic crystals. By calculating Eq. (16) for magnetic superlattices with $\hat{\mathbf{n}}$ parallel and perpendicular to the interfaces a first-principles, consistent theory of transport and magnetism can be achieved. First results have been obtained for Co_1/Cu_2 ⟨111⟩-oriented superlattices forced into the spin-parallel (P) and spin-antiparallel (AP) configurations. The conductances are 1.14 (P) and 0.96 (AP) for the CIP geometry and 0.83 (P) and 0.64 (AP) for the CPP geometry, all in $10^{15}\ \Omega^{-1}\ \mathrm{cm}^{-2}$. The magnetoconductance (P-AP)/AP is therefore 19% for the CIP geometry in contrast to 30% in the CPP geometry, explaining a significant fraction of the experimental value as a purely ballistic effect. A detailed analysis will be published in due course.[33]

V. CONCLUSIONS

In summary, we have derived analytical semiclassical expressions for perpendicular transport through disordered interfaces. An experiment to check the theory is proposed which might lead to a deeper understanding of the scattering process and the microscopic structure of disordered interfaces. In the two-current model the expressions are easily generalized to describe the giant magnetoresistance in terms of the mean free number of traversed interfaces for the majority and minority spins. First results indicate the importance of taking realistic band structures into account.[33]

We discuss the fabrication and microstructuring techniques of pillar structures made of high vacuum sputtered Fe/Cr multilayers and of molecular beam epitaxy evaporated Co/Cu multilayers, for which we measured the giant magnetoresistance effect with the current perpendicular to the multilayer plane from 4 K to 300 K. Using optical lithography and reactive ion etching techniques we obtained structures with a typical height of 0.5 μm and a width ranging between 3 and 10 μm. For both Fe/Cr and Co/Cu multilayers we find an enhanced magnetoresistance with respect to the in-plane case. The perpendicular magnetoresistance of the Fe/Cr pillars strongly decreases with temperature, while for the Co/Cu samples the temperature dependence is weaker, indicating electron-magnon scattering processes of different strength.

I. INTRODUCTION

Following the discovery of antiferromagnetic (AF) coupling[1] and the associated giant magnetoresistance (MR) effect in Fe/Cr magnetic multilayers,[2] numerous magnetoresistance studies on a variety of multilayer systems have been reported.[3–9] In these experiments, the measuring current is in the plane of the multilayer, the so-called current-in-plane (CIP) geometry. The situation where the measuring current is perpendicular to the multilayer plane (the so-called CPP-geometry) has been studied more extensively theoretically[10–15] than experimentally. Up to now only two *experimental* groups reported on the CPP-MR in magnetic multilayers. The first experiments were done for Co/Ag and Co/Cu multilayers at Michigan State University.[16] In these experiments no microfabrication techniques were used; the multilayer was sandwiched between a superconducting Nb top and bottom contact electrode of millimeter size and the very small multilayer resistance (typically 0.01–0.1 $\mu\Omega$) was measured at 4.2 K using an ultra-sensitive SQUID-based system. This implies that measurements are only possible at liquid helium temperatures. Following another approach, we have used microstructuring techniques and fabricated Fe/Cr pillar structures, enabling us to study the CPP-MR effect from 4 K up to room temperature.[17] This experiment is not at all straightforward, primarily because the perpendicular resistance of a microstructured thin film generally is much smaller than the sheet resistance $R_\square$ of the contact leads. To overcome this problem, a specific contact geometry has been developed, which allows a proper measurement of the perpendicular resistance of a metal film without excessive spurious resistance contributions from the contact leads.[18] Our experiments provided the first data on the *temperature dependence* of the CPP-MR effect, which still represents a theoretical challenge. In particular the role of spin-flip scattering on the giant MR remains to be elucidated.

Here, we will discuss experiments on the temperature dependence of the CPP-MR[19] of microstructured Fe/Cr multilayers, grown · sputtering. These are compared with new experimental results on the CPP-MR of Co/Cu multilayers, grown by molecular beam epitaxy (MBE) evaporation. In Sec. II, we will discuss the growth and characterization of the multilayers followed by an outline of the microstructuring methods to fabricate the samples. Attention will also be given to finite element calculations of the current distribution pattern in the different sample geometries. In Sec. III, we present the CPP-MR results for the Fe/Cr and Co/Cu multilayers. The CPP-MR of typically 100% at low temperatures are a factor 2 to 4 larger than the corresponding CIP-MR. For Fe/Cr the CPP-MR decreases strongly on increasing the temperature, whereas experiments on Co/Cu show a much slower decrease. The different temperature dependence of Fe/Cr and Co/Cu can be related to the role of electron-magnon scattering in the two multilayer systems. Finally, in Sec. IV, conclusions will be formulated.

II. LAYER DEPOSITION AND MICROSTRUCTURING

In this section we will first discuss the deposition, characterization, and microstructuring of the Fe/Cr multilayers; second, for the Co/Cu multilayers, the MBE deposition and characterization is explained, whereas the microstructuring is practically the same as for the Fe/Cr layers.

The processing of a Fe/Cr pillar sample is schematically shown in Figs. 1(a)–1(d). First a 0.4 μm thick Cr base layer is rf sputtered onto a SiO_2 substrate held at room temperature. Then a 0.4-0.7 μm thick Fe/Cr multilayer is deposited, using dc sputtering for the Fe and rf sputtering for the Cr, followed by a dc sputter deposition of a 0.3 μm thick Au layer. The central part of the structure consists typically of a $100\times$(3 nm Fe + t_{Cr} Cr) multilayer with a variable Cr thickness t_{Cr}. All depositions were done during one vacuum run. The system pressure prior to deposition was 4×10^{-7} mbar and the Ar-pressure during sputtering was 4×10^{-3} mbar. X-ray diffraction shows predominantly (110) growth of the multilayer. For lithography the sample is covered by a 0.1 μm thick Mo layer, then by a 0.2 μm thick Al_2O_3 layer, followed by the deposition of another 0.1 μm thick Mo layer. The latter is structured using conventional lithography and using wet etching [Fig. 1(a)] and serves as a mask for the structuring of the Al_2O_3 layer, which is carried out in a CHF_3/Ar plasma (10 sccm CHF_3/40 sccm Ar, 25 μbar, 0.52

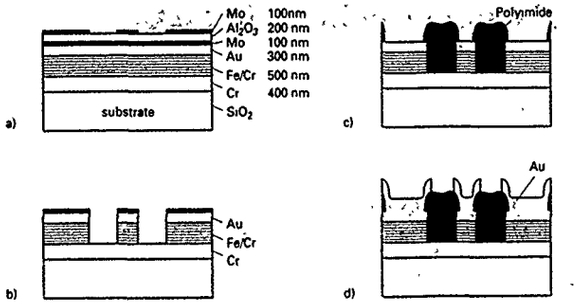

FIG. 1. Schematic diagram of different processing steps in the pillar structuring and contact fabrication.

W/cm^2). The structured Al_2O_3 layer in turn is used as a mask for the etching of the Au and the Fe/Cr multilayer; this is done in an HCl plasma (40 μbar, 2.1 W/cm^2) [Fig. 1(b)]. After removal of the remaining Al_2O_3, the sample is covered with an insulating polyimide layer. Contact holes in the polyimide are made using reactive ion etching, after which the remaining Mo in the hole is removed by wet etching [Fig. 1(c)]. Subsequently, the structure is covered by a 1.9 μm thick Au film, in which the contact electrode pattern is made [Fig. 1(d)]. The pillar in the middle is the actual sample; finally two Au contact leads are attached on top of it for the resistance measurement; also the side parts of the structure are contacted and serve as the lower contact leads for the pillar in the middle.

In Figs. 2(a)–2(d), microscopic images of the structure are shown. Figure 2(a) corresponds to the schematic diagram of Fig. 1(b) and shows the pillar after the structuring in the HCl-plasma. Figure 2(b) is a top view of the final structure, showing the upper Au contact structured on top of the hole in the polyimide layer. The upper and lower current contact is indicated by I^+ and I^-, respectively; the upper and lower voltage contact is indicated by V^+ and V^-, respectively.

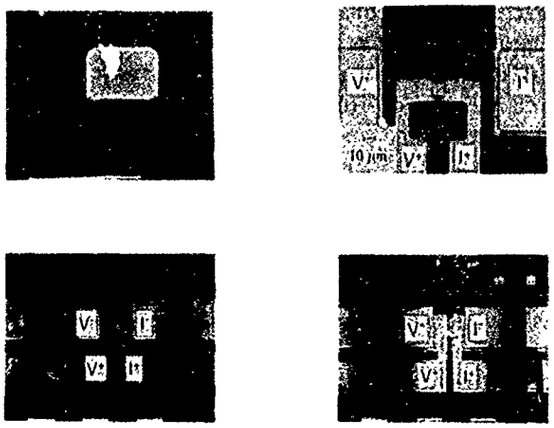

FIG. 2. (a) Micrograph of a pillar structure after the etching in the HCl plasma; (b) micrograph showing the upper Au electrode on top of the hole in the polyimide; upper and lower current contacts are indicated by I^+ and I^-, respectively; upper and lower voltage contacts are indicated by V^+ and V^-, respectively; (c) complete pillar device; (d) pillar device with additional laser trenches.

Figure 2(c) is an over-all view of the structure, as described so far, showing clearly the relative magnitude of the pillar with respect to the contact electrodes. Figure 2(d) is an improved measuring structure, which differs from Fig. 2(c) only by the presence of two trenches, etched down to the substrate using a Nd-YAG laser (532 nm). For the largest pillars fabricated on the substrate (width 10–12 μm), the trench ends at the edges of the pillar, so that the only connection between the two parts of the structure is established through the pillar. This trench plays a crucial role in the measurement of the Fe/Cr pillars, because it strongly reduces the spurious spreading resistance effect of the contact leads (particularly of the lower Cr electrode), which is necessary for a proper measurement of the very small perpendicular resistance (typically a few mΩ). The resistance of the structure without trench [Fig. 2(c)] is dominated by resistance contributions from the electrodes. The difference between the two measurement geometries can be well understood using the three dimensional simulation package TOSCA.[20] More specifically, electrostatic calculations, based on the finite element method, were done for a structure consisting of two 140×140 μm^2 square films with a thickness of 1.9 μm and 0.3 μm, respectively, centrally connected by a 4×4 μm^2 pillar with a height of 1 μm. This structure is schematically shown in Fig. 3(a); the location of the current and voltage contacts is indicated. The actual pillar in between the two contact layers is grey shaded. When a current is flowing from I^+ to I^-, we find equipotential lines in the 0.3 μm thick bottom electrode as shown in Fig. 3(b). Figure 3(c) is the corresponding vector plot of the electric field. The direction of the arrows corresponds to the direction of the field and their thickness to the field magnitude. It is clear that, between the voltage probes V^+ and V^-, a large spurious voltage contribution from the leads is present. For the simulated structure, we find, using contour integration, that only 3% of the totally measured voltage actually corresponds to a voltage drop over the perpendicular resistance. The structure *with* trenches is schematically shown in Fig. 3(d). Corresponding voltage and electric field plots of the lower contact electrode are given in Figs. 3(e) and 3(f), respectively. In Fig. 3(e) there is no voltage drop at all in the left voltage sensing electrode, which of course is equivalent to the locally zero electric field in Fig. 3(f). Having eliminated the electrode spreading resistance, the resistance of the multilayer pillar is still of the same order of magnitude as the residual serial contact resistance (probably located at the pillar-contact interface), which is determined experimentally by comparing different multilayer thicknesses. Also the pillar height is relatively small compared to its width w, which gives rise to a nonuniform current distribution in the pillar. Analytical calculation using Ohms law gives for the geometry with trench that $(V^+-V^-)w^2 \propto (w/L)/\sinh(w/L)$ with L a parameter of typically 2–3 μm.[21] This dependence was checked independently by numerical simulations based on the finite element method. In the following, quoted MR values for the Fe/Cr multilayers were corrected for the serial contact resistance and are extrapolations for $w \to 0$.

The fabrication of the Co/Cu multilayer pillars is similar to that of the Fe/Cr samples. However, it is well known that

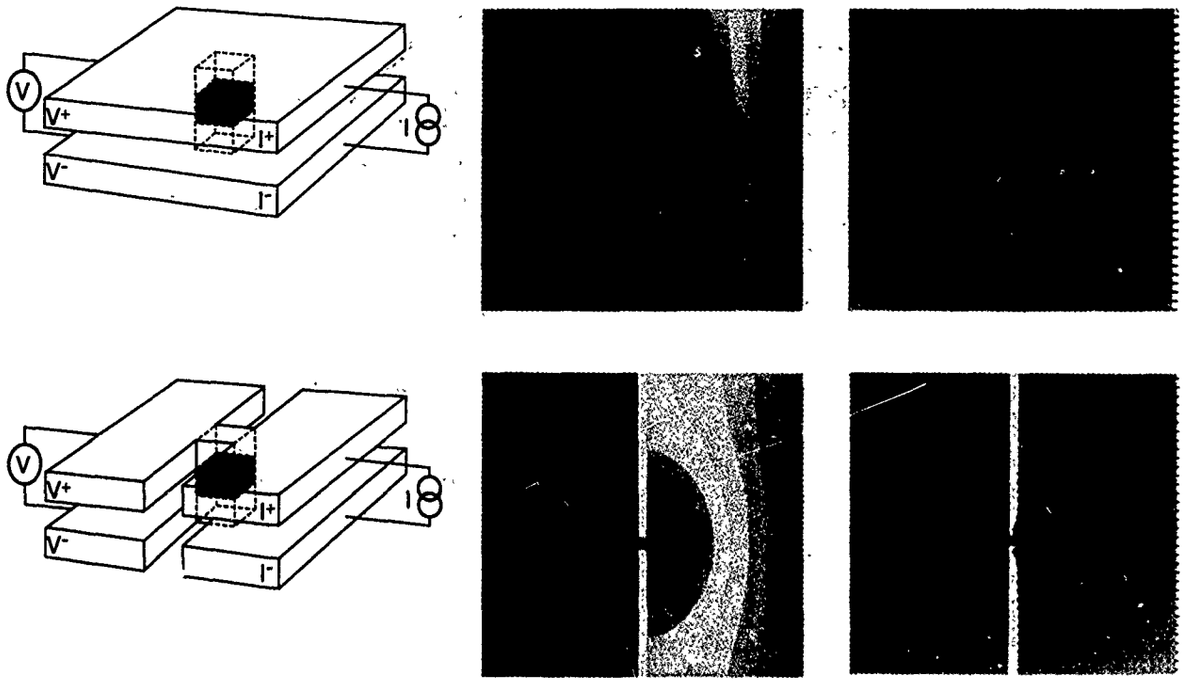

FIG. 3. (a) Schematic diagram of the simulated structure without trench. The actual pillar is grey shaded; current and voltage contacts are indicated. (b) Finite element calculation of the equipotential line distribution in the bottom electrode of a structure without trench. (c) Finite element calculation of the electric field modulus and vector plot of the electric field in the bottom electrode of a structure corresponding to a structure without trench. (d) Schematic diagram of the simulated structure with trench. The actual pillar is grey shaded; current and voltage contacts are indicated. (e) and (f): same as (b) and (c), but for a structure with laser-etched trenches. For each simulation the current drain is on the right and voltage probes are situated on the left.

the growth of AF coupled Co/Cu multilayers with large MR is very sensitive to, for instance, the choice of the substrate and the use of a buffer layer.[5] We have investigated Co/Cu(100) oriented layers. The multilayer stacks were prepared on single crystalline Si(100) substrates in a multichamber MBE system (VG Semicon V80M). Prior to introduction into the MBE system, the substrates were HF dipped, a procedure which resulted in a sharp low energy electron diffraction (LEED) pattern, characteristic of the Si(100) substrate. All depositions were carried out at room temperature, at a pressure of better than 10^{-10} mbar. The first stage of the multilayer stack involved deposition of a 300 nm Cu layer, later to be employed as the lower electric contact. A deposition rate of 0.053 nm/s, as registered by a calibrated quartz crystal thickness monitor, was used for the deposition. LEED analysis of the resulting Cu layer indicated that a clear (100) orientation was produced. Perpendicular and parallel lattice spacings have been determined kinematically by measuring the primary Bragg LEED reflections along the [0,0] rod, and by comparison of the LEED patterns with those of a Cu(100) single crystal. In both directions, the Cu layer displayed identical lattice spacings to that of a single crystal Cu(100). Subsequent deposition of the Co/Cu multilayer [250×(1.2 nm Co + 1.1 nm Cu)] with identical Cu rate and a Co deposition rate of 0.05 nm/s, maintained the (100) orientation established for the Cu base layer. The in-plane lattice spacing is, within experimental error, identical to the underlying Cu base layer, establishing the presence of coherent epitaxial growth. Quantification of the perpendicular lattice spacings of thin multilayers is not reliable within the kinematic approximation (due to multiple diffraction effects); the most probable scenario however being that the growth proceeds in an equivalent manner to that established by de Miguel *et al.*,[22] where Cu layers are observed to maintain their bulk perpendicular spacing (0.181 nm) and the Co layers contract in the perpendicular direction (to 0.170 nm) to accomodate the coherent in-plane expansion. X-ray diffraction studies revealed that the repeat period of the Co/Cu multilayer was (2.27±0.04) nm. The multilayer stack was completed with a deposition of 300 nm of Au (deposition rate 0.03 nm/s), to be used as the top electrical contact.

The microstructuring process of the Co/Cu layers is similar to that of Fe/Cr. The only difference is that, during the pillar etching in the HCl plasma, only 180 repeats of the Co/Cu bilayer are etched through, so that the lower 70 Co/Cu bilayers become part of the lower contact electrode. The reason for this is the extremely high etching rate of pure Cu in the HCl plasma, which makes the etching down to the last Co/Cu bilayer extremely critical. The quoted MR values for the Co/Cu multiayer are as-measured; the intrinsic MR effect might be larger, as the contribution of a serial pillar contact resistance so far could not be discriminated.

Typically, a few hundred pillars with a cross section S ranging between 6 μm^2 and 130 μm^2 are fabricated on one substrate for each multilayer composition, 15–20 different pillar structures of the same cross-section were measured to check reproducibility. After wire bonding, the samples are mounted in a ^{4}He flow cryostat. Pillar resistances are measured using an ac bridge technique in the 4–300 K temperature range and in fields up to 1600 kA/m (2 T).

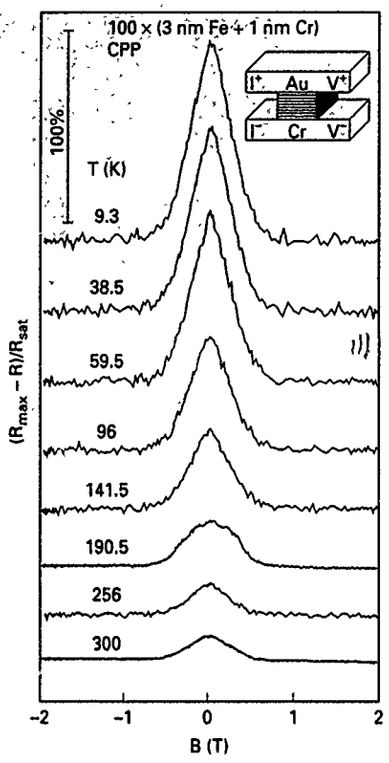

FIG. 4. Giant magnetoresistance of a microstructured pillar in a 100×(3 nm Fe + 1 nm Cr) multilayer with the current perpendicular to the multilayer plane (CPP) and as a function of temperature. The inset shows a schematic diagram of the pillar structure with the current and voltage contacts.

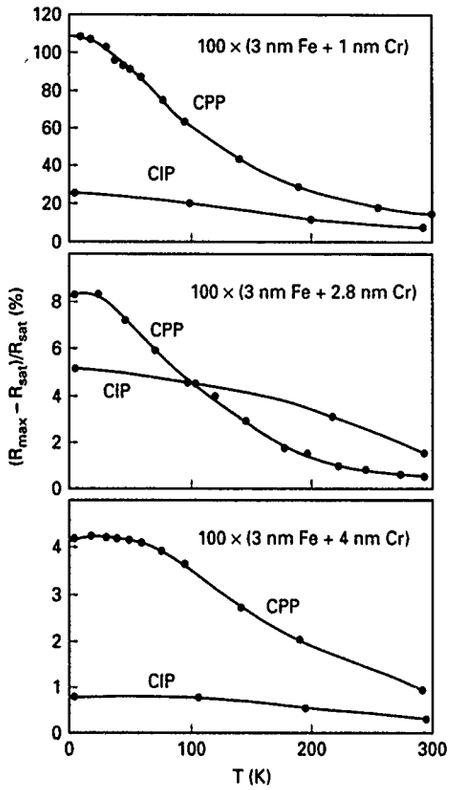

FIG. 5. Temperature dependence of the CPP-magnetoresistance of pillar structures made in 100×(3 nm Fe + t_{Cr} Cr) multilayers with (a) t_{Cr} = 1 nm, (b) t_{Cr} = 2.8 nm, and (c) t_{Cr} = 4 nm. Corresponding CIP-MR data are given for comparison. The full curves are a guide to the eye.

III. EXPERIMENTAL RESULTS AND DISCUSSION

Figure 4 shows CPP-MR curves at different temperatures for a Fe/Cr pillar with a cross-section $S = 90\ \mu m^2$ structured in a 100×(3 nm Fe + 1 nm Cr) multilayer; for clarity the curves are displaced vertically. At 9.3 K we observe a MR effect of 108%, more than four times higher than the corresponding CIP-MR effect in unstructured films.[8] The MR effect is weakly temperature dependent below about T=60 K; above that temperature the decrease is much stronger. At room temperature a 14% CPP-MR remains, two times larger than the corresponding CIP-MR. The saturation field $B_s(\equiv \mu_0 H_s)$ is defined by the crossing point of the low field resistance decrease with the horizontal line of constant resistance at higher fields. We find that B_s=0.54 T, nearly independent of temperature. This B_s-value corresponds with an interlayer exchange coupling energy per unit surface of 1.3 mJ/m^2 (see Ref. 8). Hence, the interlayer coupling energy is orders of magnitude larger than the thermal energy for our microstructures. This implies that the strong temperature dependence of the CPP-MR cannot be attributed to incomplete AF-coupling at higher temperatures. This was verified using temperature dependent magnetization measurements. In contrast to the structure of Fig. 4 with 1 nm Cr layer, we did find a hysteretic magnetoresistance for larger thicknesses, e.g., for the 100×(3 nm Fe + 4 nm Cr) sample. This seems very reasonable as, for this Cr-thickness, we do not expect perfect AF coupling anymore. Rather, one is in a weakly AF coupled/uncoupled situation, which is also confirmed by magnetization data for this sample.

In Figs. 5(a)–5(c) the temperature dependence of the CPP-MR is shown for multilayers with different t_{Cr}; a comparison is made with the corresponding CIP data.[8] Fig. 5(a) is for t_{Cr}= 1 nm and corresponds with the measurements presented in Fig. 4. The enlarged CPP-MR effect and its strong decrease with temperature is immediately clear. This decrease is also pronounced for the sample of Fig. 5(b) (t_{Cr}= 2.8 nm, a Cr thickness corresponding to the second AF coupled peak, and $S = 20\ \mu m^2$). Above about 100 K, the CPP-MR even becomes smaller than the CIP-MR. Presently it is hard to discriminate if this is an intrinsic effect or if this crossing of the curves arises from an excessive serial contact resistance for this CPP sample. In Fig. 5(c), the sample with t_{Cr}= 4 nm and $S = 6\ \mu m^2$ is shown. Again, we observe that the CPP-MR is enhanced with respect to the CIP-MR and that the temperature dependence is markedly stronger.

In Fig. 6 we present results on the temperature dependence of the CPP-MR of a 180×(1.2 nm Co + 1.1 nm Cu) (100) oriented multilayer grown by MBE evaporation ($S = 125\ \mu m^2$), compared with a CIP-MR reference experiment. The sample used for the CIP-experiment was grown on a 30 nm thick Cu buffer layer on a Si(100) substrate. For a Cu thickness of 1.1 nm, one is in the first AF coupling peak of the Co/Cu(100) system. The latter is characterized by a

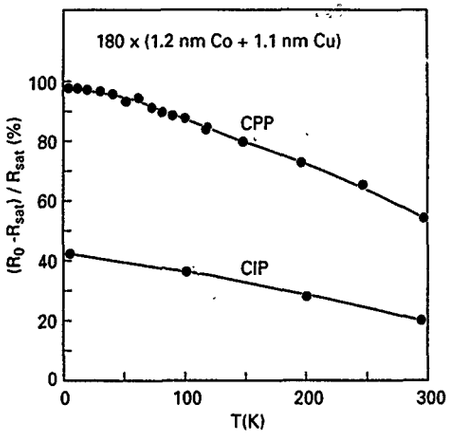

FIG. 6. Temperature dependence of the CPP-magnetoresistance of a Co/Cu(100) pillar structure made from a 180×(1.2 nm Co + 1.1 nm Cu) multilayer. Corresponding CIP-MR data are given for comparison. The full curves are a guide to the eye.

peak with maximum at 1.0 nm Cu and a width of 0.3 nm.[23] The CIP-MR is 43% at 4 K and 21% at room temperature. This last value is one third of the maximum MR, obtained for a 100% AF coupled (100) oriented Co/Cu multilayer,[24] similar to the results for (111) oriented Co/Cu multilayers.[5,25] Magnetization experiments indeed confirm that approximately one third of our CIP and CPP sample is AF coupled. Just as in the Fe/Cr case, the CPP-MR is larger than the CIP-MR: we find 98% at 4 K and 56% at room temperature. One should note again that these are as-measured numbers and hence represent minimum values for the intrinsic CPP-MR of Co/Cu(100).

The low temperature CPP-MR of Fe/Cr has been discussed elsewhere in terms of models based on spin-dependent bulk and interface scattering parameters.[8,26] Figures 5 and 6 show that an important difference between the CPP-MR of our Fe/Cr and Co/Cu multilayers is the temperature dependence. Physically, when increasing the temperature, spin-flip scattering due to thermally excited magnons equalizes the two spin currents (the classical spin-mixing effect) and also reduces the spin-flip diffusion length l_{sf}. The strong decrease with temperature of the Fe/Cr CPP-MR (a decrease by a factor of 5–7 over the temperature range studied) is indicative for strong electron-magnon scattering.[8] On the other hand, the Co/Cu CPP-MR decreases only by a factor 2. The weaker temperature dependence of the MR of Co/Cu multilayers with respect to that of Fe/Cr multilayers also is a general trend seen in CIP-MR experiments. The same holds for the anisotropic MR of bulk dilute alloys based on Fe or Co.[27,28] These observations may be related to the relatively large magnon scattering for Fe, which is a weak ferromagnet [spin-up (d↑) band not completely filled], resulting in an increased spin mixing at higher temperatures.

IV. CONCLUSIONS

We have discussed the fabrication and microstructuring of pillar-shaped structures of Fe/Cr sputtered multilayers and of Co/Cu MBE evaporated multilayers and studied the CPP-MR effect for these systems from 4 K up to room temperature. The CPP-MR is larger than the CIP-MR of similarly prepared reference samples, certainly at low temperature where electron-magnon scattering is minimum. The temperature dependence of the CPP-MR of Fe/Cr is much stronger than that of Co/Cu, which may be attributed to the different strength of electron-magnon scattering processes in both systems.

Spin polarization of gold films via transported (invited)

Mark Johnson
Bellcore, 331 Newman Springs Rd., Red Bank, New Jersey 07701

The spin injection technique has been adapted to a thin-film geometry. Measurements of the spin-coupled voltage V_s as a function of film thickness d result in a determination of the spin diffusion length $\delta_s = \sqrt{DT_1}$ with D the electron diffusion constant, in polycrystalline gold films. The conduction electron spin relaxation time T_1 is found to be $4.6\pm2.5\times10^{-11}$ s, for the temperature range 4 K$<T<$70 K. The magnitude of V_s is large enough to suggest device applications. In a three-terminal trilayer device, an electric current I_e biasing a thin permalloy film injects spin-polarized electrons into gold films of thickness 100 nm$\leq d\leq$5.1 μm, and induces a nonequilibrium magnetization $\tilde{M}$. A second permalloy film detects the bipolar, spin-coupled voltage $eV_s=\beta\tilde{M}/\chi$, where β is the Bohr magneton, χ the Pauli susceptibility and e the electron charge. The sign of V_s depends on the relative orientation of the magnetizations of the permalloy films. In the thin limit, $d<\delta_s$, the magnitude of the spin-coupled impedance $Z_s=V_s/I_e$ scales inversely with d. In the thick limit, $d>\delta_s$, Z_s is exponentially diminished.

I. INTRODUCTION

The spin injection effect[1] can be thought of in two parts. The first idea is that there is a relationship, at the interface between a ferromagnetic (F) and paramagnetic (P) metal, between a current of charges (an electric current I_e) and a current of magnetic dipoles (a magnetization current I_M). For example, an electric current driven from F to P will enter the latter with a net spin polarization. After Meservey *et al.*[2] showed that current tunneling out of a ferromagnetic electrode was spin polarized, Aronov[3] proposed the generalization that any transport current entering a nonmagnetic metal (or semiconductor) from a ferromagnetic metal would be polarized. The spin injection experiment[1] was the first empirical demonstration of this fact. Conversely and of equal importance, the presence of spin-polarized conduction electrons (equivalently a nonequilibrium magnetization $\tilde{M}$) in P has an effect on F. Under closed-circuit conditions, $\tilde{M}$ can generate electric currents, and under open circuit conditions it can alter the chemical potential of F. Silsbee[4] predicted this converse effect, called charge-spin coupling, and the spin injection experiment provided the first empirical proof of this as well. The second idea is that one can use charge-spin coupling to study details of conduction electron spin transport in the nonmagnetic material. For example, the experiments of Ref. 1 measured the spin relaxation time T_1 in bulk Al. Similarly, the value of T_1 reported herein for gold films is in agreement with the spin-orbit scattering time τ_{so} deduced by weak localization experiments, but is an order of magnitude longer than a theoretical estimate.

The original spin injection experiment used a four-probe, injection/detection scheme with a ferromagnetic current injector F1 and a ferromagnetic counterelectrode detector F2, fabricated on bulk samples. A constant current was driven into the sample in a steady state, and three method were utilized to demonstrate the ideas described above: (i) The axes of magnetization $\hat{M}_1$ and $\hat{M}_2$ of F1 and F2 were independently manipulated, causing changes in the detected voltage (or current); (ii) the distance between F1 and F2 was varied, resulting in a magnitude of the detected, spin-coupled signal that decreased as the interprobe distance increased; (iii) a transverse magnetic field was applied causing the spin-polarized electrons to precess, and resulting in a spin-coupled signal that varied as a function of external field.

In this article, the adaptation of the spin injection technique to a thin-film geometry[5] is presented. Once again, each of the three methods listed above has been used to demonstrate the validity of the spin injection ideas in this new geometry. The observed spin-coupled signals are so large that spin dynamics dominates over charge dynamics; the large magnitude of the effect may make it appropriate for device applications.[6] Finally, several samples have shown strong magnetic anisotropies. Because these anisotropies can affect implementation of the spin injection technique, examples are discussed.

II. CHARGE-SPIN COUPLING

The technique is conceptualized with the aid of Fig. 1.[1,5] Figure 1(a) depicts a cross-sectional view of a pedagogical, three-terminal device. Nonmagnetic metal film P (a Pauli paramagnet) is sandwiched between two ferromagnetic films F1 and F2. Each ferromagnetic film is a single domain, and

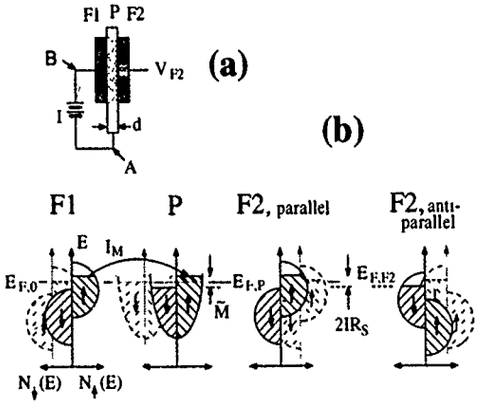

FIG. 1. (a) Pedagogical model of three-terminal device. Arrows in F1 and F2 refer to magnetization orientation as determined by majority spin subband. (b) Diagrams of the densities of state $N(E)$ as functions of energy E of the ferromagnet-paramagnet-ferromagnet system depicted in (a).

the axis of magnetization of each film, $\hat{M}_1$ and $\hat{M}_2$, lies in the plane of the film. For simplicity we consider the case where $\hat{M}_1$ points down and $\hat{M}_2$ points either down or up. A battery is connected as shown, and a third wire is attached to F2 and leads to a gedanken voltmeter, one which can read the voltage V_{F2} of F2 with a single input and does not need a ground.

Details of charge and spin transport, and of the effect of current transport on V_{F2}, can be understood by using the microscopic model depicted with density-of-state diagrams in Fig. 1(b). For the sake of simplicity this model has neglected the resistance of the films and of the interface between the films,[7] and it assumes there is no spin scattering at the interface itself. The diagrams have been drawn out of proportion to demonstrate the nonequilibrium effects. The faint diagrams in the background represent the state of the device when the switch is open. The ferromagnets are depicted in a band model where the majority spin subband lies entirely below the Fermi level. This would be appropriate, though oversimplified, for the $3d$ band, or a hybridized s-d band, of transition-metal ferromagnets such as Ni, Fe, Co, or an alloy such as Permalloy Ni_xFe_{1-x}. The paramagnet is represented with a free-electron model. With the switch open, the Fermi levels of the contiguous metals align with value $E_{F,0}$.

When the switch is closed, I_e is driven from F1 into P and returns back to the battery. However, current transport involves only electrons within a thermal energy range $E_F \pm k_B T$, where k_B is Boltzmann's constant and T is temperature. Since the down-spin subband is well below E_F, only the up-spin subband is available to carry the current. Thus, the electric current is spin polarized; it is a current of oriented magnetic dipoles, $I_M = \eta_1 \beta I_e/e$. Here η is a phenomenological parameter,[1] $\eta=(J_\uparrow - J_\downarrow)/(J_\uparrow + J_\downarrow)$, with $J_{\uparrow,\downarrow}$ the current densities of each spin subband, which describes the efficiency of spin transport. In the simplified model of Fig. 1(b) $\eta=1$, but more generally the magnitude of η can be diminished by current contributions from the other spin subband and $|\eta| \leq 1$. Conceptually, the ferromagnetic film F1 acts as a spin polarizer in a manner loosely analogous to a polarizing film for light, but with the important difference that conduction electrons move diffusively, in contradistinction with photons.

The thickness d of P is chosen to be less than a spin depth δ_s, the characteristic length over which an electron can diffuse before the orientation of its spin is randomized by scattering. In the vicinity of F1, in a steady-state process, polarized spins are constantly being added to P at a rate I_M, and the polarization is being lost because of random scattering at a rate $1/T_1$. As a result, a nonequilibrium magnetization builds up in P, $\tilde{M} = I_M T_1/Ad$, where A is the area of contact and Ad is the volume that the spins occupy in P. This is depicted in Fig. 1(b), where the net increase in occupation of the up-spin subband is offset by a decrease in occupation of the down-spin subband so that charge neutrality is preserved. In Fig. 1(a) the nonequilibrium spin magnetization is represented by the dotted "cloud" in P.

The rise in the up-spin subband chemical potential of P has an effect on F1: The chemical potential of F1 must rise so that the chemical potential of its up-spin subband aligns with that of P. If this did not occur, there would be a backflow of spin-polarized electrons from P to F1. In more precise terms,[7] there is a generalized thermodynamic force F_m associated with $\tilde{M}$ which acts to drive up spins back into F1. Because spin and charge are attached to the same carrier, the electron, this force also acts as an electrical impedance which appears as an interfacial resistance at the F1-P interface. Thus, a constant-current source encounters an extra, spin-coupled impedance which is labeled in the figure as Z_s and is calculated below. This can be pictured[8] as a "spin bottleneck:" The buildup of spins acts to impede the continued flow of spins (and therefore of electrons) into the region. It is important to note that charge-spin coupling occurs at the F1-P interface, and the effect has been observed[9] in a bilayer geometry (with F2 absent).

When $\hat{M}_1$ and $\hat{M}_2$ are parallel, the chemical potential of F2 rises so that its up-spin subband chemical potential aligns with that of P [$E_{F1,F2}$ in Fig. 1(b)]. If the floating probe to F2 were to be short circuited to ground, a current of upspins would be driven through F2 to ground. By imposing an open-circuit condition on the probe at F2, no current can flow and the chemical potential of F2 must rise by an amount eV_{F2}, where $V_{F2}=IZ_s$. Similarly, when $\hat{M}_1$ and $\hat{M}_2$ are antiparallel, the chemical potential of F2 must lower so that its down-spin chemical potential aligns with that of P. For orientations of $\hat{M}_1$ and $\hat{M}_2$ that vary between parallel and antiparallel, V_{F2} will vary as $V_{F2}=IZ_s \cos\theta$, where θ is the angle between $\hat{M}_1$ and $\hat{M}_2$. The change of chemical potential has been derived[1,4] to be $eV_s = \eta_2 \beta \tilde{M}/\chi$. Some physical insight can be gained by noting that $\tilde{M}/\chi$ has the units of magnetic field, and can be thought of as the effective magnetic field associated with the nonequilibrium spins. Then $\beta\tilde{M}/\chi$ is the effective Zeeman energy of a spin-polarized electron in the presence of the effective field of all of the other nonequilibrium spins (and is the source of the thermodynamic force F_m). Combining the above expressions for I_M, $\tilde{M}$, and V_s, and using a free-electron expression for susceptibility, $\chi=\beta^2 N(E_F)=\beta^2 3n/2E_F$, where n is the density of conduction electrons, one finds (for the case $d \ll \delta_s$)

$$Z_s = \frac{V_s}{I_e} = \frac{\eta_1 \eta_2}{e^2} \frac{T_1 E_F}{1.5nAd} = \eta_1 \eta_2 \frac{\rho \delta_s^2}{Ad} , \qquad (1)$$

where the second form has used an Einstein relation for the resistivity of the gold, $\rho = 1/e^2 DN(E_F)$. Note that V_s is expected to be linear with I_e and should have units of impedance, and that the magnitude of Z_s is inversely proportional to the sample dimensions A and d. This follows from the fact that $\tilde{M}$ has dimensions of magnetic dipoles per unit volume, so that a constant number of nonequilibrium spins will result in a larger value of $\tilde{M}$ when the volume is diminished. In addition, recall that Eq. (1) was derived for the thin limit case, $d < \delta_s$. The density of nonequilibrium spins decreases exponentially as a function of thickness, $\tilde{M} \propto e^{-d/\delta_s}$, so that a measurement of the diminished value of V_{F2} at thicknesses $d > \delta_s$ gives a direct measurement of δ_s.

In order to measure the floating voltage V_{F2} it is necessary to define a ground. A logical choice would be the base of P [point A in Fig. 1(a)]. With this choice, the bipolar voltage V_s will be superposed on top of the ohmic voltage

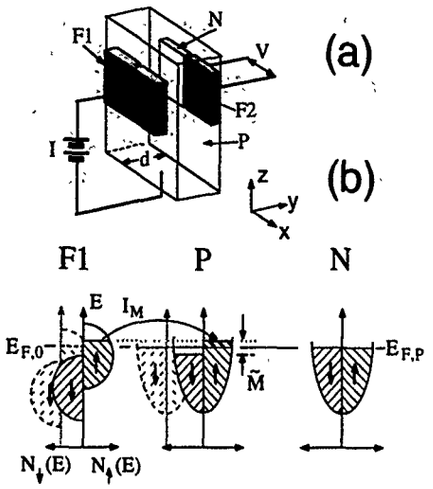

FIG. 2. (a) The geometry used to measure V_{F2}. P is depicted transparent. (b) Diagrams of the densities of state $N(E)$ showing how the chemical potential of N always align with the average chemical potential in P.

drop I_eR from the sheet resistance R of P. Data of this kind are presented below, but it is preferable to demonstrate directly the bipolarity of V_s. Although grounding to point B would be a suitable choice, the best method of grounding is depicted in Fig. 2(a): V_{F2} is measured with respect to a normal metal counterelectrode N whose chemical potential is always aligned with the average chemical potential of P [$E_{F,P}$ in Fig. 2(b)].

Next, it is necessary to manipulate the orientations of $\hat{M}_1$ and $\hat{M}_2$. Each film can be characterized by a coercivity $H_{c,i}$, and application of an external field H in the plane of the films will result in $\hat{M}_1$ and $\hat{M}_2$ traversing the hysteresis loops sketched in Fig. 3(a). When F1 and F2 are composed of the same material, the voltage V_{F2} is expected to be positive whenever the orientations $\hat{M}_i$ are aligned, and negative when antialigned [Fig. 3(b)]. This effect was demonstrated in the original spin injection experiment.[1] Since antiparallel orientation occurs only over the field range $H_{c,2}-H_{c,1}$ it is necessary to maximize this difference by fabricating films with differing values $H_{c,i}$. This can be achieved by using shape anisotropies, by using different materials for F1 and F2 (with intrinsically different coercivities), or by using anisotropies associated with the substrate or with deposition conditions. The effect of anisotropies on the qualitative characteristics of the signals is discussed in Sec. V.

III. EXPERIMENT

The samples were fabricated on sapphire substrates. The ferromagnetic films F1 and F2 of four samples were composed of Permalloy which was deposited in a vacuum of $\sim 10^{-6}$ Torr by e-beam evaporation from a single source of $Ni_{79}Fe_{21}$, and had thicknesses of 70 nm. A fifth sample used Permalloy for F1 and Co for F2. The coercivities of test films of Permalloy and Co were of order 10 G. The gold films were deposited by thermal evaporation from 5-9's gold after cleaning the Permalloy base electrode with an Ar-ion mill. The geometry was defined using photolithography and liftoff to create "windows" in insulating films of Al_2O_3. These windows had area $A=10^{-2}$ mm^2. The voltage measurements were made with two rf superconducting quantum interference device (SQUID)[10] amplifiers, and one of these was calibrated by measuring the resistance of a gold wire. This calibration also verified the polarity of the voltage measurements.

An example of data is shown in Fig. 4(a). The signals were linear with current, and the signal magnitude is given in units of impedance. Currents of typically 0.1–10 mA were used, and voltages of order 10^{-8}–10^{-7} V were recorded; the dynamic range of the SQUID voltmeters is 10^{-7} V and this was the only limit to the voltage magnitudes observed. The shape, width, and sign of the data of Fig. 4(a) conform to the expectations of a spin injection signal [Fig. 3(b)], and similar

signals were recorded for sweeps of magnetic field along $\hat{x}$ and $\hat{z}$ (i.e., sweeps in the plane of the films). Note that the signal is bipolar. The nonzero median is consistent with a slight asymmetry in the placement of the "windows" F2 and N [refer to Fig. 2(a)]. Because the coercivities of F1 and F2 are so close in value, the spin-coupled signal is observed only over a small range $H_{c,1}-H_{c,2}\approx 4$ G. The observed signals must represent a lower limit of the actual value of Z_s because it is impossible to know whether the films are completely antiparallel. Despite this possible source of error, the signals were quite reproducible, typically $\pm 25\%$, and consistent from sample to sample.

An example of a memory effect is shown in Fig. 4(b). Initially the external field was negative, and both $\hat{M}_1$ and $\hat{M}_2$ were oriented along $-\hat{H}$ [refer also to Fig. 3(a)]. An increasing field sweep is halted when the voltage begins to drop due to the realignment of one of the films in the vicinity of $H=+H_{c,1}$. Reversing the field sweep results in a low voltage value until this film reorients at $H=-H_{c,1}$, and the original voltage is recovered. Note the existence of two stable voltage states, associated with two stable magnetization states, at $H=0$. The fact that these two states differ by less than the full voltage dip $2IZ_s$ is probably because $H_{c,1}$ and $H_{c,2}$ are so close in value that F1 (or F2) had not completely flipped its orientation at the point where the external field sweep was reversed.

IV. QUANTITATIVE ANALYSIS

From Eq. (1) we see that the magnitude of Z_s is proportional to the parameters η and T_1. While η should be temperature independent, a simple picture of spin scattering in metals suggests that any scattering event has a small, constant probability a_s of flipping a spin, and therefore $T_1^{-1}\propto\tau^{-1}=a_s\tau^{-1}$, where τ is a scattering time derived from Matthiessen's rule. It follows that $Z_s\propto\tau$, and in this approximation $Z_s(T)$ should have the same temperature dependence as the electrical conductivity σ of the gold, which also is linearly proportional to τ. Figure 5(a) demonstrates the comparable temperature dependence of $Z_s(T)$ and $\sigma(T)$ over the experimental range 4 K$<T<$70 K.

The expression in Eq. (1) predicts that the product Z_sAd should be constant as a function of d, for thicknesses $d<\delta_s$. This scaling is demonstrated in Fig. 5(b), where the open symbols refer to comparable samples (F1 and F2 are both permalloy). It is interesting to note, in Fig. 5(b), that the resistance across the thickness of the 1.6-μm-thick film is about 1.3 $\mu\Omega$, somewhat smaller than the 3.5 ± 0.5 $\mu\Omega$ spin-coupled impedance, but of the same order of magnitude. However, the resistance across the gold film decreases linearly with decreasing thickness d whereas Z_s increases in proportion to $1/d$. Thus, at a thickness of about 100 nm the spin-coupled voltage is three to four orders of magnitude larger than the resistive voltage drop; spin dynamics dominate charge dynamics in this system.

The spin depth may be determined by fitting the data of Fig. 5(b) to Eq. (1) in the thin limit, $d<1$ μm, and to the thick limit form,[5] $Z_s=(\eta_1\eta_2\rho\delta_s/A)e^{-d/\delta_s}$, for $d>1$ μm. The best fit gives the result $\delta_s=1.5\pm 0.4$ μm. The spin relaxation time can be calculated from the expression $\delta_s=\sqrt{DT_1}\approx\sqrt{(v_F^2\tau/3)T_1}$, where v_F is the Fermi velocity. Using a Drude time for τ (and values of ρ measured on test strips) one finds, for the temperature range 4 K$<T<$70 K, $T_1=4.6\pm 2.5\times 10^{-11}$ s, and $a_{s,\mathrm{Au}}\approx 2\times 10^{-3}$.

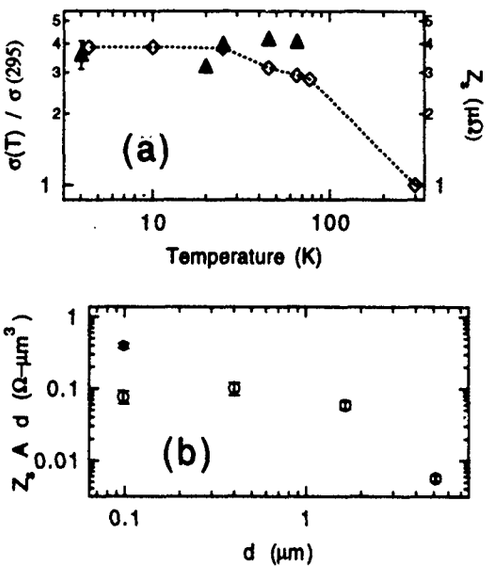

FIG. 5. (a) Comparison of $\sigma(T)$ (left-hand axis: ◇) with $Z_s(T)$ (right-hand axis; ▲) for $d=1.6$ μm sample. (b) Z_sAd as a function of d. Z_s is referred to the current through a single window. Open symbol: F1 and F2 are Permalloy; solid symbol: F2 is Co.

A comparison can now be made between the observed magnitude of the effect and that predicted by Eq. (1). Using the above value for T_1, the largest magnitude predicted, for the optimum value $|\eta|=1$, is $Z_sAd\approx 3\times 10^{-2}$ Ω μm^3. However, the signals in Permalloy-Au-Permalloy samples are about three times larger, and in the Permalloy-Au-Co sample it is about 12 times larger, than predicted by theory. I note that the theory has used a simplified expression for χ, and has neglected many-body effects. Furthermore, the discrepancy suggests the possible existence of a mechanism (such as Overhauser coupling to the nuclear spins or phonon trapping) that enhances the value of T_1 in the thin limit over that in the thick limit.

The theory of spin relaxation in metals implies that the spin-orbit interaction in gold should be the dominant spin scattering effect and predicts a high scattering probability[11] $a_{s,\mathrm{Au}}=5\times 10^{-2}$. The observed probability $a_{s,\mathrm{Au}}=2\times 10^{-3}$ is significantly smaller than expected, but is in good agreement with weak localization studies[12] of gold films which have measured a ratio $\tau/\tau_{so}=8\times 10^{-3}$, where τ_{so} is the spin-orbit scattering time. I note that τ_{so} is not identically the same as T_1, though T_1 should approach τ_{so} in the limit of strong spin-orbit interactions.

The surprisingly long value measured for T_1 is intriguing, and experiments were performed on Nb samples in an effort to further test this result. Niobium was chosen because its resistivity is about ten times greater than gold (τ is ten times smaller), but the atomic number is smaller so the spin-orbit effect should be less important. The magnitude of the product Z_sAd for Nb was two to four times larger than for

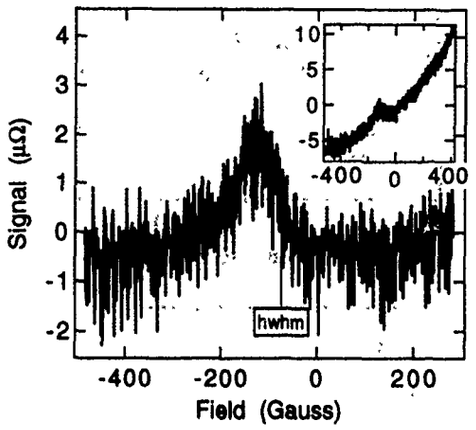

FIG. 6. Field sweep along $\hat{y}$ axis of Nb sample with $d=940$ nm showing a feature with characteristics of a Hanle effect. The half-width at half-maximum (HWHM) is marked. Inset: raw data. The sloped baseline probably results from $\hat{M}_1$ and/or $\hat{M}_2$ tipping out of the film plane.

Au. Data for five samples were quantitatively analyzed (using $\eta=2$, as deduced herein for Permalloy-Au-Permalloy structures)[13] to deduce T_1, finding a value ranging from 4.8 to 6.3×10^{-10} s for four thin samples, each with residual resistivity ratio (RRR) of about 2, and $T_1=1.4\times10^{-9}$ s for a thick sample ($d_{Nb}=940$ nm, RRR$\approx$4). A corroborating measurement of T_1 was made on the thick sample by applying a magnetic field along $\hat{y}$, transverse to the plane of the injected spin polarization. A feature appeared (Fig. 6) whose characteristics were consistent with a Hanle effect,[1] and had a half-width at half-maximum $1/\gamma T_2\approx70$ G corresponding to $T_2=7\times10^{-10}$ s, in fair agreement with the value of T_1 deduced from the amplitude.[14] This value of T_1 agrees with the limit $T_1>10^{-11}$ s established by transmission electron-spin-resonance (TESR) studies of Cu-Nb bilayers,[15] and corresponds to a spin-flip probability of about $a_{Nb}\sim2\times10^{-5}$.

In summary, all deduced values of T_1 are surprisingly long but reasonable, and values of η are enhanced above their theoretically limiting value of 1 by factors of 2–6. The observations $a_{Nb}\ll a_{Au}$ is qualitatively consistent with the idea that spin-orbit interactions contribute to spin scattering, but the value of T_1 measured in Au is longer than a spin-orbit calculation predicts.

V. EFFECT OF MAGNETIC ANISOTROPIES

Many samples (particularly Nb) have exhibited strong magnetic anisotropies (easy and hard axes of magnetization of F1 and F2). Because of the importance of manipulating $\hat{M}_i$ in implementing the spin injection technique, examples of these anisotropies, and their qualitative effect on the spin coupled signal, are briefly discussed. Data which imply that both F1 and F2 have an easy magnetization axis along $\hat{z}$ and a hard axis along $\hat{x}$ are shown in Fig. 7(a), and can be interpreted in the following way. The dotted trace was taken sweeping H down along the $\hat{z}$ axis over a large field range. In these experiments the detector ground was downstream from the injector [point A in Fig. 1(a)], so the bipolar spin-coupled signal is superposed on the ohmic resistance of a portion of the Nb film, $R\approx42.7$ mΩ. The changing orientation of $\hat{M}_1$ and $\hat{M}_2$ is modeled with the arrows at the top of the figure. These arrows correspond to the overall sequence of changes of $\hat{M}_1$ and $\hat{M}_2$; the location of any pair of arrows is not intended to be associated with the corresponding field value.

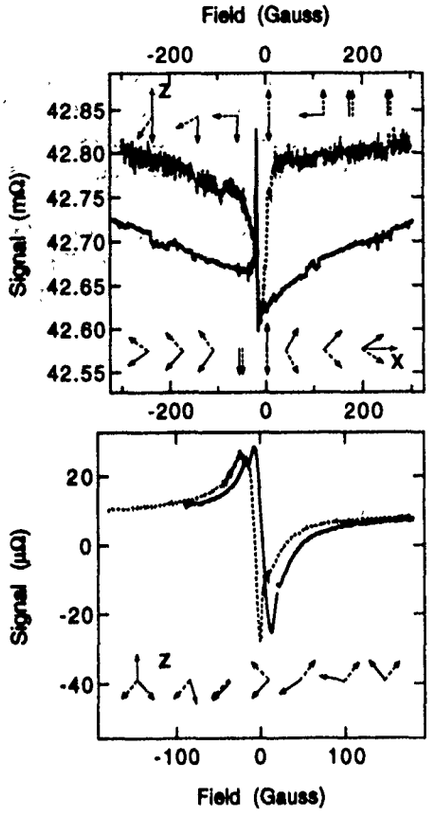

FIG. 7. Examples of magnetic anisotropies (easy and hard magnetization axes) in Nb samples. (a) Geometry with V_{F2} grounded at point A of Fig. 1(a). Dotted line: sweeping field down along $\hat{z}$; solid line: sweeping field down along $\hat{x}$. (b) Example of anisotropy axes oriented about 45° to sample axes. Field sweeps along $\hat{x}$ and $\hat{z}$ had qualitatively similar shapes. Here, sweep is along $\hat{z}$. Geometry of Fig. 2(a). An offset of 205 $\mu\Omega$ results from imperfect window alignment and has been subtracted from the baseline. Solid line: sweeping up in field; dotted line: sweeping down.

The solid trace was taken sweeping H down along the $\hat{x}$ axis. Values of the baseline resistance (at ±300 G) were confirmed using dc I-V measurements. Beginning at the right, an applied field of 300 G is insufficient to orient $\hat{M}_1$ and $\hat{M}_2$ along $\hat{x}$, their hard axis; $\hat{M}_1$ ($\hat{M}_2$) is oriented about ±35° relative to $+\hat{x}$ [refer to the arrows at the bottom of Fig. 7(a), which represent the sequence of changes of $\hat{M}_1$ and $\hat{M}_2$] and V_s is small. As H_x is diminished, $\hat{M}_1$ and $\hat{M}_2$ rotate further away from $\hat{x}$, in opposite directions, in order to align with their easy axis $\hat{z}$. When $\hat{M}_1$ and $\hat{M}_2$ are perpendicular $V_s=0$ (the measured signal is entirely from the spreading resistance, $R\approx42.7$ mΩ), and as θ opens up past 90°, V_s becomes negative. At about $H_x=-20$ G, $\hat{M}_1$ and $\hat{M}_2$ are both oriented along $\hat{z}$, in opposite directions, and V_s reaches its full negative value (corresponding to the signal minimum, $V=IR-|V_s|$). This is verified by comparison with the full negative value of V_s as measured by sweeping H along $\hat{z}$, i.e., comparison with the minimum value of the dotted curve. Once oriented along $\hat{z}$ it is easy for $\hat{M}_1$ and $\hat{M}_2$ to flip by

180°. The orientation of $\hat{M}_1$ flips at a slightly different value than that of $\hat{M}_2$ so that for a small field range, $H_x \approx -22 \pm 2$ G, $\hat{M}_1$ and $\hat{M}_2$ are parallel and V_s reaches its full positive value (compare with the signal maximum, as determined by the $\hat{z}$ sweep). As H is further increased along $-\hat{x}$, $\hat{M}_1$ and $\hat{M}_2$ rotate away from $\hat{z}$ to an orientation nearly perpendicular, and again the contribution to the signal provided by V_s is nearly zero. Further increasing H along $-\hat{x}$ gradually pulls $\hat{M}_1$ and $\hat{M}_2$ into closer alignment along $-\hat{x}$ and V_s gradually increases. This interpretation relies on two reasonable assumptions, as follows.

(i) The field axes are not exactly aligned with the anisotropy axes. Thus, a field H_x $(-H_x)$ has a small component $H_{z'}$ $(-H_{z'})$ along the easy axis of F1 causing $\hat{M}_1$ to flip near $H_x = 0$. In one sample, the field axes were oriented about 45° with respect to the sample axes [refer to Fig. 7(b)], supporting the assumption that the field and anisotropy axes need not be well aligned.

(ii) F1 and F2 are weakly coupled by magnetostatics, so that stray fields from the edges of F1 induce the orientation of $\hat{M}_2$ to be antiparallel with that of F1. The effect of weak coupling will be to result in the flip of $\hat{M}_2$ (along $\hat{z}$) following that of $\hat{M}_1$.

A systematic study of transport and magnetic properties of polycrystalline $Sm_{2-x}Ce_xCuO_{4-y}$ ($0.15 \leqslant x \leqslant 0.18$) specimens obtained from a sol-gel precursor reveals a striking double resistive superconducting transition. One of the resistive transitions takes place at a temperature T_{ci} and is almost insensitive to Ce concentration, applied magnetic field, and current density, while the other transition occurs at a lower temperature T_{cj} and is very sensitive to Ce content, applied magnetic field, and current density. Alternating-current magnetic susceptibility χ_{ac} measurements reveal two interesting features. There is only one contribution to the diamagnetic signal below ~20 K, which is particularly evident in the resistive component χ'' of χ_{ac} where a peak at T_{cj} can be identified. The application of an applied magnetic field shifts the χ'' peak to lower temperatures and reveals a spin-glass-like behavior. All the results can be satisfactorily explained in terms of weakly linked Josephson junctions between small superconducting islands. The small islands have a superconducting transition at a higher temperature T_{ci}, and the long-range phase coherence is achieved through Josephson coupling at lower temperatures T_{cj}. All the results suggest a superconducting glass state in a disordered Josephson network.

The occurrence of the double resistive superconducting transition in polycrystalline samples of $Sm_{2-x}Ce_xCuO_{4-y}$ ($0.13 \leqslant x \leqslant 0.20$) (Refs. 1–4) opens up a wide area of investigation in these electron-doped superconductors. This behavior is easily seen in electrical resistivity $\rho(T)$ measurements which reveal two well-defined drops in $\rho(T)$ before the system attains the zero-resistance state.[1] The first drop, which occurs at an upper transition temperature T_{ci}, has been attributed to a genuine superconducting phase,[5] and a ~25% drop in the magnitude of $\rho(T)$ is often observed at T_{ci}. Below this temperature, it has been suggested that the sample is comprised of small superconducting islands embedded in a nonsuperconducting host, and $\rho(T)$ exhibits a well-defined plateau down to a lower transition temperature T_{cj}.[1,2] It is also believed that Josephson coupling develops at T_{cj}, and a second ~75% sharp drop in $\rho(T)$, culminating in the zero-resistance state, is frequently observed.[1,2,5] The above explanation involving small superconducting islands embedded in a nonsuperconducting host is useful in separating contributions from inter- and intragrain properties. One important point in such a separation is that both T_{ci} and T_{cj} can be controlled by means of Ce doping[1,2] or oxygen removal.[6] This provides the unique opportunity to investigate properties arising from both contributions individually: the genuine superconducting phase and the disordered Josephson-coupled network.

In this work, we will focus on additional properties of the disordered Josephson-coupled network shown in polycrystalline samples of $Sm_{2-x}Ce_xCuO_{4-y}$ ($0.15 \leqslant x \leqslant 0.18$) obtained from a sol-gel precursor. We found that all the samples exhibit a double resistive superconducting transition, suggesting an intrinsic property of these polycrystalline samples. From results of ac magnetic susceptibility measurements, the resistive χ'' component peaks only at the Josephson-coupling temperature T_{cj}, demonstrating that the superconductivity is confined to small islands within grains. In addition, a field dependence of the χ'' peak provides clear evidence that all these samples can be understood within a superconducting glass scenario.

Polycrystalline samples of $Sm_{2-x}Ce_xCuO_{4-y}$ ($0.15 \leqslant x \leqslant 0.18$) were prepared using the sol-gel route. Stoichiometric amounts of the nitrates $Sm(NO_3)_3 \cdot 6H_2O$, $(NH_4)_2Ce(NO_3)_6$, and $Cu(NO_3)3 \cdot 3H_2O$ were dissolved in ≈200 ml of water. A 50 mol % excess of citric acid was added to the solution until it was completely dissolved under stirring and low heating. Afterwards, excess ethylene glycol was added to the solution. Decomposition of nitrates and evolution of NO_2 occurred when the solution was placed on a hot plate and stirred magnetically, until the solution became colloidal. Thereafter, this solution was transferred to an alumina crucible and placed in a box furnace and the tempera-

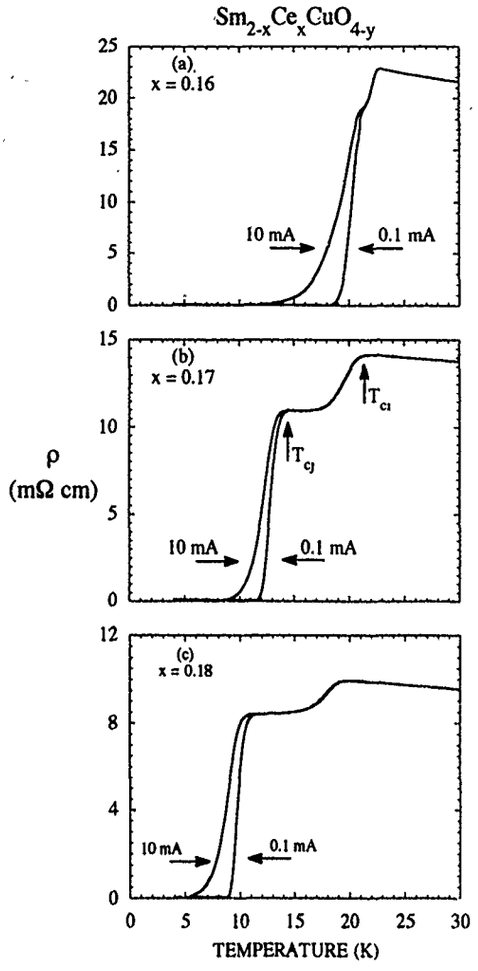

FIG. 1. Temperature dependence of electrical resistivity $\rho(T)$ for polycrystalline samples of $Sm_{2-x}Ce_xCuO_{4-y}$, (a) $x=0.16$, (b) $x=0.17$, and (c) $x=0.18$. The two transition temperature T_{ci} and T_{cj} are indicated. Excitation currents of 0.1 and 10 mA are also indicated in the figure.

ture raised to ~500 °C. At this temperature, the organic precursor partially decomposed into the simple oxides with consequent formation of a dark powder. The powder was sintered at 1000 °C for four days with intermediate grinding. A slight reduction of the oxygen is necessary to induce superconductivity in these compounds. Sample disks were placed in a ceramic boat in a tube furnace with flowing helium gas, and heated at a constant temperature of 950 °C for 20 h. The disks were split in two and then cooled to room temperature for either 1 or 2 h. Further details of this chemical route and the reduction processes employed for these samples are given elsewhere.[4] All samples were characterized by x-ray diffraction using Cu K_α radiation on a Rigaku RU-200B diffractometer and had no additional phases except for the $x=0.18$ sample, which had small amounts of a $Sm_{1-x}Ce_xO_y$ spurious phase.[7]

Electrical resistivity as a function of temperature, $\rho(T)$, was measured with a Linear Research LR-400 ac bridge operating at a frequency of 16 Hz. The excitation current could be adjusted over several orders of magnitude. Alternating-current magnetic susceptibility χ_{ac} measurements, made on bar-shaped samples, were performed with a mutual-inductance bridge operating at frequencies f in the range 17 Hz$\leq f\leq$5555 Hz and modulation fields H_m in the range 0.01 Oe$\leq H_m\leq$17 Oe. External dc magnetic fields were produced with a NbTi superconducting coil up to 35 kOe.

It is useful to begin this discussion with Fig. 1 which shows the temperature dependence of the electrical resistivity $\rho(T)$ of polycrystalline samples of $Sm_{2-x}Ce_xCuO_{4-y}$ ($0.16\leq x\leq 0.18$) with excitation currents of 0.1 and 10 mA. The first interesting feature of these curves is associated with the double resistive superconducting transitions where the electrical resistivity attains the zero-resistance state after two well-defined drops in $\rho(T)$. The double resistive superconducting transition persists even when samples are prepared through the sol-gel route, suggesting that it is an intrinsic property of these polycrystalline samples.[2,4]

Another point to be stressed here concerns the first drop in $\rho(T)$ at T_{ci}. As discussed elsewhere,[1] the transition at T_{ci} appears to be associated with a genuine superconducting phase and not, for example, a structural transition. One might also imagine that such a drop in $\rho(T)$ at T_{ci} could be due to a insulator-metal (I-M) transition as observed, for example, in $Nd_{2-x}Sr_xNiO_{4+y}$ (Ref. 8) and $PrNiO_3$ (Ref. 9). However, if there was an I-M transition at T_{ci}, the electrical transport data would be hysteretic due to the first-order signature of the I-M transition. This is not observed in our electrical resistivity measurements, suggesting that the transition observed at T_{ci} is really associated with a genuine superconducting phase. Figure 1 also provides information regarding the transition at T_{cj}. From excitation current dependences of resistive data, a broadening and shift of T_{cj} with increasing excitation current are always observed. Such behavior strongly suggests that Josephson weak coupling develops at T_{cj}, as already proposed elsewhere.[1,2,4,5]

Additional understanding of these polycrystalline samples can be obtained from $\chi_{ac}(T)$ data shown in Fig. 2. Here, both components of χ_{ac} for $Sm_{1.82}Ce_{0.18}CuO_{4-y}$ are plotted as a function of temperature for several applied magnetic fields. The first important feature revealed by these data is the total absence of a peak in the χ'' component at T_{ci}. There are several possible explanations for this. First, there may be an insufficient total grain volume which is consistent with a very low superconducting volume fraction.[1] It is also possible that the grain size, or more appropriately, the region where the order parameter is not depressed, may be of the order of the London penetration depth λ. On the other hand, it is also possible that all the grains have a shell-core morphology, in which the superconducting properties are confined to a thin shell that is evidently comparable to λ, as proposed elsewhere.[3,5] Two other candidates for explaining the absence of a peak in χ'' at T_{ci} are inconsistent with previous results in these samples: (1) that in very-high-quality grains H_{c1} may be very large just below T_{ci}; and (2) that in well-coupled systems, a small measuring field will cause the coupling peak to obscure the so-called intrinsic peak. In any event, the absence of the peak in χ'' at T_{ci} can be understood if there is a combination of insufficient total grain volume; i.e., a very low superconducting volume fraction,[1,3] and that superconducting properties are confined to small islands with size comparable to λ.[2,4] Thus, it is reasonable to assume that

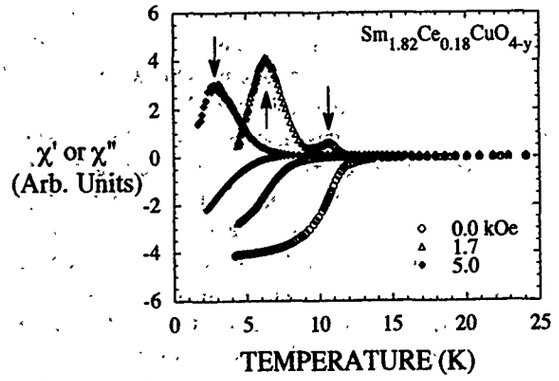

FIG. 2. Temperature dependence of the inductive and resistive components, χ' and χ'', of the ac magnetic susceptibility χ_{ac} for different applied magnetic fields in $Sm_{1.82}Ce_{0.18}CuO_{4-y}$. The modulation field was $H_m'=4$ Oe and the frequency was $f=15$ Hz. Arrows denote the temperatures of the peaks in χ''.

these polycrystalline samples are comprised of small superconducting islands, which are not necessarily the physical grains, linked by Josephson coupling.

Figure 2 also shows that the application of a magnetic field shifts the peak in χ'' at T_{cj} towards lower temperatures. Such a peak has been widely attributed to the so-called irreversibility line in these cuprates and often used for constructing magnetic-field temperature phase diagrams. However, for the samples studied here, the peak in χ'' occurs at the Josephson coupling temperature T_{cj}, which is well below the intrinsic critical temperature T_{ci}. In such a scenario, it seems to be reasonable to associate the peak in χ'' with a transition in the Josephson coupling and its dependence on applied magnetic field to a phase diagram of a disordered Josephson array.[2,5]

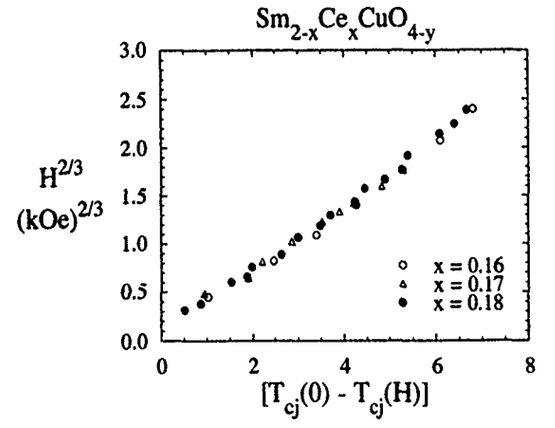

FIG. 3. Magnetic field $H^{2/3}$ against the reduced Josephson-coupling temperature $T_{cj}(0)-T_{cj}(H)$. $T_{cj}(0)$ is defined as the temperature at which χ'' peaks in zero applied magnetic field. A linear behavior suggests a quasi-de Almeida–Thouless line, characteristic of a superconducting glass state in a disordered Josephson array.

Values of $T_{cj}(H)$ were extracted from curves similar to those shown in Fig. 2 and used to construct the $H^{2/3}$-vs-$[T_{cj}(0)-T_{cj}(H)]$ plots shown in Fig. 3. It can be seen that, in the low-field regime, the Josephson-coupling temperature displays the expected behavior of a disordered Josephson array, i.e., a quasi-de Almeida–Thouless behavior. This was proposed by Ebner and Stroud[10] in their pioneering studies in granular superconductors and recently discussed in Ref. 11. Such an experimental result obtained in polycrystalline samples, where T_{ci} is well separated from T_{cj}, strongly suggests that contributions from the disordered array are predominant in the low-field regime, revealing the so-called superconducting glass state in a disordered Josephson array.[2] In this scenario, one would also expect that contributions arising from the genuine superconducting phase would dominate at higher fields. This is because with increasing field all the superconducting properties of the genuine phase are expected to be strongly field dependent, inducing a crossover in the H-vs-T phase diagram. This point is now being explored.

In summary, from the temperature dependence of the χ'' peak in polycrystalline samples of $Sm_{2-x}Ce_xCuO_{4-y}$ ($0.16\leqslant x\leqslant 0.18$), we found evidence that these systems are comprised of small superconducting islands surrounded by Josephson junctions. The application of an applied magnetic field shifts the peak towards lower temperatures and an appropriate H-vs-T phase diagram reveals that these samples can be understood in analogy with granular superconductors. Arguments for a superconducting glass state in a disordered Josephson junction array have also been proposed.

We report the results obtained by x-ray, dc magnetization, ac magnetic susceptibility, microwave magnetic absorption, and electron paramagnetic resonance of the magnetic and superconductive properties of a large series of compounds of the form $A_{2-x-y}B_xCe_yCuO_4$ with $A,B \equiv$La, Pr, Nd, Sm, Eu, Gd, and Y. For $y=0$ antiferromagnetic ordering of the copper moments is present at $T_N \approx 280$ K for all the compounds formed in the tetragonal T' phase. Weak ferromagnetism (WF) associated with the canting of the copper moments is observed in all the compounds with a lattice parameter, $a<a_0$, $a_0 \approx 3.91$ Å, regardless of the rare-earth (R) ions present in the system. Superconductivity is observed only in the Ce-doped compounds with $a>a_1$, $a_1 \approx 3.92$ Å. The maximum onset temperature T_c is found for $a \approx 3.95$ Å. A phase diagram was obtained by varying the lattice parameter size as a function of A, B, and x. The correlation between the appearance of WF in the undoped compounds and the disappearance of superconductivity in the Ce-doped systems is discussed.

The R_2CuO_4 ($R \equiv$Pr, Nd, Sm, Eu, Gd) compounds form in the so-called T' phase, where the Cu is in a fourfold coordination, with no apical oxygen.[1] We report here detailed studies on powder samples of $A_{2-x}B_xCuO_4$ and $A_{1.85-x}B_xCe_{0.15}CuO_4$ with $A,B \equiv$Pr, Nd, Sm, Eu, Gd, La, Y. Antiferromagnetic (AF) ordering of Cu is observed in the undoped R_2CuO_4 compounds below ~280 K.[2] A weak ferromagnetism (WF) component due to the canting of the Cu moments in the xy plane is present in compounds containing rare earths with smaller radii.[2-4] The size boundary between WF and perfect AF in R_2CuO_4 compounds occurs near that of Eu_2CuO_4.[2,3] It has been proposed that WF is associated with displacements of the oxygen ions in the CuO_2 planes.[4-6] These displacements lower the symmetry from tetragonal to orthorhombic at the rare-earth site for compounds with lattice parameter a smaller than ~3.91 Å.[2-6] Thus, the existence of an antisymmetric exchange interaction of the Dzyaloshinski-Moriya type becomes possible for these compounds. Such a term is not compatible with tetragonal symmetry. Also, a critical value for the in-plane Cu—O distance seems necessary for these systems to become superconductors.[7] In this paper we present results of x-ray powder diffraction, dc magnetization, ac susceptibility, microwave absorption, and electron paramagnetic resonance (EPR) with the purpose of finding a relationship between WF, superconductivity (SC), and Cu—O bond length.

Ceramic samples were prepared as follows: (i) The lanthanide oxides were dried in air at 900 °C. (ii) Specific stoichiometric amounts of Ln_2O_3 and CuO were mixed and reacted at 900 °C for about 24 h in alumina crucibles. (iii) The mixture was ground and sintered at 1000 °C for about 1 h. This process was repeated several times. (iv) The mixtures were pressed into $\frac{3}{8}$-in. pellets at ~4 kbar, then placed in alumina crucibles and sintered in air for ~48 h at temperatures between 1050 and 1150 °C depending on the compound. To promote SC it is necessary to lower the oxidation state of Cu by doping with Ce or Th as well as to anneal the sample in a reducing atmosphere.[8] For that purpose the samples were reduced in argon or sealed in a quartz tube under a vacuum in the presence of an appropriate amount of Zr. The reducing time and temperature (T) were adjusted to obtain the best SC transition. We found that temperature was critical and it varied from ~800 to ~1050 °C for the different compounds studied. Phase purity and lattice parameters were determined by x-ray powder diffraction. EPR was used as a more sensitive technique to determine the presence of impurity phases such as R_2CuO_5, R_2O_3, etc. Such phases were detected by EPR in $Eu_{2-x}Y_xCuO_4$ and $Sm_{2-x}Y_xCuO_4$ for $x \geq 0.4$ and 0.5, respectively. WF and SC were measured by dc magnetization, ac susceptibility, and microwave absorption techniques.

In Fig. 1 ac susceptibility measurements for $Eu_{1.8}Y_{0.2}CuO_4$ are shown. Similar data were obtained by ac susceptibility, dc magnetization, and microwave absorption in all the systems studied with a lattice parameter $a<a_0$, $a_0 \approx 3.91$ Å. Microwave absorption is found to be the most sensitive technique to measure the onset of WF and SC in these compounds. In Fig. 2 we present a typical spectra taken with an EPR spectrometer in a WF compound. The data shown for $Sm_{2-x}Y_xCuO_4$ were taken at 9 GHz and 263 K; in

general, two signals are seen. One signal is a narrow line centered at zero field which corresponds to the rapid increase of dc magnetization and ac susceptibility for temperatures below the onset of WF.[2,9] A second signal, which in powder samples looks like a broad shoulder, appears at a field different from zero. The second signal is always observed if WF is present.[2] It is the first indication of WF found in pure Eu_2CuO_4 and by adding just 1% of Y, WF is also observed in $Eu_{1.99}Y_{0.01}CuO_4$ by dc magnetization and ac susceptibility. For the last system both lines are observed in spectra similar to that shown in Fig. 2. The narrow line is not a true spin resonance but a microwave absorption signal observed because of the unbalanced EPR bridge. The second signal is a true spin resonance line which is found in all the WF compounds and is caused by a weak ferromagnetic resonance mode of the Cu moments. An analysis of this WF mode has been published already.[9] In Fig. 3 we present the intensity of $d\chi''/dH$ as a function of temperature for $Sm_{2-x}Y_xCuO_4$ at different values of x. The onset, maximum, and general shape of the spectra do not change with x, but instead, the intensity of the signal increases with the concentration of Y. A similar behavior is observed for all the WF compounds where the average radii of the rare earth is reduced. At sufficiently high magnetic fields with $T<T_N$ the dc magnetization becomes linear, and when extrapolated back to zero an internal field H_i can be defined.[2] H_i increases with x in $Eu_{2-x}Y_xCuO_4$ and $Sm_{2-x}Y_xCuO_4$. The values obtained for H_i at the higher concentrations of Y are larger than the value measured for pure Gd_2CuO_4.[2] The lattice parameter a at the boundary between WF and perfect AF for some of the compounds studied is given in Table I. Figure 4 is a phase diagram for the undoped R_2CuO_4 systems and those doped with Ce=0.15, $R_{1.85}Ce_{0.15}CuO_4$. As mentioned above, the onset of WF is at ~280 K in the undoped materials. A value of the same order has been found for T_N by neutron diffraction for the compounds which do not show WF.[10] The lattice parameters given in Fig. 4 for Ce-doped compounds were measured in samples before oxygen reduction. Doping with Ce results in a contraction of the c axis and an expansion of the in-plane lattice parameter a.[7] Thus, doping with Ce possibly reduces the distortion of the CuO_2 plane. This may explain why $Eu_{1.85}Ce_{0.15}CuO_4$ becomes a superconductor, even though Eu_2CuO_4 shows, as discussed above, indications of incipient WF. The value of the onset temperature for WF is depressed with the increase of Ce concentration. For Ce =0.15, the onset of WF is found at ~160 K for $Eu_{1.65}Y_{0.2}Ce_{0.15}CuO_4$ and $Sm_{1.45}Y_{0.4}Ce_{0.15}CuO_4$, similar to the value obtained for $Gd_{1.85}Ce_{0.15}CuO_4$.[11]

For compounds close to the boundary, such as Gd_2CuO_4, x-ray measurements suggest an average T' phase with some displacement of the oxygen atoms. Long-range correlation seems to occur only within each CuO_2 plane.[12] As no super-

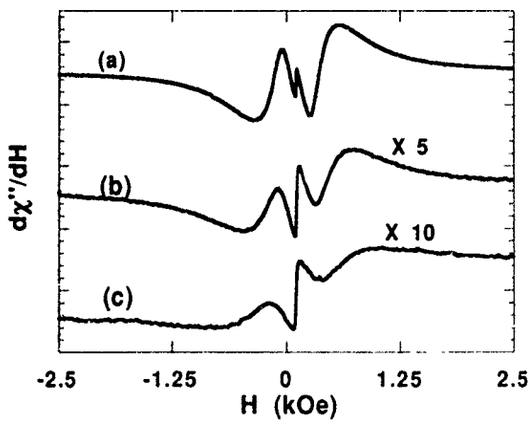

FIG. 2. Spectra for $Sm_{2-x}Y_xCuO_4$ measured at 9 GHz and 263 K, where (a), (b), and (c) correspond to $Sm_{1.4}Y_{0.6}CuO_4$, $Sm_{1.5}Y_{0.5}CuO_4$, and $Sm_{1.6}Y_{0.4}CuO_4$, respectively.

TABLE I. Lattice parameter a for the boundary between WF and perfect AF for some of the compounds studied.

Compound	a (Å)
$Eu_{1.99}Y_{0.01}CuO_4$	3.906
$Sm_{1.65}Y_{0.35}CuO_4$	3.906
$Gd_{1.00}Sm_{1.00}CuO_4$	3.904
$Gd_{1.30}Nd_{0.70}CuO_4$	3.908
$Gd_{1.60}La_{0.40}CuO_4$	3.910
$Gd_{1.55}Pr_{0.45}CuO_4$	3.906

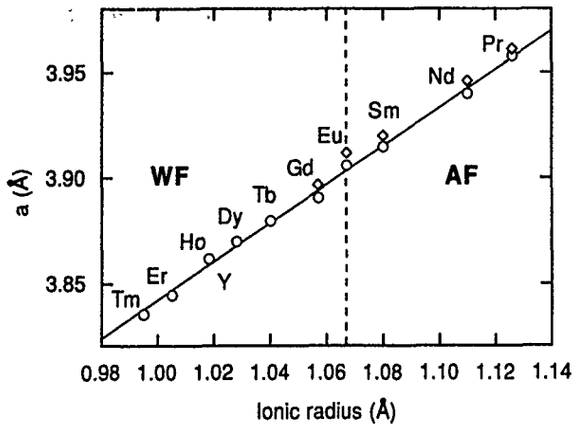

FIG. 4. In-plane lattice parameter a as a function of the ionic radius of the rare earth. The broken vertical line indicates the boundary between the WF compounds, which when doped with Ce do not show SC, and the AF compounds, which when doped become superconductors: (◇) doped, (○) undoped.

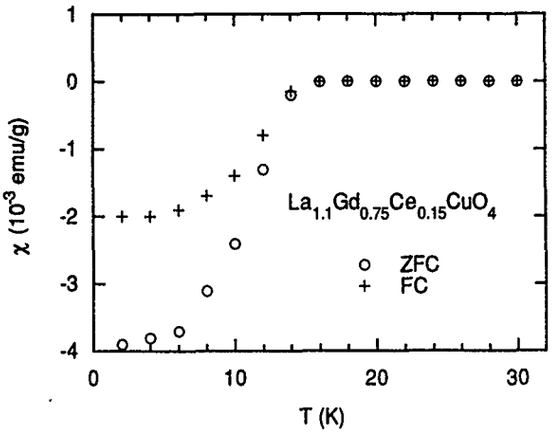

FIG. 5. dc susceptibility measured at 10 Oe on a powder sample of $La_{1.1}Gd_{0.75}Ce_{0.15}CuO_4$. The sample was reduced under vacuum in the presence of Zr.

structures are observed in Gd_2CuO_4 it appears clear that only short-range interplanar correlations could exist in systems close to the boundary. For these systems the average structure remains tetragonal, and the distortions from a perfect square in the CuO_2 plane are due to displacements of the oxygen atoms along the normal to the Cu—O bond. This distortion becomes larger as the size of the rare-earth ion becomes smaller. Electron paramagnetic resonance, x-ray, Mössbauer, and Raman techniques have confirmed this picture.[4–6,12] From those results it is also possible to conclude that the local symmetry at the R site is orthorhombic.[4–6,12] X-ray and Raman studies in systems with smaller R, such as Y_2CuO_4 and Tm_2CuO_4 which are farther from the WF-AF boundary, show extra peaks which may be associated with superstructures or a reduction in symmetry for those compounds.[6,12]

We were not able to induce superconductivity in any of the Ce-doped compounds which showed WF measurable by dc and ac susceptibility. We attempted to induce SC in them by reducing the samples as described above. In the Ce=0.15 doped compounds that we studied superconductivity was observed in the compounds which had a lattice parameter a larger than ~3.92 Å. The maximum value of T_c, ~20 K, was measured for compounds with an in-plane distance between the Cu ions of ~3.95 Å. Away from this optimum length T_c decreases, for smaller as well as larger values of a. In Fig. 5 we present data for $La_{1.1}Gd_{0.75}Ce_{0.15}CuO_4$ with a T_c~15 K and a~3.96 Å. Attempts to obtain SC samples with larger concentrations of Gd and smaller values of a were unsuccessful. We do not have an explanation for this.

In summary, we found that the presence or absence of WF and SC in the T'-phase R_2CuO_4 compounds is independent of whether the rare-earth ion is magnetic or not. In these compounds SC and WF seem to be definitively exclusive, i.e., the distortion from a perfect square in the CuO_2 plane seems to be incompatible with SC in these systems. A strong correlation between WF, SC, and the Cu—O bond length is observed. Values of ~3.91, ~3.92, and ~3.95 Å are the maximum, minimum, and optimum planar lattice parameters for the presence of WF, SC, and maximum T_c, respectively.

We wish to thank Professor R. Lilly, P. Lincoln, and M. Queen for their help. Alkali metals impurities influence on the magnetic and electrical properties of YBCO

I. Nedkov and A. Veneva
Institute of Electronics, Bulgarian Academy of Sciences, 72, Tzarigradsko Chaussee, 1784 Sofia, Bulgaria

The samples were prepared using the primary batch formula $Y_{1-0.2x}Ba_{2-0.2x}Cu_{3+0.3x}(Me)_{0.4x}O_y$, where $x=0-1.20$ and Me denotes alkali metals (Na, K, Rb) introduced as carbonates. The presence of alkali carbonates during the process allows one to influence the YBCO grain size and improve the homogeneity of the structure. Despite the large concentration range of additives in the initial batch after the second treatment at temperatures higher than 900 °C, only traces of the alkali metals were revealed. The influence of Na, K, and Rb impurities in concentrations for Na about 5×10^{-1} wt %; for K to 4×10^{-2} wt %, and Rb to 2×10^{-2} wt % in polycrystalline YBCO was investigated. For Rb and K, the $R(T)$ transitions were comparable to that of pure YBCO. The microwave surface resistance R_s was least influenced by the impurities, but strongly depended on the polycrystalline microstructure. Each impurity had a specific effect on $\chi(T)$ and J_c which are related to the grain-boundary structure.

I. INTRODUCTION

Investigating the influence of the different impurities on the magnetic and electrical high-temperature superconducting (HTSC) properties is of interest, as much for the understanding of the intragranular phenomena, as for solving technological problems. However, to our knowledge, only a few isolated papers have appeared on the alkali metals impurities in YBCO[1,2] and the data published are controversial. There have been reports on obtaining $T_c=135$ K in a YBCO system substituted with K.[3] It has been assumed that the effect of adding K is due to the formation of a KCu-compound participating indirectly in the YBCO-phase formation process.[2] Our recent work[4] showed that K_2CO_3 may be added to the initial batch in significant quantities without causing deterioration of the general HTSC properties; we also attributed this fact to the KCu-compound.

The aim of this work is to compare the HTSC properties of Na-, K-, and Rb-containing samples and to clarify the role of the excess of Cu when it is in quantity comparable with the alkali metal additive.

II. EXPERIMENTAL

The samples were prepared using the primary batch formula $Y_{1-0.2x}Ba_{2-0.2x}Cu_{3+0.3x}(Me)_{0.4x}O_y$, where $x=0-1.20$ which allowed us to have Cu excess in the initial batch and a comparable amount of an alkali metal (Me=Na, K, Rb). Attention was paid to the purity of the initial components: the basic content of Y_2O_3 was 99.99%; of $BaCO_3$, 99.99%, and CuO, 99.99%. The additives were introduced as alkali carbonates with high purity (more than 99.9 wt %). After preliminary baking of the batch at 900 °C, 1 μm grain-size powder was used to press pellets which were sintered a second time. The final temperature was different for each additive (from 900 to 980 °C for 50 h) and was selected using the differential thermal analysis (DTA) data. The single-phase YBCO ($x=0$), which we used for comparison with the doped system, was obtained via final sintering treatment consisting in baking at 980 °C for 60 h in oxygen atmosphere; its HTSC properties were close to the best quoted in the literature for polycrystalline untextured YBCO.

The phase content and polycrystalline microstructure were characterized using x-ray powder diffraction (XRD) and scanning electron microscopy (SEM) with x-ray microanalyzer (EPMA). The resistivity $R(T)$ transition was measured at liquid-nitrogen temperature using the standard four-probe technique (measuring current value 100 mA). The ac magnetic susceptibility $\chi(T)$ transition was followed using the contactless "pick-up coil" techniques (magnetic field 0–25 mT). To determine the critical current J_c and the surface resistance R_s (at 14.3 GHz) we developed our original equipment described in Ref. 5.

III. RESULTS AND DISCUSSION

Our investigation showed that the Na_2CO_3, K_2CO_3, and Rb_2CO_3 influence was well pronounced when the carbonates were in significant concentrations: for Na, $x=0.40$ (1.42 wt % Na_2CO_3) to 1.20 (4.37 wt % Na_2CO_3); for K, $x=0.40$ (2.38 wt % K_2CO_3) to 0.75 (4.49 wt % K_2CO_3), and for Rb, $x=0.20$ (2.57 wt % Rb_2CO_3) to 0.40 (5.07 wt % Rb_2CO_3). The cases of additives concentrations below these limits are well described in the literature.[1,2] When these ranges are exceeded, it is difficult to obtain reproducible single-phase samples with HTSC properties. Our investigation was, therefore, focused on the ranges of additives concentrations mentioned.

After the first heat treatment (900 °C/24 h) the YBCO phase was about 75 wt % and the XRD data showed (and SEM and EPMA confirmed it) that in samples with Na_2CO_3 and Rb_2CO_3 additives, Na_2O, Rb_2O, and CuO phases existed in the powder, while for the case of K_2CO_3, the analysis revealed the presence of a K_3CuO_2 phase.

Each additive had a specific influence on the final temperature of the second treatment compared with pure $Y_1Ba_2Cu_3O_y$—generally, the sintering temperature decreased. HTSC samples for Na ($x>0.4$) were obtained at 940 °C, for K ($x>0.4$) at 950 °C and for Rb ($x>0.2$) at 930 °C. The SEM and EPMA data indicated differences in the microstructure after the second treatment. For samples

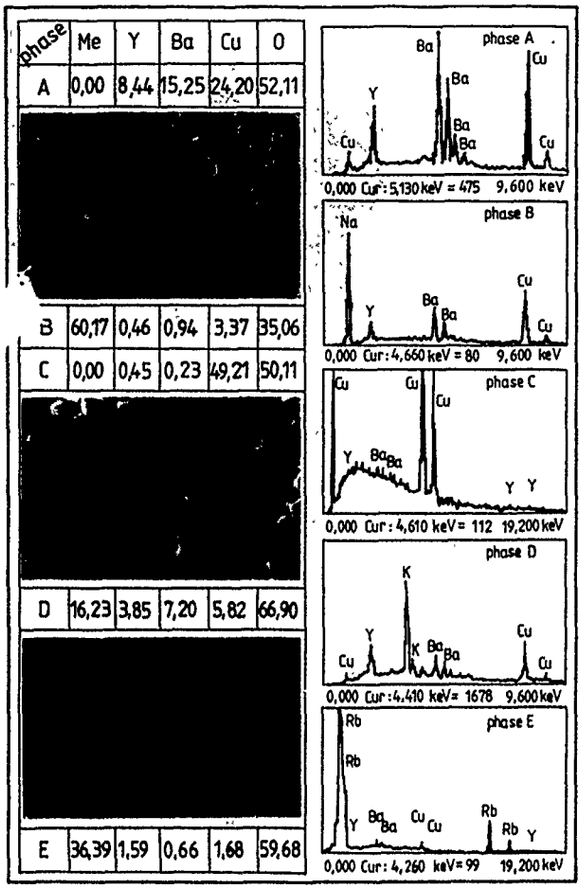

FIG. 1. SEM and EPMA data for Na-, K-, and Rb-doped samples—surface layer. The unit is at %.

with Na additive, CuO excess remained in the material as a second phase; from 2 to 5×10^{-1} wt % Na (Na_2O) was also found in the end product.

For the K_2CO_3 additive, the XRD and EPMA data revealed the existence of a K_3CuO_2 phase which evaporated above 900 °C and only traces of K were revealed on the surface of the samples. To explain the disappearance of the K and Cu excess from the samples above 950 °C, we analyzed our crucibles (made of Al_2O_3) after sintering. Atomic absorption spectroscopy (AAS) showed about 0.66 wt % of Cu in the crucible (as compared with 0.00024 wt % Cu in crucibles without sample) and 13.8 wt % of K in a crucible where a sample with $x=0.75$ (4.49 wt % K_2CO_3) was sintered.

The XRD, SEM, and EPMA data showed the existence of a glass-like Rb_2CO_3 phase at 840–890 °C. This made us suppose that alkali-containing liquid phases participate in the polycrystalline structure formation during the second treatment by enhancing the diffusion processes thus helping the CuO excess move to the surface. On the other hand, the alkali-containing phases evaporated above 900 °C. AAS study of crucible walls where the Rb doped with $x=0.4$ (5.07 wt % Rb_2CO_3) sample were baked indicated about 14.1 wt % of Rb.

Figure 1 illustrates typical surface structure and EPMA phase analysis. Five phases were identified in the specimens. For Na-doped samples: (A) with basic structure $Y_1Ba_2Cu_3O_y$ crystals, (B) dark—Na_2O, and (C) gray—CuO. For the K- and Rb-doped samples: (D) yellow—K_3CuO_2, (E) dark—Rb_2O, and (A) $Y_2Ba_2Cu_3O_y$ phase. The measurement accuracy of the EPMA method for metal ion analysis was 1%. The SEM studies proved that samples with K and Rb additives possessed a low-density surface layer and their thickness was about 200 μm. Their chemical content depended on the alkali carbonate added: according to the EPMA data for Rb-doped samples, the layer consisted of YBCO and Rb and Cu oxides; for K, we found K_3CuO_2 (see Fig. 1). When this layer was removed, the XRD showed that the basic structure was single-phase $Y_1Ba_2Cu_3O_y$. Atomic absorption spectroscopy (AAS) revealed only traces of the alkali additives: about 4×10^{-2} wt % K and 2×10^{-2} wt % Rb. To avoid the influence of the low-density layer, we polished the sample surface before the HTSC measurements.

We accumulated a large amount of data about the Rb, Na, and K additives influence on the HTSC properties in a wide concentration range. We present here the more characteristic results for comparable concentrations of alkali carbonates (mentioned above) to illustrate the influence of different impurities on the HTSC properties. The term "impurities" was chosen because only traces of alkali metals (4×10^{-2} wt % for K and Rb and 5×10^{-4} wt % for Na) were found after the second treatment and surface layer removal. The studies allowed us to assume that the K and Rb impurities are located at the grain boundaries. Despite the fact that insignificant amounts of the additives were found in the end product, differences could be seen in the magnetic and resistive behavior of the samples as illustrated by Figs. 2(a) and 2(b). In a large concentration range, the $R(T)$ superconducting transitions were similar and better (for Rb, the initial temperature was in the order of 94.6 K and for K 93.4 K) than those of pure YBCO. In Na-containing YBCO, the impurities (Na_2O and CuO) influence on the $R(T)$ was the most significant [see Fig. 2(a)].

Each impurity had a specific influence on the $\chi(T)$ dependence [see Fig. 2(b)]. The observed worsening of the $\chi(T)$ dependence in the case of Na doping is obviously related to the presence of nonsuperconducting (Na_2O and CuO) phases in considerable amounts. In the case of K_3CuO_2-containing boundaries ($x=0.75$ in the initial batch) we observed the best $\chi(T)$ transition with T_{end} as high as in pure YBCO, but ΔT was larger. The lower amount of Rb_2O impurities in the grain boundaries shifted the transition-onset temperature towards the lower temperatures. Rb- and K-doped samples with similar impurities concentration in the grain boundaries exhibited different $\chi(T)$ behavior. This confirmed the important role of the grain-boundary structure in influencing the $\chi(T)$.

To clarify the influence of the impurities, we investigated the parameters most sensitive to the grain structure, namely, J_c and R_s. Table I summarizes the data.

The microwave measurement showed that R_s depended weakly on the grain-boundary impurities, while being

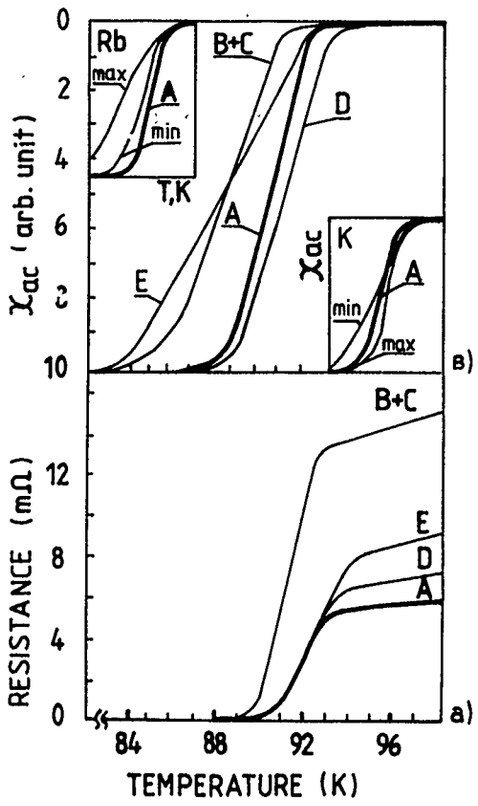

FIG. 2. (a) $R(T)$ transitions and (b) $\chi(T)$ transition for pure $Y_1Ba_2Cu_3O_y$. (A) compared with Na-, K-, and Rb-doped samples, where the basic phase is $Y_1Ba_2Cu_3O_y$ and impurity phases are (B), (C) Na_2O and CuO; (D) K_3CuO_2, and (E) Rb_2O are found.

strongly affected by the grain size and homogeneity. Using SEM photographs, we carried out a statistical analysis of the grain size in doped samples in comparison with pure YBCO polycrystalline structure. The YBCO grains had the specific shape of a parallelepiped. We compared the grains with different longitudinal and similar transverse dimensions and calculated the average longitudinal dimension. Figure 3 shows the grain-size distribution in doped and undoped samples. It is clear that adding Na_2CO_3 allowed us to obtain a polycrystalline structure with small average grain size and high homogeneity. These samples exhibited the best R_s, despite the low density of those with Na_2O and CuO phases, but J_c was about 40 A/cm^2. The K_2CO_3 additive kept the grain size relatively high which worsened R_s, but resulted in high homogeneity which was probably responsible for the good $R(T)$ transition data. We assumed, furthermore, that the

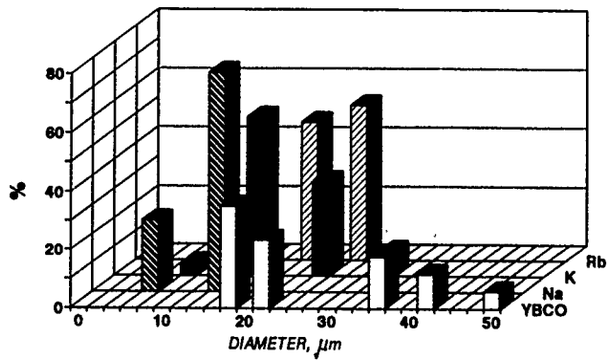

FIG. 3. The statistical analysis for grain-size distribution in polycrystalline YBCO obtained from initial batches include excesses from CuO and Na, K, and Rb carbonates in concentration about 4.5 wt %.

worse J_c in K-doped samples had to do with different grain-boundary structure.

We associated the influence of the Rb impurity on the microstructure and electrical properties with the existence of a liquid phase during the technological process which enhanced the recrystallization process. This impurity was most insignificant in the end product and only the $\chi(T)$ behavior was sensitive to its existence on the grain boundary. It is interesting to note that the samples density for Rb-containing samples was better in a larger range of concentrations and the best values of J_c and R_s were observed for this additive.

IV. CONCLUSIONS

The alkali additives react differently with CuO excess in the initial batch. Na_2CO_3 does not remove this excess; CuO and Na_2O phases remain disseminated in the entire sample. Rb_2CO_3 enhances the CuO diffusion towards the sample surface. The carbonate dissociates at 890 °C, with only traces of Rb_2O remaining as impurity at the grains boundaries after the second heat treatment. The K_2CO_3 reacts with the CuO excess and forms a KCu-compound which diffuses towards the surface and evaporates above 900 °C.

For Rb- and K-doped samples with similar impurities in the order of $2–4\times10^{-2}$ wt %, $R(T)$ transitions are comparable to the best one of pure YBCO. Each additive has a specific effect on $\chi(T)$ transition which is related to the grain-boundary phase structure. A lower quantity of Rb_2O leads to deterioration of the $\chi(T)$ transition and the same concentration of the KCu-compound improves T_{end} of YBCO.

The HTSC parameter most sensitive to the impurities is J_c. Only in the case of Rb, impurities at the grain boundaries in the order of 2×10^{-2} wt % virtually do not affect J_c. The experiments demonstrated that R_s is least influenced by the impurities, but strongly depends on the grains size and homogeneity.

Hubbard model of two layers of strongly correlated electrons with interlayer hopping is investigated. The temperature T_c of superconducting transition and magnetic suspectibility are calculated. The external pressure dependence of T_c is discussed.

I. INTRODUCTION[1]

Discovery of high-T_c layered perovskite compounds galvanized the theorists' interest to the role of interlayered coupling for superconductivity. In high-T_c cuprates it is noted that the influence of apical oxygen on T_c increases the throw and changes the effective interlayer hopping: the apical oxygen provides for the effective tunneling of electrons between copper cations in neighboring CuO_2 layers.

We have suggested the simplest Hubbard model of two layers of strongly correlated electrons with interlayer hopping integral τ:

$$H=-\sum_{ij\sigma} t_{ij}c^{+}_{i\sigma}c_{j\sigma}+I\sum_{i} n^{\uparrow}_{i}n^{\downarrow}_{i}-\mu\sum_{i}(n_i+n_i), \quad I=\infty, \tag{1}$$

where $t_{ij}=t$ if i and j belong to the same layer, and $t_{ij}=\tau$ if i and j belong to different layers.

The interlayer hopping decreases the normal ground state energy of the system. This hopping τ gives rise to the Van Hove singularity in initial rectangular density of states in the points $\pm 2\tau$. Density of states (DOS) has the following form:

$$\rho(\epsilon)=(2/t)K\left[\sqrt{1-\left(\frac{|\epsilon|+2\tau}{4t}\right)^2}\right], \tag{2}$$

where K is complete elliptic integral. We have calculated the concentration dependence of the kinetic and interaction energies of the given system. The energy of interaction has the following form:

$$E_{\text{int}}=\frac{n^2(1.5n-1)w}{2(2-n)}-(1.5-1)f(n,\tau), \tag{3}$$

where $f(n,\tau)<1$ is a positive function.

E_{int} acquires the negative sign at an electron concentration above $n=2/3$ per site which corresponds to the sign changing of Born amplitude of mutual (σ,σ) electron scattering.

II. SUPERCONDUCTIVITY

The superconducting transition was investigated in the framework of the kinematical high-T_c mechanism.[1,2] We have calculated the concentration dependence of superconducting transition temperature T_c. For example, when chemical potential $\mu<2\tau(1-n/2)-T_c$, T_c is as follows:

$$T_c=(1/2)[(2t+\tau)^2(2-n)^2-\mu^2]\times\exp\left(\frac{t(2-n)\mu}{[\tau^2(2-n)^2-\mu^2]}\right). \tag{4}$$

For $\tau=0$ the limiting case,[1] reproducing in Ref. 3 is obtained. Depending on the chemical potential position relative to the Van Hove singularities it is possible that the T_c increases with interlayer hopping integral τ.

We have also calculated the derivatives dT_c/dt and $dT_c/d\tau$ in connection with experimental investigations of baric derivatives of T_c.[4] It is significant that the variation of T_c with the bandwidth is connected with electron concentration as well. Assume that the system is coupled with a reservoir of electrons: it may be Cu-O chains or BiO, TlO layers in HTSC cuprates. From the equations on electron concentration in these systems

$$\begin{cases} n=\frac{1}{3}\rho\mu+\frac{2}{3} \text{ (for correlated electrons)},\\ n_r=\rho_r\mu_r+\frac{1}{2} \text{ (for noncorrelated electrons of reservoir)},\\ \mu=\mu_r, \end{cases} \tag{5}$$

we can see that electron concentration n depends on the densities of state ρ,ρ_r, which are determined by corresponding bandwidths. In Fig. 1 are shown the calculated derivatives of T_c. We can see from Fig. 1 that derivatives of T_c, with respect to the hoppings, can be negative as well as positive. This may explain a number of experiments in which different signs of baric derivatives were observed.[5]

III. MAGNETIC PROPERTIES

It is interesting to calculate the static magnetic spin susceptibility with DOS (2) which rises steeply in the points $\epsilon=\pm 2\tau$. It was approximated by

$$\rho(\epsilon)=\frac{A}{2}\left(\frac{w}{(\epsilon-2\tau)^2+w^2}+\frac{w}{(\epsilon+2\tau)^2+w^2}\right)\theta(w^2-\epsilon^2) \tag{6}$$

where $A=2/\pi$.

We used the general formula

$$\chi(T)=\frac{-2\int\rho(\epsilon)\,\frac{\delta}{\delta\epsilon}\,[n_F(\epsilon)]d\epsilon}{1-\int\rho(\epsilon)\,\frac{\delta}{\delta\epsilon}\,[\epsilon n_F(\epsilon)]d\epsilon} \tag{7}$$

and obtained the following expression of Curie–Weiss type:

$$\chi(T)\sim\frac{C}{T+\theta}, \tag{8}$$

where

$$C=\frac{8(1-n/2)^2}{3\pi^2},$$

$$\Theta=\frac{\tau^2}{\pi W}\,(2-n).$$

It must be emphasized that for rectangular DOS the $\chi(T)$ is essentially independent of temperature.

IV. CONCLUSION

The T_c dependence on electron concentration and magnetic spin susceptibility has been calculated for layered system of Eq. (1) type.

The calculated features of model (1) are responsive to the position of Van Hove peaks of the DOS. T_c increasing can occur for appropriate mutual positioning of the peak and chemical potential.

In relation to experiments on baric derivatives of T_c in layered high temperature superconductors we have noted also that the variation of charge carriers under pressure must be taken into account in the interpretation of these experiments. The DOS depends on external pressure and in turn

$$\frac{dT_c}{dt}=\frac{\partial T_c}{\partial t}+\frac{\partial T_c}{\partial n}\frac{\partial n}{\partial t}. \tag{9}$$

From the condition of equality of chemical potentials μ [cf. Eq. (5)] for superconducting electrons n and reservoir ones n_r it follows the dependence of electron concentration on external pressure.

Ground-state properties and excitations of an integrable one-dimensional model with δ-function interaction involving several bands

P. Schlottmann
Department of Physics, Florida State University, Tallahassee, Florida 32306

We consider an integrable model consisting of n parabolic bands of electrons of equal mass with a δ-function exchange interaction. The interaction is attractive or repulsive depending on whether the interacting particles are in a spin-singlet or triplet state. The structure of the Bethe ansatz and the classification of states is similar to that of the n-channel Kondo problem. The attractive interaction leads to Cooper-pair-like boundstates. Some ground-state properties and the excitation spectrum are discussed for the special situation of degenerate bands.

Several multiband models[1,2] have been proposed to explain properties of high-T_c compounds. In particular, the anomalous dependence of the Hall coefficient and T_c in $La_{2-x}Sr_xCuO_4$ and $Nd_{2-y}Ce_yCuO_4$ on doping has been attributed to an admixture of the $3d_{z^2}$ orbital.[3] This admixture is consistent with polarized x-ray absorption data.[3] Motivated by the possibility that both the $3d_{x^2-y^2}$ and $3d_{z^2}$ orbitals may play a role in high-T_c cuprates, we considered[2] an integrable model involving two one-dimensional bands separated by a crystalline field splitting, and a δ-function exchange interaction, which leads to singlet bound states of the Cooper type. In this paper we extend the results of Ref. 2 to an arbitrary number n of equal bands. The model is still integrable and the generalization to n bands changes the results of Ref. 2 only quantitatively (but not qualitatively). In addition, we discuss here the spectrum of elemental excitations. The Hamiltonian is

$$H=\sum_{m\sigma}\int dx\; c^{\dagger}_{m\sigma}(x)(-\partial^2/\partial x^2)c_{m\sigma}(x)$$
$$+c\sum_{mm'\sigma\sigma'}\int dx_1\int dx_2\,\delta(x_1-x_2)$$
$$\times c^{\dagger}_{m\sigma}(x_1)c^{\dagger}_{m'\sigma'}(x_2)c_{m'\sigma}(x_2)c_{m\sigma'}(x_1), \qquad (1)$$

where $m=1,\ldots,n$ labels the bands, and $c^{\dagger}_{m\sigma}(x)$ creates an electron of spin σ at the site x in the band m. Since the number of particles with up and down spin and the electrons in each band are conserved, it is straightforward to incorporate magnetic and crystalline field splittings between the bands. The interaction is an exchange, i.e., it depends on the spin and orbital indices. Electrons within the same band (and opposite spin) are attracted, while for electrons of equal spin but in different bands the interaction is repulsive. All the bands have equal mass; this is a necessary condition for the integrability of the model.

It is useful to study the two-particle problem first. The two-electron wave function can be written as a product of three factors: (i) a coordinate wave function referring to the positions and momenta, (ii) a spin wave function, and (iii) an orbital wave function involving the band labels m. The fermionic character mandates the global wave function to be antisymmetric under the exchange of the particles. Hence, if the spin and orbital wave functions have the same parity, the coordinate wavefunction has to be antisymmetric and vanishes if $x_1=x_2$, and the two particles cannot interact. Interacting fermions then necessarily form a spin singlet and orbital triplet (*attractive* interaction) or a spin triplet and orbital singlet (*repulsive* potential). The scattering matrix is the product of the spin and orbital scattering matrices,[2]

$$\hat{S}(k)=\frac{k\hat{I}_\sigma-ic\hat{P}_\sigma}{k-ic}\times\frac{k\hat{I}_m+ic\hat{P}_m}{k+ic}, \qquad (2)$$

where $\hat{I}_\sigma(\hat{I}_m)$ and $\hat{P}_\sigma(\hat{P}_m)$ are the identity and permutation operators for the spins (band indices), respectively, $k=k_1-k_2$, and k_1 and k_2 are the wave numbers. Note that each factor just yields one, when applied to the triplet state. Hence, (2) only acts on the (orbital or spin) singlet parts of the wave function. For the case of spin and orbital singlets the two phase factors cancel and there is no effective interaction. In summary, the orbital and spin spaces factorize. Since the scattering matrix for each channel (spin and orbital) satisfies the triangular Yang–Baxter relation,[4] their product also does and model (1) is integrable for any number of bands.

Each state of the Hamiltonian is specified by one set of N "charge" rapidities $\{k_j\}$, one set of M "spin" rapidities $\{\lambda_\alpha\}$ and $n-1$ sets of $m^{(l)}$ "orbital" rapidities $\{\xi^{(l)}_\alpha\}$, $l=1,\ldots,n-1$. Imposing periodic boundary conditions we obtain the discrete Bethe ansatz equations satisfied by the rapidities[2,4–7]

$$\exp(ik_jL)=\prod_{\alpha=1}^{M}e_1(k_j-\lambda_\alpha)\prod_{\beta=1}^{m^{(1)}}e_1(k_j-\xi^{(1)}_\beta),\quad j=1,\ldots,N,$$

$$\prod_{j=1}^{N}e_1(\lambda_\alpha-k_j)=-\prod_{\beta=1}^{M}e_2(\lambda_\alpha-\lambda_\beta),\quad \alpha=1,\ldots,M,$$

$$\prod_{\beta=1}^{m^{(l-1)}}e_1(\xi^{(l)}_\alpha-\xi^{(l-1)}_\beta)\prod_{\beta=1}^{m^{(l+1)}}e_1(\xi^{(l)}_\alpha-\xi^{(l+1)}_\beta)$$
$$=-\prod_{\beta=1}^{m^{(l)}}e_2(\xi^{(l)}_\alpha-\xi^{(l)}_\beta),\quad \alpha=1,\ldots,m^{(l)}, \qquad (3)$$

where $l=1,\ldots,n-1$, $\{k_j\}\equiv\{\xi^{(0)}_\alpha\}$, $m^{(n)}=0$, L is the length of the box, and $e_j(x)=(x-ijc/2)/(x+ijc/2)$. The energy, the magnetization and the number of electrons in each band are given by $E=\Sigma_{j=1}^{N}k_j^2$, $S_z=\frac{1}{2}N-M$, and $m^{(l-1)}-m^{(l)}$, respec-

 0021-8979/94/75(10)/6731/3/$6.00 © 1994 American Institute of Physics

tively. For $n=1$ Eqs. (3) reduce to those of the gas of electrons with attractive interaction,[4] for $M=0$ to the multicomponent Fermi gas[4] and for $n=2$ to the model diagonalized in Ref. 2. The Bethe ansatz Eq. (3) are also closely related to those of a variant of the two-channel Kondo problem which includes charge (valence) fluctuations, except for the impurity terms and the expression of the energy.[5–7]

In the thermodynamic limit and for the ground state the solutions to Eq. (3) can be classified in analogy to the n-channel Kondo problem:[2,7] (i) $N-2M$ real charge rapidities k representing unpaired propagating electrons; (ii) M pairs of complex conjugated charge rapidities, $k=\lambda\pm ic/2$, corresponding to bound states of the Cooper pair type; (iii) $m_1^{(l)}$ real orbital rapidities of the set l, and $m_2^{(l)}$ two strings forming interband bound states of two electrons, $\xi^{(l)}=\xi_2'^{(l)}\pm ic/2$. Here λ, and $\xi_2'^{(l)}$ are real parameters representing the motion of the center of mass of the bound state. Note that necessarily $m^{(l)}=m_1^{(l)}+2m_2^{(l)}$.

The solutions are now inserted into the Bethe ansatz Eqs. (3), which are then made logarithmic since they represent relations among phase shifts. They are defined modulo 2π and yield sets of integers (or half-integers), one for each class of states, which are the quantum numbers of the many-body problem. All integers (half-integers) within a given set have to be different, since the rapidities have to be different to guarantee the linear independence of the wave functions. A quantum number is either represented in a set (particle) or missing (hole) giving rise to Fermi statistics for all rapidities. In the thermodynamic limit the distribution of rapidities becomes dense and we introduce density functions for the particles and holes of each class of states: $\rho(k)$ and $\rho_h(k)$ are the densities for states in class (i), $\sigma(\lambda)$ and $\sigma_h(\lambda)$ the densities for class (ii), and $\phi_j^{(l)}(\xi)$ and $\phi_{jh}^{(l)}(\xi)$ the densities for the real ξ ($j=1$) and two strings ($j=2$), $l=1,\ldots,n$. Differentiating with respect to the rapidities we obtain a set of linear integral equations for the density distributions; Fourier transforming we have[2,5–7]

$$

\tag{4}
$$

where the hat denotes Fourier transform, $\hat\phi_1^{(0)}(\omega)\equiv\hat\rho(\omega)$, $\hat\phi_2^{(0)}(\omega)\equiv\hat\sigma(\omega)$, $\hat\phi_1^{(n)}(\omega)=\hat\phi_2^{(n)}(\omega)\equiv 0$, and $f_j(\omega)=\exp(-j|\omega c|/2)$.

The kinetic energy, the number of electrons, and the magnetization are given by

$$
\begin{aligned}
&\frac{E}{L}=\int dk\;k^2\rho(k)+2\int d\lambda(\lambda^2-c^2/4)\sigma(\lambda),\\
&\frac{N}{L}=\int dk\;\rho(k)+2\int d\lambda\sigma(\lambda),\quad \frac{S_z}{L}=\frac{1}{2}\int dk\;\rho(k).
\end{aligned}
\tag{5}
$$

We now restrict ourselves to the situation of degenerate bands, i.e., the absence of crystalline fields. For degenerate bands the ξ rapidities (both the real rapidities and the two strings) fill the entire real axis, so that the hole functions $\phi_{1h}^{(l)}(\xi)$ and $\phi_{2h}^{(l)}(\xi)$ vanish identically. This is mathematically similar to the orbital singlet condition in the n-channel Kondo problem. The densities for the orbital rapidities can then be expressed in terms of ρ and σ and eliminated from Eqs. (4)

$$
\begin{aligned}
&\hat\phi_1^{(l)}(\omega)=\hat F_l(\omega)\hat\rho(\omega),\quad \hat\phi_2^{(l)}(\omega)=\hat F_l(\omega)\hat\sigma(\omega),\\
&\hat F_l(\omega)=\sin[(n-l)\omega c/2]/\sinh(n\omega c/2),
\end{aligned}
\tag{6}
$$

$$
\rho_h(k)+\rho(k)=\frac{1}{2\pi}+\int_{-B}^{B}dk'G_1(k-k')\rho(k')-\int_{-Q}^{Q}d\lambda D(\lambda-k)\sigma(\lambda),
\tag{7a}
$$

$$
\sigma_h(\lambda)+\sigma(\lambda)=\frac{1}{\pi}+\int_{-Q}^{Q}d\lambda' G_2(\lambda-\lambda')\sigma(\lambda')-\int_{-B}^{B}dkD(k-\lambda)\rho(k),
\tag{7b}
$$

where $G_j(k)$ and $D(k)$ are the Fourier transforms of

$$
\begin{aligned}
&\hat G_j(\omega)=\exp(-j|\omega c|/2)[\sinh((n-j)\omega c/2)/\sinh(n\omega c/2)],\\
&\hat D(\omega)=\exp(-(n-2)|\omega c|/2)[\sinh(\omega c/2)/\sinh(n\omega c/2)].
\end{aligned}
\tag{8}
$$

From energy considerations we have that $\rho(k)$ and $\sigma(\lambda)$ are symmetric functions, being nonzero only in the intervals $[-B,B]$ and $[-Q,Q]$, respectively; the hole distributions are the complementary functions. B and Q are determined through Eq. (5) by the number of electrons and the magnetization.

We define energy potentials for each class of states, i.e., $\epsilon(k)$, $\psi(\lambda)$, and $\kappa_j^{(l)}(\xi)$, which are related to the density functions via

$$
\begin{aligned}
&\rho_h(k)+\rho(k)=-\partial\epsilon(k)/\partial(2\pi\mu),\\
&\sigma_h(\lambda)+\sigma(\lambda)=-\partial\psi(\lambda)/\partial(2\pi\mu),\\
&\phi_{jh}^{(l)}(\xi)+\phi_j^{(l)}(\xi)=-\partial\kappa_j^{(l)}(\xi)/\partial(2\pi\mu),
\end{aligned}
$$

where μ is the chemical potential. States for which the potential is negative (positive) correspond to particles (holes), in accordance with the Fermi statistics obeyed by the rapidities. Note that at $T=0$ $\epsilon(\pm B)=0$, $\psi(\pm Q)=0$ and for degenerate bands, $\kappa_j^{(l)}(\pm\infty)=0$ for $j=1,2$. The integral equations satisfied by $\epsilon(k)$ and $\psi(\lambda)$ are (degenerate bands)

$$\epsilon(k)=k^2-\mu-H/2+\int_{-B}^{B}dk'G_1(k-k')\epsilon(k')$$

$$-\int_{-Q}^{Q}d\lambda D(\lambda-k)\psi(\lambda), \tag{9a}$$

$$\psi(\lambda)=2\left(\lambda^2-\frac{1}{4}\ c^2-\mu\right)+\int_{-Q}^{Q}d\lambda' G_2(\lambda-\lambda')\psi(\lambda')$$

$$-\int_{-B}^{B}dkD(\lambda-k)\epsilon(k). \tag{9b}$$

The orbital potentials with string index $j=1,2$ are negative everywhere

$$\kappa_1^{(l)}(\xi)=\int_{-B}^{B}dkF_l(\xi-k)\epsilon(k),$$

$$\kappa_2^{(l)}(\xi)=\int_{-Q}^{Q}d\lambda F_l(\xi-\lambda)\psi(\lambda). \tag{9c}$$

Equations (9) contain the same physical information as Eqs. (6) and (7); the zeroes of $\epsilon(k)$ and $\psi(\lambda)$ provide relations between B, Q, μ, and the magnetic field H.

In zero magnetic field, $H=B=0$, the potential $\epsilon(k)$ is positive for all k. Hence, the band of unpaired electrons is empty and all electrons are spin paired in Cooper-pair-like bound states. Equations (7b) and (9b) then reduce to single Fredholm integral equations for $\sigma(\lambda)$ and $\psi(\lambda)$. A magnetic field H larger than a critical value

$$H_c=-2\mu-2\int_{-Q}^{Q}d\lambda D(\lambda)\psi(\lambda) \tag{10}$$

is needed to overcome the binding energy of the Cooper pairs, and there is no response to a field smaller than H_c. The depaired electrons for $H>H_c$ occupy the unpaired-electron band, $\epsilon(k)$, and give rise to magnetization. The critical field is a decreasing function of the band filling and increases with c. H_c vanishes as $c\to 0$. The spin-paired bound states are hard-core bosons; although bosons from the symmetry of the wave function and their spin, the Cooper pairs must have all different quantum numbers, i.e., they have a Fermi surface. They do not undergo a condensation and hence there is no long-range order.

The magnetization is proportional to $(H-H_c)^{1/2}$ if the field is only slightly above the critical one,[2,8,9] as a consequence of the one-dimensional van Hove singularity of the empty $\epsilon(k)$ band. Hence, $H-H_c\propto B^2$ and $S_z\propto B$, while the susceptibility diverges proportionally to $(H-H_c)^{-1/2}$. The specific heat at low temperatures is obtained by a Sommerfeld expansion of the free energy and the potentials. C is proportional to T, except when the Fermi level is at a van Hove singularity, where it is proportional to $T^{1/2}$.[2,8,9] The Cooper-pair bound states do not cease to exist at finite temperature ($T_c=0$) and are still the dominant states if T is low. At $T\neq 0$ the system responds to a small magnetic field, but the susceptibility is exponentially small as $T\to 0$.

As $c\to 0$ the integration kernels in Eqs. (7) and (9) reduce to δ functions yielding algebraic equations. In zero field we obtain $\sigma(\lambda)=n/(2\pi)$ and $\rho_h(\lambda)=0$ for $|\lambda|<Q$, and $\sigma_h(\lambda)=1/\pi$ and $\rho_h(\lambda)=1/(2\pi)$ if $|\lambda|>Q$. Similarly, we have $\psi(\lambda)=n(\lambda^2-Q^2)$ and $\epsilon(\lambda)=0$ for $|\lambda|<Q$, and $\psi(\lambda)=2(\lambda^2-Q^2)$ and $\epsilon(\lambda)=\lambda^2-Q^2$ for $|\lambda|<Q$. The critical field vanishes in this limit. As $c\to\infty$, on the other hand, the Cooper-like bound states become strongly bound and the H_c required to depair them is very large. Another interesting limit is $n\to\infty$, where the integration kernels reduce to Lorentzians. Note that the limits $c\to 0$ and $n\to\infty$ cannot be interchanged.

Finally, we briefly discuss the excitation spectrum. There are three types of excitations: (i) charge, (ii) spin, and (iii) interband excitations. Elemental excitations are obtained by adding or removing a rapidity from the corresponding set. The energy of the excitation is given by the absolute value of the energy potential, e.g., for a charge with rapidity λ_0 we have $\Delta E_{ch}(\lambda_0)=|\psi(\lambda_0)|$. The charge excitation vanishes for $\lambda_0=\pm Q$, which corresponds to the Fermi surface; for $|\lambda_0|<Q$ the excitations are holes and for $|\lambda_0|>Q$ they correspond to particles. The spin excitation energy $\Delta E_s(k)=|\epsilon(k)|$ is finite if $H_c>H$ [spin gap of $2(H_c-H)$]; however, if $H>H_c$ also this band has a Fermi surface given by $\pm B$. For degenerate bands the interband excitations are of the hole type; their excitation energies are $|\kappa_j^{(l)}(\xi)|$ which vanish for $\xi=\pm\infty$. The momentum of each excitation is parametrized by the added or removed rapidity, e.g., for the charges it is $p_{ch}(\lambda_0)=2\pi\int_0^{\lambda_0}d\lambda[\sigma_h(\lambda)+\sigma(\lambda)]$ similar expressions hold for the other classes of excitations. The Fermi momentum for the charges is $p_F=(\pi/2)(N/L)$, while the one for the spin excitations ($H>H_c$) is determined by the magnetization.

Two-band model for Kondo insulators: Thermodynamic and scaling properties

M. A. Continentino and G. M. Japiassu

Recently a new family of heavy fermions (e.g., $Ce_3Bi_4Pt_3$) has been discovered which is characterized by an insulating ground state. Similar behavior has been found in some transition metal compounds like FeSi. We introduce a two-band model to describe the physical properties of these systems. Coulomb correlations in the narrow band are treated beyond the mean field approach. We find that a critical value of the hybridization $\tilde{V}_c$ is required to open a gap that produces an insulating ground state. We discuss the scaling properties of these systems close to $\tilde{V}_c$. The temperature-dependent magnetic susceptibility calculated in our model is in good agreement with experimental results.

Recently a new family of heavy fermions has been discovered which is characterized by an insulating ground state.[1–3] Similar behavior has also been found in the transition-metal-based compound FeSi. Although the general approach to the former systems is based on an Anderson lattice Hamiltonian,[4,5] we shall introduce here a two-band model aiming for a unified description of both kinds of materials. The Hamiltonian describing our system is

$$H=\sum_{ij\sigma} t_{ij}^{s} c_{j\sigma}^{+} c_{i\sigma}+\sum_{ij\sigma} t_{i,j}^{f} f_{j\sigma}^{+} f_{i\sigma}+\frac{U}{2}\sum_{i\sigma} n_{i\sigma}^{f} n_{i-\sigma}^{f}$$

$$+V\sum_{i\sigma}\left(c_{i\sigma}^{+} f_{i\sigma}+f_{i\sigma}^{+} c_{i\sigma}\right), \tag{1}$$

where $t_{ij}^{s,f}$ gives the hopping probability for electrons in the large, uncorrelated s-like band and in the narrow d or f band, which from now on we refer to generally as an f band. The $c_{i\sigma}^{+}$, $c_{i\sigma}$ create and destroy, respectively, electrons in the wide band and $f_{i\sigma}^{+}$, $f_{i\sigma}$ are creation and annihilation operators for electrons in the narrow f band. The Coulomb interaction between f electrons in the same site is given by U. V is the mixing term and $n_{i\sigma}^{f}=f_{i\sigma}^{+}f_{i\sigma}$. If it were not for the Coulomb term, the Hamiltonian above could be exactly diagonalized giving rise to two hybrid bands. However, the many body term due to the strong interaction U makes this a difficult problem for which an approximation must be introduced. Here we shall extend for the two-band problem the so-called Hubbard I approximation[6] which goes beyond the mean-field treatment. It is very appropriate for the problem studied here where the systems we are describing have insulating ground states and no long-range magnetic order. Employing the equation of motion method,[7] we find for the f electron propagator, in the limit $U\to\infty$,

$$G_{k\sigma}^{ff}(w)$$

$$=\frac{(1-\langle n_{-\sigma}^{f}\rangle)(w-\epsilon_k^{s})}{2\pi\{[w-\epsilon_k^{f}(1-\langle n_{-\sigma}^{f}\rangle)](w-\epsilon_k^{s})-V^{2}(1-\langle n_{-\sigma}^{f}\rangle)\}} \tag{2}$$

and a similar expression is obtained for the s-electron propagator.

We can see from Eq. (2) that the main role of the interactions is to renormalize the mixing term V^2 and the f-electron propagator through the contraction factor $(1-\langle n_{-\sigma}^{f}\rangle)$. The effective mass m_f defined by $\epsilon_k^{f}=\hbar^2k^2/2m_f$ is also renormalized. Incidently the contraction factor obtained here is different from the one which arises using the Slave–Boson[4,5] or Gutzwiller[8] approaches where it is given by $(1-\langle n^{f}\rangle)$ with $\langle n^{f}\rangle=\Sigma_\sigma\langle n_\sigma^{f}\rangle$.

Since we are interested in paramagnetic solutions, $\langle n_{-\sigma}^{f}\rangle=\langle n_{\sigma}^{f}\rangle$. Besides due to a special symmetry of the bands we shall consider here and the fact that we have one electron f per unit cell, the largest value these averages can assume is $\frac{1}{2}$. In this case the contraction factor is given by $(1-\langle n_{-\sigma}^{f}\rangle)=\frac{3}{4}$ and the effective hybridization $\tilde{V}$ remains finite at all temperatures.

The new excitations of the system are given by the poles of the propagators

$$(w-\epsilon_k^{s})(w-\tilde{\epsilon}_k^{f})-\tilde{V}^{2}=0\,, \tag{3}$$

where

$$\tilde{V}=V[(1-\langle n_{\sigma}^{f}\rangle]^{1/2}\,, \tag{4}$$

$$\tilde{\epsilon}_{k\sigma}^{f}=\epsilon_k^{f}(1-\langle n_{-\sigma}^{f}\rangle)\,. \tag{5}$$

Equation (3) has the following roots:

$$w_{1,2}(k)=\tfrac{1}{2}\left(\epsilon_k^{s}+\tilde{\epsilon}_k^{f}\pm\sqrt{(\epsilon_k^{s}-\tilde{\epsilon}_k^{f})^{2}+4\tilde{V}^{2}}\right). \tag{6}$$

In order to obtain explicit results for the density of states we introduce a model of homothetic bands[9] which consists in taking

$$\epsilon_k^{s}=\epsilon_k\,,$$

$$\tilde{\epsilon}_{k\sigma}^{f}=\alpha\epsilon_k+\beta\,. \tag{7}$$

The quantity α may be interpreted as taking into account the different effective masses of the f and s electrons, i.e., $(m_s/m_f^{*})=\alpha$. We have included in the parameter α the renormalization of the f-electron mass due to the contraction factor $(1-\langle n_{-\sigma}^{f}\rangle)$ arising from the Coulomb, repulsion between

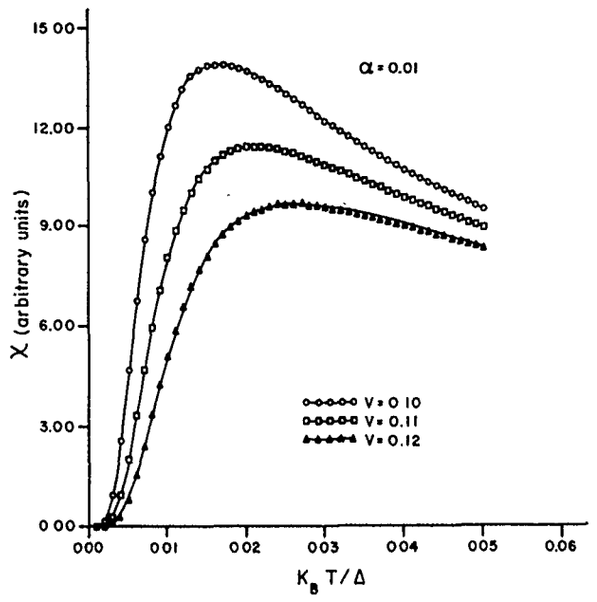

FIG. 1. The magnetic susceptibility, in arbitrary units, as a function of temperature for different parameters (see the text). Δ is the bandwidth of the large band.

electrons of opposite spins in the same site. The quantity β which gives the shift of the f band with respect to the large s band also includes the contraction factor. Introducing two new functions $g_1(w)$ and $g_2(w)$ through the equation

$$[w-w_1(k)][w-w_2(k)]=\alpha[g_1(w)-\epsilon_k][g_2(w)-\epsilon_k] \quad (8)$$

we get, in terms of these new functions, the s and f contributions to the density of states of the new hybrid bands. For the f contribution to the first hybrid band we find

$$n^f_{\sigma 1}(w)=\frac{|f'[w,g_1(w)]|}{\alpha|g_1(w)-g_2(w)|}\sum_k \delta[g_1(w)-\epsilon_k] \quad (9)$$

and for the second

$$n^f_{\sigma 2}(w)=\frac{|f'[w,g_2(w)]|}{\alpha|g_1(w)-g_2(w)|}\sum_k \delta[g_2(w)-\epsilon_k]\,, \quad (10)$$

where

$$f^f_k(w)=(1-\langle n^f_{-\sigma}\rangle)(w-\epsilon^s_k) \quad (11)$$

with similar equations for the s contribution to the density of states. Now it remains to find the functions $g_{1,2}(w)$ which can be obtained from Eq. (8). We get

$$g_{1,2}(w)=\frac{1}{2\alpha}\left((1+\alpha)w-\frac{1}{2}\Delta(1-\alpha)\pm\left\{\left[(1-\alpha)w-\frac{1}{2}\Delta(1-\alpha)\right]^2+4\alpha\tilde{V}^2\right\}^{1/2}\right). \quad (12)$$

Δ is the width of the large s band and appears in the above equation because the parameter β, which determines the position of the f band, was fixed by the condition that the center of this f band coincides with that of the large band at the energy $\Delta/2$ for $V=0$. For symmetric bands this arrangement is particularly useful since when the hybridization is turned on and is sufficiently strong, we obtain two symmetric hybrid bands separated by a gap, each one of which can accommodate exactly two electrons. Then in the case of the 1.5 electrons per unit cell that we are considering, the Fermi level sits in the middle of the gap and does not shift with temperature. Further for symmetric hybrid bands it can be easily shown that the factors $\langle n^f_\sigma\rangle$ are temperature independent implying that this is also the case for the parameters α and β. Since the total number of f electrons is $\langle n^f\rangle=\frac{1}{2}$, we get $\langle n^f_\sigma\rangle=\frac{1}{4}$, for paramagnetic solutions and the contraction factor is given by $(1-\langle n^f_{-\sigma}\rangle)=\frac{3}{4}$ independent of temperature. Within a contraction solution the same ground state occurs for $\langle n^f_\sigma\rangle+\langle n^f_{-\sigma}=\frac{1}{2}$ with the total number of electrons being two per unit cell.

The equation for the gap can be obtained from the difference in energy between the top of the first hybrid band and the bottom of the second. We find

$$\Delta_G=\left(\frac{\Delta^2(1-\alpha)^2}{4}+4\tilde{V}^2\right)^{1/2}-(1+\alpha)\frac{\Delta}{2}\,. \quad (13)$$

Consequently for a two-band system the opening of a hybridization gap, contrary to what occurs for the Anderson lattice model, requires a critical value of the hybridization which is given by

$$\tilde{V}_c=\frac{\Delta}{2}\sqrt{\alpha}\,. \quad (14)$$

For transition metal compounds where the ratio $\alpha_d=(m_s/m^*_d)$ is larger than that for rare-earth systems $\alpha_f=(m_s/m^*_f)$, a larger value of the hybridization is required to open a gap. A comparison of the magnitude of the critical hybridization parameter with the usual values of the hybridization for Ce, U systems and for transition metals, shows that $\tilde{V}_c$ may be sufficiently large to make the phenomenon of hybridization gaps rather unusual especially in transition-metal-based compounds where α_d is not such a small number. Note that the many-body contraction factor, which renormalizes both V^2 and α, cancels out in Eq. (14). Consequently whenever the interacting system is insulating the same holds for the noninteracting one ($U=0$) in agreement with Luttinger's theorem. Sufficiently close to $\tilde{V}_c$, the gap opens as

$$\Delta_G\cong\frac{4\sqrt{\alpha}}{1+\alpha}(\tilde{V}-\tilde{V}_c)\,. \quad (15)$$

Consequently, the gap exponent s, defined as $\Delta_G\sim(\tilde{V}-\tilde{V}_c)^s$, assumes within our approach the value $s=1$. This gap defines a characteristic temperature $T_c\sim|\tilde{V}-\tilde{V}_c|$, which for $\tilde{V}-\tilde{V}_c$ appears in the argument of the scaling functions[10] of the thermodynamic quantities as $f(T/T_c)$. The scaling form of the energy density f, close to $\tilde{V}_c$ is given by

$$f\sim|\tilde{V}-\tilde{V}_c|^{2-\alpha}f_0(T/T_c)\,. \quad (16)$$

The physical behavior of the system dictates the limiting form of the scaling function $f_0(x)$. We have $f_0(x\to 0)\sim e^{-1/x}$, appropriate to an insulator and at high temperatures, as expected, one has a degenerate Fermi gas. The specific heat $C=T\partial^2 f/\partial T^2$ behaves as $C\sim$

$AT^{-3}e^{-T_c/T}$ for $T_c \ll T$ and $C=AT$ for $T \gg T_c$ where $A \sim |V-\tilde{V}_c|^{2-\alpha-2\nu z}$. The mean field exponents $\alpha=0$, $\nu z=1$ yield $A=$constant, independent of pressure for example. Since in our approach the effect of an external magnetic field is essentially to shift the bands, the scaling form of the free energy density in the pressure of such a field h is $f \sim |\tilde{V}-\tilde{V}_c|^{2-\alpha} f_1(T/T_c,\ h/h_c)$, where $h_c \sim |\tilde{V}-\tilde{V}_c|$. From this equation the susceptibility can be easily obtained.

We can see that the effect of the interactions are solely incorporated in the parameter α in Eq. (15), its role being to reduce the gap, as compared to the noninteracting system. However, the inclusion of interactions does not modify the critical exponent s. This mean field exponent ($s=1$) may well be appropriate to describe the strongly correlated Kondo insulators due to dimensionality shifts associated with quantum phase transitions.[10] In Fig. 1 we show the magnetic susceptibilities for different values of the ratio of effective masses α and effective mixing $\tilde{V}$, with $\tilde{V}>\tilde{V}_c$. They show the same qualitative behavior of the experimental data and in particular that for FeSi where the susceptibility actually goes to zero exponentially after subtracting a tail due to paramagnetic impurities.[1] Other thermodynamic quantities can be readily obtained using the hybrid band density of states and the Kubo–Greenwood formula.[11] and will be preseneted in a future publication.[12]

The metal *ytterbium* has physical properties which are useful to compare with those of the materials studied here. For moderate applied pressures, Yb has a metal-insulator transition due to the opening of a hybridization gap.[13] This material can then be considered as a typical case for which the condition $\tilde{V}>\tilde{V}_c$ is not fulfiled but can be reached by applying pressure. On the other hand, the essential difference between Yb and the Kondo insulators is the strength of the many-body interaction which should be negligible in the former system. It is interesting that a large T^2 term occurs in the resistivity of metallic Yb which is enhanced as the metal-insulator transition is approached even though the f electrons are always sufficiently below the Fermi level and do not play any role in this transition.[14]

Local magnetic moments and intermediate valence state of cerium impurities in ferromagnetic rare-earth metals

C. E. Leal
Instituto Nacional de Pesquisas Especiais (INPE), Av. dos Astronautas 1758, São José dos Campos, SP, Brazil

A. Troper
Centro Brasileiro de Pesquisas Físicas (CBPF), Rua Dr. Xavier Sigaud 150, 22290, Rio de Janeiro, RJ, Brazil

Using experimental data for magnetic hyperfine fields obtained through the technique of time differential perturbed $\gamma-\gamma$ angular correlations (TDPAC) in the highly diluted system CeR (R=Gd, Tb), we theoretically discuss the formation of the local moments at the Ce impurity site, adopting an intermediate valence model. The ferromagnetic rare-earth host is considered as a transition metal in the beginning of a $5d$ series and the CeR alloys are described as strongly $d-f$ correlated and hybridized systems. One calculates the hyperfine field which reproduces quite well the experimental data. The Ce valence in these systems is also obtained, giving values in good agreement with experimental results and theoretical claims involving Gd and Tb band calculations. Some comments about the diluted systems YbR (R=Gd, Tb) are also made.

At the present very extensive experimental data on the hyperfine fields at the sites of diluted $n-d$ transition impurity ions (n=3,4) in ferromagnetic Gd are available in the literature.[1] More recently, Boysen *et al.*[2] reported systematic experimental hyperfine data of diluted $3d$ ions in ferromagnetic Tb and also some hyperfine data of diluted $5d$ ions in this same host were obtained.[3] From the measured magnetic hyperfine fields in these locally perturbed rare-earth hosts one can estimate the local magnetic moments formed at the impurity sites. For instance, the local magnetic moments change sign when one goes from the first-half to the second-half of the $3d$ series.[1,2,4,5]

In order to explain these data, it has been invoked[2,4] that the main interaction between rare-earth host ions (Gd or Tb) is due to a direct $d-d$ mechanism, thus neglecting the Ruderman–Kittel–Kasuya–Yosida (RKKY) interaction between rare-earth $4f$ moments. The proposal is based on Moriya[6] rules: if one regards a ferromagnetic rare-earth host like Gd or Tb as a transition metal in the beginning of a $5d$ series, one always should expect a sign reversal in the local moments when one passes from the first- to second-half of the $n-d$ series. These predictions agree qualitatively for the case of $3d$ impurities. On the other hand, all $5d$ impurities diluted in Gd have negative moments (with the possible exception of Lu)[6] and the available data of $5d$ ions diluted in Tb (e.g., TaTb and IrTb) show a total negative magnetic hyperfine field and small negative moments.[3,5]

So, it was suggested that an alternative theoretical approach[5–7] based on an extended RKKY picture which can describe adequately the hyperfine field systematics of all d-transition impurities placed in the heavy ferromagnetic hosts Gd and Tb. This picture brings out the fundamental role played by the $4f$ moments in driving the ferromagnetic properties of these metals and takes into account properly the transition metal-like character of these materials, i.e., the existence of conducting s and d bands. Within this picture, we explained adequately the hyperfine field systematics of the d impurities placed in Gd and Tb.

In this work we want to discuss some available hyperfine field data on CeR and YbR (R=Gd, Tb) alloys trying to insert them in the hyperfine field systematics of $5d$ impurities placed in these rare-earth hosts. Experimental results concerning isomer shifts of the $5d$ Mössbauer element ^{193}Ir diluted in Gd and Tb show that they are nearly constant, the value of 2 mm/s being in good agreement with the systematic of isomer shifts of ^{193}Ir in $5d$ transition metal hosts.[3,8] The same feature of almost constant isomer shifts is obtained for the $3d$ Mössbauer element Fe placed in FeR (R=Gd, Tb).[2,9] This suggests that the host $s-p$ and d-band occupations are quite the same for these rare-earth metals. Band calculations[10,11] have shown indeed that Gd and Tb exhibit d bands contributing a high density of states around the Fermi level.

One can estimate[7] from the above-mentioned band calculations the d- and $s-p$ band occupation numbers for both metals as being, respectively, $\langle n_d\rangle$=2.2 electrons (per host atom) and $\langle n_c\rangle$=0.8 electrons (per host atom) giving a 3^+ configuration: $\langle n_d\rangle+\langle n_c\rangle$=3.0 electrons (per host atom). Gd is the only rare-earth metal which goes directly from the paramagnetic phase to the ferromagnetic one with a Curie temperature T_C equal to 298 K. The saturation magnetic moment at very low temperature is $7.63\mu_B$ which is larger than the $7\mu_B$ value corresponding to the trivalent Gd^{3+}. Tb metal undergoes two magnetic transitions characterized by the Néel temperature T_N (T_N=229 K) and the Curie temperature T_C (T_C=221 K) and at very low temperature the saturation magnetic moment is $9.34\mu_B$, which has to be compared to the theoretical value of $9\mu_B$, expected for the trivalent ion Tb^{3+}.

The ferromagnetism of these "normal" rare-earth metals is described in a simple Stoner-type picture by two d-spin subbands split by and exchange energy, driven mainly from the exchange interaction between the effective $4f$ moment and the d electrons. Moreover, one assumes that, due to host hybridization, the $s-p$ and d-conduction bands have antiparallel magnetizations, as occur in Fe metal.[5,6,12]

 0 8973/94/75(10)/6737/3/$6.00 © 1994 American Institute of Physics

The technique of time differential perturbed $\gamma-\gamma$ angular correlations (TDPAC) has been widely used in the last years to obtain new information about the formation of local magnetic moments of Ce impurities in metallic elements.[13] In particular the CeR (R=Gd, Tb) systems where studied through this technique by Thiel *et al.*,[14,15] suggested that the single Ce ion in CeR systems (R=Gd, Tb) is in an intermediate valence (IV) state.

We assume that in an IV regime the Ce $4f$ level ϵ_f, which is fractionally occupied, is strongly admixed with host conduction states and lies very close to the Fermi energy of the system, i.e., $E_f-\epsilon_f<\Delta$, Δ being the $4f$ resonance width. The magnetic hyperfine field at rare-earth impurity nuclei placed in Gd or Tb metals is determined by a combination arising from both conduction electron polarization (CEP) and core polarization (CP) fields. The CEP field, which is due to the polarization of $s-p$ conduction electrons, is given by

$$H_{\rm hf}^{(sp)}=A(Z)\tilde{m}_c(0)\ , \tag{1}$$

where $A(Z)$ is the hyperfine contact parameter[16] and $\tilde{m}_c(0)$ is the $s-p$ magnetization at the impurity site. Using Campbell's data[16] for La and Lu one gets for Ce the value $A(Z)=3.23\times10^3\ \mu_B^{-1}$ kOe. Due to the $5d$ character ascribed to the anomalous rare-earth Ce impurity, a CP arises from its localized d-magnetic moment which polarizes the impurity electron core, similar to the case of a transition element impurity. It can be written as

$$H_{\rm hf}^{(d)}=-A_{\rm CP}^{(5d)}\tilde{m}_d(0)\ , \tag{2}$$

where $A_{\rm CP}^{(5d)}$ is a positive CP coupling parameter, of the order of $1200\mu_B^{-1}$ kOE for the $5d$ series and $\tilde{m}_d(0)$ is the d magnetization at the impurity site. The $4f$ resonance in the local density of states ("impurity site") introduces an extra contribution to the CP hyperfine field. This extra CP hyperfine field is due to the occurrence of a $d-f$ transferred local f magnetization $\tilde{m}_f(0)$.[12] One has

$$H_{\rm hf}^{(f)}=-A_{\rm CP}^{(4f)}\tilde{m}_f(0)\ , \tag{3}$$

where $A_{\rm CP}^{(4f)}$ is a positive coupling constant, the value adopted here being $1500\ \mu_B^{-1}$ kOe.

The total hyperfine field is then

$$H_{\rm hf}=A(Z)\tilde{m}_c(0)-A_{\rm CP}^{5d}\tilde{m}_d(0)-A_{\rm CP}^{4f}\tilde{m}_f(0)\ . \tag{4}$$

In Ref. 12 it is shown that $\tilde{m}_f(0)$ is parallel to $\tilde{m}_d(0)$:

$$\tilde{m}_f(0)=\xi_{df}\tilde{m}_d(0)=U_{df}\rho_f(E_F)\tilde{m}_d(0)\ , \tag{5}$$

where U_{df} is an effective $d-f$ Coulomb type interaction and $\rho_f(E_F)$ is the density of states of the $4f$ resonance at the Fermi energy. Thus, the total hyperfine field is

$$H_{\rm hf}=A(Z)\tilde{m}_c(0)-A_{\rm CP}^{(5d)}[1+(A_{\rm CP}^{(4f)}/A_{\rm CP}^{(5d)})\xi_{df}]\tilde{m}_d(0)\ . \tag{6}$$

The self-consistent calculation of $\tilde{m}_c(0)$ and $\tilde{m}_d(0)$, which are the solution of a Koster–Slater problem are given in detail in Refs. 5 and 6;

$$\tilde{m}_\alpha(0)=\sum_\sigma \sigma\int_{-\infty}^{\mu}\frac{\rho_{\alpha\sigma}(E)f(E)dE}{[1-V_{\alpha\sigma}F_{\alpha\sigma}(E)]^2+[\pi V_{\alpha\sigma}\rho_{\alpha\sigma}(E)]^2}\ , \tag{7}$$

where $\rho_{\alpha\sigma}(E)$ is the unperturbed density of states of a α subband with spin σ ($\alpha=s-p$ or d), $F_{\alpha\sigma}(E)$ is its Hilbert transform, $f(E)$ is the Fermi Dirac function, and μ is the chemical potential. At $T=0$ K, one has $\mu=E_F$. The localized potentials are self-consistently obtained via the Friedel sum rule

$$\Delta Z^\alpha=\sum_\sigma \Delta Z_\sigma^\alpha(V_{\alpha\sigma})=-\frac{K_\alpha}{\pi}\sum_\sigma \arctan\frac{\pi V_{\alpha\sigma}\rho_{\alpha\sigma}(E_F)}{1-V_{\alpha\sigma}F_{\alpha\sigma}(E_F)}\ , \tag{8}$$

where ΔZ_σ^α is the charge displaced by the potential $V_{\alpha\sigma}$ in the σ subband of α electrons and K_c accounts for degeneracy; one has $K_c=4$ and $K_d=5$.

Let us now focus our attention to the CeGd system. It is believed that the Ce valence in an IV state lies in the range (3.2–3.4). This implies in our picture that ν electrons in the range 0.2–0.4 are transferred to the d band and are screened via Eq. (8), thus fixing a local d magnetization $\tilde{m}_d(0)$ obtained through Eq. (7). Thus, the total hyperfine field is fixed when ξ_{df} is specified, since all the other terms in Eq. (6) are known if one adopts the same parameters of Refs. 5 and 6. We adopted for $\xi_{df}=U_{df}\rho_f(E_F)$ the value $\xi_{df}=3.6$. This choice yields for $T=0$ K a total negative hyperfine field $H_{\rm hf}=-537$ kOe which is in good agreement with the value obtained by Thiel *et al.*[14] which is: $|H_{\rm hf}|=540$ kOe and with the whole systematic of $5d$ impurities diluted in Gd which are always negative. The choice $\xi_{df}=3.6$ yields a valence state of 3.25 ($\nu=0.25$) and therefore the Ce configuration is $4f^{0.75}\ 5d^{1.25}\ 6s^2$, which is consistent with the results obtained in Ref. 17. The self-consistently calculated local moments are $\tilde{m}_c(0)=-0.056\mu_B$ and $\tilde{m}_d(0)=0.054\mu_B$.

Let us now discuss the CeTb system. At $T=0$ K, the experimental value estimated for the total hyperfine field is:[15] $H_{\rm hf}-550$ (80) kOe. Assuming that the Ce valence state in CeTb is the same as in CeGd, i.e., $\nu=0.25$, our calculated self-consistent local moments are $\tilde{m}_c(0)=-0.0314\mu_B$ and $\tilde{m}_d=0.0280\mu_B$. In order to fit the experimental value one adopts $\xi_{df}=9.86$ and then one obtains: $H_{\rm hf}=-543$ kOe at $T=0$ K, in good agreement with the experimental result. Notice that ξ_{df} accounts for the high density of states of the f resonance $\rho_f(E_F)$ at the Fermi level and for the strong effective $d-f$ correlation and so one can make a comparison between the adopted values of ξ_{df} for CeGd and CeTb. One has

$$\frac{\xi_{df}({\rm Ce}Tb)}{\xi_{df}({\rm Ce}Gd)}=\frac{9.86}{3.60}=2.74\ . \tag{9}$$

Remembering that $\xi_{df}=U_{df}\rho_f(E_F)$ and assuming that U_{df} is almost the same for both systems and that $\rho_f(E_F)$ is roughly proportional to the d peak of the density of states at the Fermi level of the hosts, one has

$$\frac{\xi_{df}(\mathrm{Ce}Tb)}{\xi_{df}(\mathrm{Ce}Gd)} \simeq \frac{\rho_d^{\mathrm{Tb}}(E_F)}{\rho_d^{\mathrm{Gd}}(E_F)} . \tag{10}$$

From band calculations[10,11] one has $\rho_d^{\mathrm{Tb}}(E_F)=66$ states per atom per Rydberg whereas $\rho_d^{\mathrm{Gd}}(E_F)=25$ states per atom per Rydberg; thus $[\rho_d^{\mathrm{Tb}}(E_F)]/[\rho_d^{\mathrm{Gd}}(E_F)]=2.64$, in a good agreement with our adopted values.

The existence of such sharp peaks near the position of the Fermi level are responsible for the steep drop with temperature of the local d magnetizations and therefore of the effective core polarization contributions to the hyperfine field [see the last term in Eq. (6)], whereas the $s-p$ contribution remains almost constant with temperature. This effect should be more dramatic in CeTb than in CeGd as is indeed experimentally verified.[14,15]

As a final comment let us briefly discuss the YbR systems. Yb is an anomalous rare earth with a 2^+ ionic configuration: $4f^{14}\,5d^0 6s^2$. The hyperfine field of Yb embedded in Gd was obtained from Mössbauer experiments yielding the value: $H_{\mathrm{hf}}(\mathrm{Yb}Gd)=-280(10)$ kOe,[18] which is almost temperature independent. These authors argued that the values of the hyperfine field, together with isomer shift measurements, support the assumption that Yb in YbGd is in a 2^+ state and has no f moment. We used the same $s-p$ local magnetization calculated for CeGd, since in both the Ce and Yb cases one has the same $6s^2$ ionic configuration. From Ref. 16 one gets (interpolating between the La and Lu coefficients): $A(Z)=4.67\times10^3\ \mu_B^{-1}$ kOe and then $H_{\mathrm{hf}}=H_{\mathrm{hf}}^{sp}=-260$ kOe, which agrees quite well with the experimental value.

As far as the YbTb system is concerned there are no available experimental hyperfine field measurements. Using the same assumptions as made for YbGd, one can predict the following value for the hyperfine field. $H_{\mathrm{hf}}=H_{\mathrm{hf}}^{sp}=-147$ kOe which should remain almost constant in temperature due to the flatness of the Tb $s-p$ conduction band.

We have reported recently on the revival of superconductivity in $Nd_{1.82}Ce_{0.18}CuO_y$ by doping with a divalent alkaline earth element. The doped superconductor $Nd_{1.82-x}Sr_xCe_{0.18}CuO_y$ has a Nd_2CuO_4 (T'-type) structure. This system possesses a normal state metallic resistivity [$\rho(T)$] in polycrystalline form. The $\rho(T)$ versus temperature (T) plots are, in general, linear. We report here the results of our studies of $\rho(T)$ and thermopower $S(T)$ and their dependence on the lattice oxygen content (y) that is a function of the Sr-content x. The $d\rho(T)/dT$ improves and then deteriorates with an increase in y. However, the thermopower behavior is a more complicated function of y (or x) and its results indicate that the majority of the charge carriers are electronlike. The thermopower (in absolute value) of the superconducting $Nd_{1.73}Sr_{0.09}Ce_{0.18}CuO_{3.97}$ compound gradually decreases from 250 to 150 K, remains almost constant from 150 to 75 K, decreases very fast below 75 K, and shows negative dS/dT. The overall feature of the S vs T plot suggests that the main contribution to S is from diffusion. Unlike reduced $Nd_{1.82}Ce_{0.18}CuO_{4.01}$ and other electron-doped superconductors, we have not observed a peak near the transition temperature (T_c) on the higher temperature side of the S vs T plot of the present sample. An attempt is made to explain the salient features of the thermopower.

The magnetic and superconducting properties of $Pb_2Sr_2(R/Ca)Cu_3O_8$, R=Pr, Ce, and Cm (abstract)

J. Simon Xue, C. W. Williams, and L. Soderholm
Argonne National Laboratory, Argonne, Illinois 60439

The series of compounds $Pb_2Sr_2(R/Ca)Cu_3O_8$, (R=Ce-Tm) are known to superconduct at temperatures as high as T_c=84 K. We have studied the relationship between superconductivity and magnetism in the Ce and Pr analogs. In addition, we report the synthetic route and the magnetic properties of the actinide analog $Pb_2Sr_2(Cm/Ca)Cu_3O_8$. The parent compound $Pb_2Sr_2CmCu_3O_8$ is not a superconductor, but shows evidence of long range magnetic ordering at about 18 K. This is a much higher temperature than is observed for any of the other R-ion parent compounds. These results will be discussed in terms of the different hybridization and bonding properties of the $4f$ and $5f$ electrons, and how these differences influence superconductivity. These results will be compared with the Pr and Cm analogs of the other superconducting series $YBa_2Cu_3O_7$ and $R_{2-x}Th_xCuO_4$.

^{57}Fe and ^{119}Sn Mössbauer effect studies on 0.5 at. % ^{57}Fe or ^{119}Sn doped nonsuperconducting $La_{1.25}Nd_{0.6}Sr_{0.15}CuO_4$ in the temperature region 300 K$\geq T \geq$4.2 K reveal an onset of local magnetic ordering occurring at $T_M \cong 32$ K for both ^{57}Fe as well as ^{119}Sn-doped samples. The local magnetic ordering shows up in the presence of a very large transferred hyperfine field of $B_{thf} \cong 11.0(5)$ T at the ^{119}Sn nuclei. Since such a large field is present in neither antiferromagnetic La_2CuO_4 superconducting $La_{1.85}Sr_{0.15}CuO_4$ nor overdoped $La_{2-x}Sr_xCuO_4$ ($x=0.4$), the occurrence of such local spin correlations seems to be a signature of the nonsuperconducting low temperature tetragonal phase of $La_{1.25}Nd_{0.6}Br_{0.15}CuO_4$.

Peculiarities of inelastic neutron scattering on magnons in high-T_c materials of stoichiometrical composition Nd_2CuO_4, La_2CuO_4, and $YBa_2Cu_3O_6$ (abstract)

Yu. Pashkevich and M. Larionov
Donetsk Phys.-Tech. Inst. Ukr. Acad. Sci., R. Luxemburg strasse 72, 340114 Donetsk, Ukraine

This paper focuses on the phenomenon of the "exchange amplification" of inelastic neutron scattering as compared to the elastic one around some Bragg peaks on small transferred momenta and energies. The effect is closely connected with increasing of the amplitude of uniform vibrations of some spin linear combinations. Since all the above-mentioned magnetics are multisublattice quasi-two-dimensional, those with an anomalously large intralayer exchange as compared to the interlayer one has the exchange amplification effect for the exchange and acoustic modes for all wave vectors directed perpendicularly to layers right up to the Brillouin zone edge. The same effect takes place in the region of the dispersion law being linear for small (compared with the intralayer exchange) transferred energies. The greater intensity of inelastic magnetic scattering as compared with the elastic one was observed in some experiments.[1,2] The selection laws defining Bragg peaks around which the inelastic scattering is exchange amplified have been obtained. The peculiarities of the inelastic neutron scattering in Nd_2CuO_4 for the different magnetic structures—collinear and noncollinear—are considered.

The sign reversal of the acoustoelectric effect in anisotropic superconductors (abstract)

A. V. Goltsev
Ioffe Physical-Technical Institute, St. Petersburg 194021, Russia

Experimental and theoretical investigations of high-temperature superconductors have revealed that the Fermi surface contains both electron- and hole-like parts, and the superconducting gap has large anisotropy in the a-b plane.[1] In the present paper we show that these two findings are sufficient to produce the sign reversal of the acoustoelectric effect observed in films of $YBa_1Cu_3O_{7-\delta}$ in transition from the normal to superconducting state.[2] For the purpose of studying the effect we derive a diagram method and calculate the acoustoelectric current produced by an acoustic wave in the normal state of an anisotropic metal. Then, we find that superconducting fluctuations decrease the current. Finally, we investigate the acoustoelectric effect in the mixed superconducting state. In this state the normal acoustoelectric current arises due to the quasiparticle excitation drift produced by the acoustic wave. It is compensated by the superconducting current which forces vortices to move. It is the motion that produces the acoustoelectric voltage in the superconducting state. We conclude that if the superconducting gap takes different values on the electron- and hole-like parts of the Fermi surface, then the acoustoelectric voltage can sharply change the sign near the superconducting transition. This effect is caused by the change of relative concentrations of the electron- and hole-like excitations.

Four-spin exchange in Bi_2CuO_4 (abstract)

G. Petrakovskii, V. Val'kov, K. Sablina, and B. Fedoseev
Institute of Physics, SB RAS, Krasnoyarsk 660036, Russia

A. Furrer, B. Roessli, and P. Fischer
Laboratory for Neutron Scattering, ETH Zurich, CH-5232 Villigen PSI, Switzerland

Magnetic properties of Bi_2CuO_4 single crystals are of interest owing to their relationship to the high-T_c superconductor problem. Earlier[1,2] we carried out the magnetic and neutron scattering investigations on high quality large single crystals. The Bi_2CuO_4 crystal belongs to the space group P4/ncc and the magnetic group is the collinear plane antiferromagnet with a Neel temperature of 45.8 K. The three-dimensional character of the antiferromagnetic ordering is reflected by the value of the critical magnetization exponent 0.352. The sublattice magnetization depends very little on temperature up to about 15 K. The spin-wave spectrum contains two branches with energy gaps of 2.1 and 3.4 meV. The theoretical interpretation of the experimental data shows the necessity of introducing the tensor four-site exchange in the $S=\frac{1}{2}$ spin Hamiltonian with the tetragonal anisotropic bilinear exchange. This provides the gap characteristics of the acoustic branch of spin waves and the correct temperature dependence of the sublattice magnetization. This result shows the importance of the four-site exchange for the formation of Bi_2CuO_4 magnetic properties. From the similarity of magnetic subsystems, Bi_2CuO_4, and high-T_c superconductors it is suggested that the four-site exchange is responsible for magnetic ordering of the square spin $S=\frac{1}{2}$ lattice. We also suggest a thermodynamic theory of the temperature dependence of magnetic properties of Bi_2CuO_4.

Antiferromagnetic spin correlation suppression and superconducting characteristics improvement in $YBa_2Cu_3O_{6+\delta}$ films under light illumination (abstract)

V. Eremenko, V. Fomin, I. Kachur, V. Piryatinskaya, and O. Prikhod'ko
Institute for Low Temperature Physics and Engineering, Academy of Sciences of Ukraine, 47 Lenin Ave., 310164, Kharkov, Ukraine

Improvement of $YBa_2Cu_3O_{6+\delta}$ film superconducting characteristics that are dependent on the charge carrier concentration is possible not only by means of oxygen doping, but also by light illumination.[1] New results may be presented as follows: (i) The spectral distribution of the light absorption coefficient of Y-Ba-Cu-O films strongly depends on the index δ: there are relatively narrow bands in the spectrum at small δ and their intensity falls down as δ increases. The films with $\delta \sim 0.5$–0.75 are metallized under light illumination: the resistivity at $T<T_c$ decreases, the critical temperature T_c rises, the absorption band with an energy of $E=2.2$ eV vanishes gradually, and the two-magnon band in the Raman spectrum also vanishes, which indicates a decrease of the antiferromagnetic spin correlation.[2] The above changes occur only if the photon energy is higher than that of the optical gap. The photoinduced changes are long lasting at $T<180$ K. (ii) The charge carrier density increase is not the only effect of light illumination. We have observed an increase in the critical current density J_c (measurements were carried out in the pulse regime) of $YBa_2Cu_3O_{6.9}$ films after continuous red light illumination. Such photoinduced changes are also long lasting if $T<T_c$ and a current pulse amplitude do not exceed J_c.

ac susceptibility of $Pb_xBi_{2-x}Sr_2Ca_2Cu_3O_{10}$ high T_c superconductors sintered for different durations (abstract)

S. C. Mathur, D. C. Dube, Urvija Sinha, and P. K. N. Raghavan
Indian Institute of Technology, Hauz Khas, New Delhi 110016, India

ac magnetic susceptibility measurements is one of the processes by which the superconducting properties of mixed oxide superconductors can be characterized. The study of the superconductors at an externally applied magnetic field predicts the existence of two superconducting transitions due to: (i) the one reflecting the intragrain properties and (ii) the other describing intergrain interactions which might be assumed as due to Josephson tunneling. In this abstract, we report our work on the ac susceptibility measurements in $Pb_xBi_{2-x}Sr_2Ca_2Cu_3O_{10}$ superconductors to study the real part of χ' as a function of temperature, Pb concentration, and sintering time. The results have been compared with the x-ray diffraction (XRD) results. The material preparation and the characterization techniques used would be discussed. The XRD and the susceptibility measurements indicate that too high Pb concentrations and too low sintering time does not seem to improve the high T_c phase. The weak link coupling phase determined from the χ'-T dependence is strongly dependent on both the Pb concentration and the sintering time. The transition temperature for the low T_c phase decreases with sintering time and increases with the increasing Pb concentration. The results would be discussed in the light of the best superconducting properties achieved by variation of the material preparation.

Spin magnetic moment of conduction quasiparticle (abstract)

Vladimir L. Safonov
Institute of Molecular Physics, RSC "Kurchatov Institute," 123182 Moscow, Russia

A new approach for the description of charged quasiparticles (conduction electrons and holes) with the spin of 1/2 in crystals is proposed.[1] The crystalline-field anisotropy is considered as a space-time geometry which is introduced by means of the metric tensor into the dirac equation. In the framework of this approach both the kinetic energy and the Zeeman energy depend on the tensor of effective masses $m_j^* = G_j m_0$, where G_j is the diagonal metric tensor. Components of the g factor are $g_j = 2m_0/m_{cj}^*$, m_{cj}^* being the cyclotron mass. This relation is in good agreement with the experiment for three-dimensional (3D) anisotropic metals such as Bi. For 2D motion we have only one nonzero spin magnetic component, perpendicular to the plane. This fact can be used for an explanation of two dimensional spin confinement observed experimentally in strained quantum wells. For 1D motion the spin of the quasiparticle falls out of the Hamiltonian. The fact that the spin is a hidden coordinate in this case can originate in para-Fermi statistics in which the maximal number of quasiparticles at the same energy level is equal to two (quasiparticles with up and down spins are identical). According to the theory[2] of superconductivity, the system of quasiparticles with para-Fermi statistics has much greater critical temperature than the system with Fermi statistics.

Restoration of the continuous phase transition in the vortex state due to the lattice translational symmetry: Large-*N* limit (abstract)

Boris N. Shalaev and Sergey A. Ktitorov
A. F. Ioffe Physical & Technical Institute, Russian Academy of Sciences, St. Petersburg 194021, Russia

The critical behavior of type II superconductors (SC) near the upper critical magnetic field is studied. The order parameter fluctuations in type II SC near the upper critical magnetic field were shown to destroy the off-diagonal long-range order (ODLRO) in $d<4$ dimensions.[1] In the report this result is proved to be valid in the $1/N$ expansion. Thus, there is a serious controversy between the experimentally observed phase coherence in SC and theoretical results forbidding a spontaneous breakdown of the $U(1)$ symmetry. Lattice effects breaking the continuous translational magnetic symmetry and suppressing the dimensional reduction effect[2] are shown to be responsible for the existence of the ODLRO. The lattice Hamiltonian of the uniformly frustrated $O(2N)$ symmetric nonlinear sigma model[3] is used to obtain the effective Ginzburg–Landau action which is analyzed in the large N limit. It is shown that the continuous phase transition does indeed occur with critical exponents being universal and identical to those of a superconductor with $H=0$.

Damping of spin waves in a square-lattice quantum antiferromagnet due to spin-phonon interaction (abstract)

Dirk Uwe Saenger
Institut fuer Theoretische Physik, Universitaet des Saarlandes, D-66041 Saarbruecken, Germany

The damping of spin waves due to spin-phonon interaction in a spin-1/2-Heisenberg antiferromagnet on a square lattice is calculated. The theory applies to the regimes where the sound velocities v_s are small compared with magnon velocities v_m, which is the case in antiferromagnetic high-T_c superconductor basis materials like $YaBa_2Cu_3O_6$, and $k\xi \gg 1$, where $\mathbf{k}$ and ξ are wave vector and correlation length, respectively. It is concluded that the broad spectral feature of the two-magnon line observed in layered perovskites can be explained qualitatively as a consequence of spin-phonon interaction.

The superconducting transition temperature of layered $S_i - J_{ij} - S_j$ superconductors (abstract)

Valery A. Cherenkov
The Research and Development Center of Surface and Vacuum (RDCSV), The Theoretical Physical Laboratory, Andreevskay Nab. 2, 117334 Moscow, Russia

The $S_i - J_{ij} - S_j$ multilayered superconductor structures containing different superconductors (S_{ij}) with an isolated layer are investigated. There is a theoretical model of a tunneling Hamiltonian for the defect Josephson lattice. There are the Ising magnetic and resonance valence band models between the layers. The "saturation" of $T_c(N)$ is determined. The analogy has been present for $T_c(N)$ in the representation of a plane (high-T_c) structure and the Kosterlitz–Thouless transition.

This research was supported by the American Physical Society.

Magnetism and superconductivity in heavy-fermion compounds (abstract)

A. V. Goltsev
Ioffe Physical-Technical Institute, St. Petersburg 194021, Russia

The mean-field theory based on an extended high degeneracy model is derived to describe an interplay between the Kondo effect, magnetism, and superconductivity in heavy-fermion compounds. The competition and coexistence of the Kondo effect and ferro- or antiferromagnetic orders of localized moments are considered depending on the local exchange interaction. It is shown that an antiferromagnetic order arising in the coherent Kondo state can have an anomalously small antiferromagnetic moment per f atom ($\sim 0.01\mu_B$) and stimulate superconductivity with an anisotropic superconducting gap that vanishes along lines on the Fermi surface. We apply the theory for studying thermodynamic peculiarities of the antiferromagnetic and superconducting transitions, and the microscopic structure of the antiferromagnetic and superconducting states in URu_2Si_2 and UPt_3. The theoretical estimation ($0.035\mu_B$) of the antiferromagnetic moments of U atoms in URu_2Si_2 is in good agreement with the experimental result ($0.04\mu_B$). We also study the microscopic origin of the double superconducting transition in UPt_3. The superconducting gap in the successive superconducting states is strongly anisotropic. In the former state the gap vanishes on part of the Fermi surface, while in the following state the gap vanishes on lines only.

Magnetic properties of an isolated ferromagnetic bond embedded in Heisenberg antiferromagnets

S. T. Ting, S. Haas, and J. E. Crow
Department of Physics, Center for Material Research and Technology, and National High Magnetic Field Laboratory, Florida State University, Tallahassee, Florida 32306

The magnetic properties of an isolated ferromagnetic bond of coupling constant K embedded in a layered spin-1/2 Heisenberg antiferromagnet with interplane coupling strength $J_\perp = \alpha J_\parallel$ ($0 \leq \alpha \leq 1.0$) have been studied using linear-spin-wave (LSW) theory. In the pure lattice, the sublattice magnetization $\langle S_i^z \rangle$ is 0.304 at $\alpha=0$ and saturates to 0.422 at $\alpha=1.0$. The spin correlations $\langle S_i^x S_j^x \rangle$ decrease with increasing α within the plane and increase along the interplane direction. The introduction of an isolated ferromagnetic bond into the host lattice tends to enhance $\langle S_i^z \rangle$ at lattice sites joining the bond as K approaches zero. Increasing K will drastically suppress $\langle S_i^x S_j^x \rangle$ across the bond. Whereas, $\langle S_i^x S_j^x \rangle$ is enhanced between the neighboring sites close to the impurity link resulting in the suppression of $\langle S_i^z \rangle$. This behavior persists for all α values. The LSW theory breaks down at a certain K value. Increasing α, the critical value of K extends to a larger number.

The striking magnetic properties of high temperature superconductors have led to extensive efforts in the investigation of the spin-1/2 Heisenberg antiferromagnets.[1] The La_2CuO_4 compound, which undergoes antiferromagnetic ordering at $T_N \leq 320$ K, presents quasi-two-dimension (quasi-2D) antiferromagnetic structure with a large in-plane exchange constant $J_\parallel \approx 1500$ K and a very weak interplane coupling $J_\perp$ between Cu-O planes. This small $J_\perp$ coupling plays an important role in stabilizing the three-dimensional (3D) antiferromagnetic ordering below T_N and also gives rise to interesting metamagnetic behavior associated with the small rotation of CuO_6 octahedra in the orthorhombic phase.[1,2]

The substitution of La with Sr, introducing extra holes into the Cu-O planes, drastically suppresses the long-range 3D antiferromagnetic ordering. Doping only 2% Sr into La site will completely destroy the Néel state. This interesting magnetic behavior leads to extensive study of a localized impurity and/or vacancy in a spin-1/2 2D Heisenberg antiferromagnet.[3–7] These studies exclusively concentrate on the 2D magnetic behavior, neglecting the small interplane coupling. As mentioned earlier, the weak interplane correlations between Cu-O planes becomes an important factor in the magnetic behavior below T_N. It is interesting to investigate the magnetic behavior of impure layered 2D Heisenberg antiferromagnets with varying interplane coupling constants since the crossover effects from 2D to 3D can be observed. In addition, the layered magnets themselves present quite interesting magnetic properties.[8] Therefore, in this paper we extend a previous calculation[5] on an isolated bond embedded in the spin-1/2 2D Heisenberg antiferromagnet by including the interplane coupling.

We consider a simple cubic Heisenberg antiferromagnetic lattice with in-plane nearest-neighbor antiferromagnetic coupling $J_\parallel$ and interplane coupling $J_\perp = \alpha J_\parallel$ ($0 \leq \alpha \leq 1.0$). An isolated ferromagnetic bond is introduced and replaces one inplane antiferromagnetic link joining the sites 0 and 1. The Hamiltonian is given as

$$H = \frac{J_\parallel}{2} \sum_{\langle ij \rangle} \mathbf{S}_i \cdot \mathbf{S}_j + \frac{J_\perp}{2} \sum_{\langle i'j' \rangle} \mathbf{S}_{i'} \cdot \mathbf{S}_{j'} - \frac{J_\parallel + K}{2} \mathbf{S}_0 \cdot \mathbf{S}_1, \tag{1}$$

where the first summation is over the four nearest neighbors within the plane and the second summation involves the two nearest interplane interactions. Following standard spin-wave theory,[9] the above Hamiltonian can be expressed as the product of bilinear bosonic operators using the Holstein–Primakoff transformation. The final Hamiltonian then can be analyzed using the Green's function method.[10] The Fourier transformation of the double-time one-particle Green's function in matrix form is given as

$$\hat{G}_{k,k'}(E) \equiv \begin{pmatrix} \langle\langle a_k^+ ; a_{k'} \rangle\rangle & \langle\langle a_k^+ ; b_{k'}^+ \rangle\rangle \\ \langle\langle b_k ; a_{k'} \rangle\rangle & \langle\langle b_k ; b_{k'}^+ \rangle\rangle \end{pmatrix}, \tag{2}$$

where $E = \omega + i\epsilon$ with $\epsilon \to 0^+$. The exact form of $\hat{G}_{k,k'}(E)$ can be obtained from the equation of motion.[5,6]

The sublattice magnetization $\langle S_i^z \rangle$ and the spin correlation depend on the positions of the lattice sites relative to the impurity bond and the imaginary part of the Green's function

$$\langle S_i^z \rangle = \frac{1}{2} + \frac{1}{N} \sum_{k,k'} e^{i(k-k')R_j} \int_0^\infty \frac{d\omega}{\pi} \, \mathrm{Im} \langle\langle a_k^+ ; a_{k'} \rangle\rangle, \tag{3}$$

$$\langle S_i^x S_j^x \rangle = -\frac{1}{N} \sum_{k,k'} e^{i(kR_i - k'R_j)} \int_0^\infty \frac{d\omega}{2\pi} \, \mathrm{Im} \langle\langle a_k^+ ; b_{k'}^+ \rangle\rangle, \tag{4}$$

where R_i or R_j represent the respective positions of spins. The sevenfold integration (two 3D k sums and one ω integration) of Eqs. (3) and (4) can be decoupled to an only twofold integration as follows:

 0021-8979/94/75(10)/6748/3/$6.00 © 1994 American Institute of Physics

$$\langle S_i^z\rangle^0=\frac{1}{2}-\frac{1}{\pi}\int_0^{1+\alpha/2-\epsilon}dy\,\frac{y-(1+\alpha/2)}{F(y)}\int_0^{\infty}dt\,\cos[F(y)t]\left[J_0\left(\frac{t}{2}\right)\right]^2 J_0\left(\frac{\alpha t}{2}\right), \tag{5}$$

$$\langle S_i^x S_j^x\rangle^0=-\frac{1}{2\pi}\int_0^{1+\alpha/2-\epsilon}dy\,F(y)\int_0^{\infty}dt\,\cos[F(y)t]\Delta(t), \tag{6}$$

$$\delta\langle S_0^z\rangle=-\frac{1+K}{4\pi}\int_0^{1+\alpha/2-\epsilon}dy\,\frac{2R(y)S(y)M(y)-\{[R(y)]^2-[S(y)]^2\}N(y)}{F(y)\{[M(y)]^2+[N(y)]^2\}}, \tag{7}$$

$$\delta\langle S_0^x S_1^x\rangle=-\frac{1+K}{8\pi}\int_0^{1+\alpha/2-\epsilon}dy\,\frac{[S(y)P(y)+R(y)Q(y)]M(y)-[R(y)P(y)-S(y)Q(y)]N(y)}{F(y)\{[M(y)]^2+[N(y)]^2\}}, \tag{8}$$

where $\langle S_i^z\rangle^0$ is the sublattice magnetization, $\langle S_i^x S_j^x\rangle^0$ is the spin correlation in the pure lattice, and $J_n(t)$ is the Bessel function of the first kind. The functions $\Delta(t)$, $M(y)$, $N(y)$, $P(y)$, $Q(y)$, $F(y)$, $R(y)$, and $S(y)$ are given as

$$\Delta(t)=\frac{1}{2}\left\{\left[J_0\left(\frac{t}{2}\right)\right]^2 J_0\left(\frac{\alpha t}{2}\right)-\frac{2}{t}\,J_0\left(\frac{t}{2}\right)J_1\left(\frac{t}{2}\right)J_0\left(\frac{\alpha t}{2}\right)-\left[J_1\left(\frac{t}{2}\right)\right]^2 J_0\left(\frac{\alpha t}{2}\right)-\alpha J_1\left(\frac{t}{2}\right)J_0\left(\frac{t}{2}\right)J_1\left(\frac{\alpha t}{2}\right)\right\}, \tag{9}$$

$$M(y)=1+\frac{(1+k)}{2F(y)}\int_0^{\infty}dt\,\sin[F(y)t]\left\{\Delta(t)-(1+\alpha/2)\times\left[J_0\left(\frac{t}{2}\right)\right]^2 J_0\left(\frac{\alpha t}{2}\right)\right\}, \tag{10}$$

$$N(y)=\frac{(1+k)}{2F(y)}\int_0^{\infty}dt\,\cos[F(y)t]\left\{\Delta(t)-(1+\alpha/2)\times\left[J_0\left(\frac{t}{2}\right)\right]^2 J_0\left(\frac{\alpha t}{2}\right)\right\}, \tag{11}$$

$$P(y)=\int_0^{\infty}dt\,\sin[F(y)t]\left\{\Delta(t)-[y+(1+\alpha/2)]\times\left[J_0\left(\frac{t}{2}\right)\right]^2 J_0\left(\frac{\alpha t}{2}\right)\right\}, \tag{12}$$

$$Q(y)=\int_0^{\infty}dt\,\cos[F(y)t]\left\{\Delta(t)-[y+(1+\alpha/2)]\times\left[J_0\left(\frac{t}{2}\right)\right]^2 J_0\left(\frac{\alpha t}{2}\right)\right\}, \tag{13}$$

$F(y)=[(1+\alpha/2)^2-y^2]^{1/2}$, $R(y)=P(-y)$, and $S(y)=Q(-y)$. Notice that Eqs. (7) and (8) only present the variation of $\langle S_i^z\rangle$ and $\langle S_i^x S_j^x\rangle$ at the lattice sites joining the impurity link. One can easily extend them to arbitrary lattice sites.

$\langle S_i^z\rangle^0$ and $\langle S_i^x S_j^x\rangle^0$ for the pure lattice can be obtained from Eqs. (5) and (6). At $\alpha=0.0$ (2D lattice), $\langle S_i^z\rangle^0$ is 0.3034 and saturates to 0.422 at $\alpha=1.0$ (3D lattice). $\langle S_i^x S_j^x\rangle^0$ decreases in magnitude from 0.1378 at $\alpha=0.0$ to 0.0635 at $\alpha=1.0$. These results are consistent with previous numerical calculations.[11–13] Since the spin correlations between nearest neighbors depend on the positions of spins, we also calculate $\langle S_i^x S_j^x\rangle^0$ along the interplane direction, which increases in magnitude from 0 at $\alpha=0.0$ to 0.0635 at $\alpha=1.0$. This result provides evidence that the interplane coupling stabilizes 3D antiferromagnetic ordering at low temperatures.

The introduction of a ferromagnetic bond into the host lattice will affect the sublattice magnetization and spin correlations surrounding the impurity. When $K=0$, the system corresponds to a missing link embedded in the host lattice. In this case, $\langle S_i^z\rangle$ is enhanced at the sites joining the impurity bond. This behavior persists for all α values as shown in Fig. 1. The enhancement of $\langle S_i^z\rangle$ becomes less evident for larger α values, e.g., 0.3034→0.312 at $\alpha=0.0$ and 0.422→0.4238 at $\alpha=1.0$. These results indicate that the absence of spin fluctuations is more dominant than the missing longitudinal term, especially for lattices with small interplane coupling strength. By increasing K, $\langle S_i^z\rangle$ is monotonically suppressed at the sites joining or close to the ferromagnetic bond as illustrated in Fig. 2 which shows the sublattice magnetization as a function of $K/J_{\parallel}$ at the sites adjacent to the impurity link. The spin correlations are enhanced for almost all the lattice sites surrounding the ferromagnetic link except for

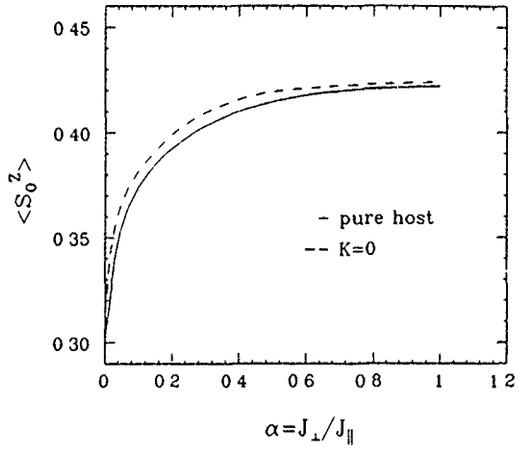

FIG. 1. The sublattice magnetization $\langle S_0^z\rangle$ at lattice site 0 joining the missing link as a function of α (dashed line), compared with that of the pure host (solid line).

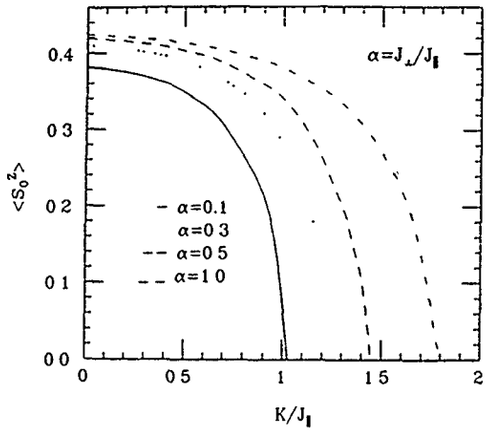

FIG. 2. The sublattice magnetization $\langle S_0^z \rangle$ at lattice site 0 adjacent to the impurity link vs $K/J_\parallel$ at different α values. The LSW approximation breaks down above certain K values.

those connecting the impurity bond. These results are illustrated in Fig. 3(a) and 3(b). In Fig. 3(a), we present $\langle S_0^x S_1^x \rangle$ vs $K/J_\parallel$ across the impurity bond. As expected, $\langle S_0^x S_1^x \rangle$ is strongly suppressed. Figure 3(b) shows $\langle S_0^x S_1^x \rangle$ as a function

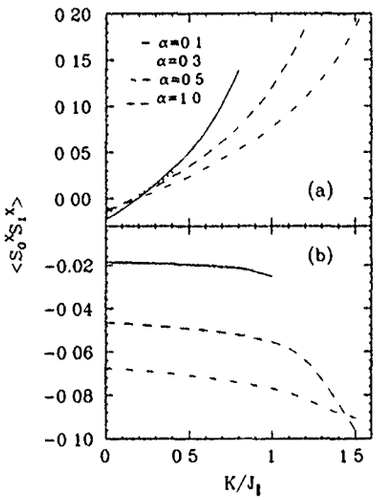

FIG. 3. The spin correlations $\langle S_0^x S_1^x \rangle$ vs $K/J_\parallel$ at different α values; (a) for spins across the impurity link [i.e., (100) direction], (b) for spins along the interplane direction ((001)).

of $K/J_\parallel$ along the interplane direction (001) which indicates that $\langle S_0^x S_1^x \rangle$ increases in magnitude with increasing K.

It is evident that the LSW approximation breaks down at a certain value of K, even at maximum $J_\perp$. The breakdown value extends to larger value as α is increased. As mentioned earlier, interplane interactions tend to strengthen the 3D antiferromagnetic ordering. To frustrate the spin correlations adjacent to the ferromagnetic bond, a stronger perturbation, i.e., a larger K value is necessary to overcome the exchange-coupling energy between the planes. The denominator of Eq. (7) or (8) represents the spin wave mode arising from the ferromagnetic link. This correspond. to a localized mode. As K approaches its critical value, a large number of spin waves is generated because of the strong local perturbation. In this case, one must consider higher order bosonic operators which describe the interactions between magnons, e.g., the spin operator S_j^+ for sublattice a is given as

$$S_{aj}^+ = \frac{1}{\sqrt{N}} \times \left(\sum_k e^{-ikx_j} a_k + \frac{1}{2N} \sum_{k,k',k''} e^{i(k-k'-k'')x_j} a_k^+ a_{k'} a_{k''} \right). \tag{14}$$

The complete details will be presented in a future publication.

Spin diffusion in classical Heisenberg magnets with uniform, alternating, and random exchange

Niraj Srivastava,[a] Jian-Min Liu, V. S. Viswanath, and Gerhard Müller
Department of Physics, The University of Rhode Island, Kingston, Rhode Island 02881-0817

We have carried out an extensive simulation study for the spin autocorrelation function at $T=\infty$ of the one-dimensional classical Heisenberg model with four different types of isotropic bilinear nearest-neighbor coupling: uniform exchange, alternating exchange, and two kinds of random exchange. For the long-time tails of all but one case, the simulation data seem incompatible with the simple $\sim t^{-1/2}$ leading term predicted by spin diffusion phenomenology.

The anomalous character of spin diffusion in the one-dimensional (1D) classical Heisenberg model,

$$H=-\sum_i J_{i,i+1}\mathbf{S}_i\cdot\mathbf{S}_{i+1}, \tag{1}$$

with uniform exchange, $J_{i,i+1}=J$, was first proposed in 1988 on the basis of a simulation study.[1] The proposition was that the spin autocorrelation function at $T=\infty$ exhibits a distinctive power-law long-time tail,

$$C_0(t)\equiv\langle\mathbf{S}_i(t)\cdot\mathbf{S}_i\rangle\sim t^{-\alpha}, \tag{2}$$

with a characteristic exponent α that exceeds the value $\alpha_{SD}=1/2$ predicted by spin diffusion phenomenology considerably.

That conclusion was challenged by Gerling and Landau[2] soon after it had appeared in print. However, the consensus emerged that the slope $\tilde{\alpha}$ inferred from the simulation data (in a log–log representation) has a value $\tilde{\alpha}=0.60$ at $Jt\simeq 25$ and a decreasing trend for longer Jt, and that the true asymptotic behavior remained out of the reach of simulation data available at the time.[2,3]

It was nevertheless another simulation study that yielded new insights into the anomalous transport mechanism of spin fluctuations in the classical Heisenberg chain. Having been alerted by the puzzling results for the spin autocorrelation function, Bonfim and Reiter[4] focused their own investigation on the q-dependent spin correlation functions and the associated current correlation function. One of their conclusions was that the asymptotic behavior of the spin autocorrelation function is of the form

$$C_0(t)\sim[Jt\ln(\Omega t)]^{-\alpha} \tag{3}$$

with $\alpha=0.472$. The implication is that the slope of $C_0(t)$ in a log–log plot can be described by an effective exponent,

$$\tilde{\alpha}=\alpha[1+1/\ln(\Omega t)]. \tag{4}$$

Böhm, Gerling, and Leschke[5] were quick to point out that the asymptotic form of the q-dependent correlation function used in Ref. 4 is in contradiction to the non-negativity of $\langle\mathbf{S}_i(t)\cdot\mathbf{S}_{i+n}\rangle$, for which strong numerical evidence exists. They proposed an alternative asymptotic expression, which also implies an effective exponent (4), but with asymptotic value $\alpha=0.5$.

Since neither of the two conclusions was primarily based on the analysis of spin autocorrelation functions, we wish to use our own new simulation data for $C_0(t)$ as a discriminant between expressions (4) with $\alpha=0.472$ and $\alpha=0.5$, respectively. We have carried out the simulation for a system of 1024 spins with periodic boundary conditions. We have employed CM-5 machines with various numbers of processors programmed in Connection Machine FORTRAN for up to 4096 parallel time integrations. For the integration over the time interval $0\leq Jt\leq 102.2$, we have used a fourth-order Runge–Kutta method with fixed time step $Jdt=0.005$. In this massively data-parallel programming mode we can reach previously unattained statistics with no undue effort.

For the intended analysis, we have determined the average slope $\tilde{\alpha}$ of the simulation data in a log–log representation over a time interval of length Jt_{av} as follows: each data point of $\tilde{\alpha}(t)$ is calculated by linear regression from N_{av} consecutive data points $[\ln Jt,\ln C_0(t)]$ spaced at $J\Delta t=0.2$ and assigned the Jt value at the midpoint of the interval of length $Jt_{av}=N_{av}J\Delta t$. Figure 1 shows the slope function $\tilde{\alpha}$ plotted versus $1/Jt$ for three different sizes of Jt_{av}.[6] This representation enhances the visibility of the subtle features in the long-time tail, but it also magnifies the statistical fluctuations. The latter are kept under control by adjusting Jt_{av}.[7]

In order to facilitate a direct comparison of our simulation results with the proposed functional form (4) for the effective exponent $\tilde{\alpha}(t)$, we have subjected the asymptotic expression $\sim[Jt\ln(\Omega t)]^{-\alpha}$ to the same exponent analysis as the data. The resulting slope function $\tilde{\alpha}(t)$ still depends on the parameters α and Ω. There is no compelling reason for setting Ω equal to J in the logarithmic correction as was done in Refs. 4 and 5. Minimizing the relative rms deviation between the two slope functions $\tilde{\alpha}(t)$, namely the one representing the simulation data and the one representing the averaged exponent $\tilde{\alpha}(t)$ over the interval $5+Jt_{av}/2\leq Jt\leq 102.2-Jt_{av}/2$, yields parameter values in the range $\alpha=0.478\pm0.001$, $\Omega/J=2.30\pm0.02$ for the three values of averaging intervals Jt_{av} used. The solid lines represent $\tilde{\alpha}$ vs $1/Jt$ for the optimal parameter values. The agreement with the simulation data is quite satisfactory. If we perform the fit for fixed $\alpha=0.5$, we obtain the optimal value $\Omega/J=9.70\pm0.05$ for the other parameter, and the result, represented by the dashed lines, is in clear disagreement with the simulation data.

We have repeated the analysis with more of the (evidently nonasymptotic) data at small times omitted (up to

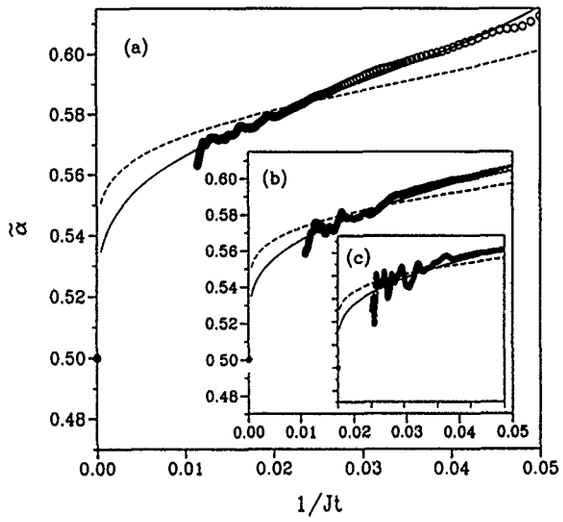

FIG. 1. Slope function $\tilde{\alpha}(t)$ for the 1D classical Heisenberg model (1) with uniform exchange, $J_{i,i+1}=J$ as determined from the slope of $C_0(t)$ in a log–log plot. The data for $C_0(t)$ represent an average over 404 484 randomly chosen initial conditions and over the 1024 sites of the lattice. Each data point $\tilde{\alpha}$ is determined by linear regression from N_{av} consecutive data points $[\ln Jt, \ln C_0(t)]$ spaced at $J\Delta t=0.2$ and plotted vs $1/Jt$ at the midpoint of the interval of length $Jt_{av}=N_{av}J\Delta t$. The simulation data are represented by the circles. The asymptotic form (3) subjected to the same procedure yields the dashed lines for $\alpha=0.5$ and the solid lines for $\alpha=0.478$. The three plots correspond to different sizes of averaging time interval: (a) $Jt_{av}=30$, (b) $Jt_{av}=20$, (c) $Jt_{av}=10$.

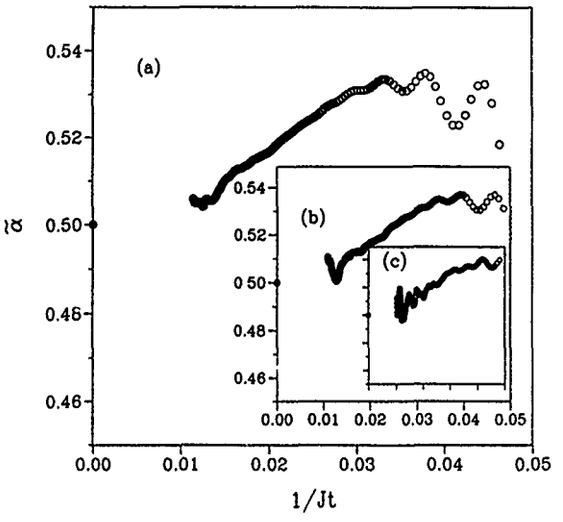

FIG. 2. Slope function $\tilde{\alpha}(t)$ for the 1D classical Heisenberg model (1) with alternating exchange, $J_{i,i+1}=(-1)^iJ$, produced by the same method as that of Fig. 1. The number of integrations with randomly chosen initial conditions was 479 232 for this case.

$15+Jt_{av}$) and found a decreasing trend of the optimal exponent value (now in the range $\alpha=0.472\pm0.002$, in even better agreement with the value proposed in Ref. 4). Nevertheless, the problems attached to this scenario, as pointed out in Ref. 5, cannot be dismissed and suggest that the true asymptotic behavior is even more subtle.

How typical is the occurrence of anomalous long-time tails in 1D classical spin systems with isotropic exchange? It had already been noted[4] that the anomaly disappears in the presence of uniaxial anisotropy. The question is what happens if we modify the spin coupling without altering the rotational symmetry in spin space, for example, by reducing or removing the translational symmetry along the chain.

In order to investigate that question, we have carried out simulations of comparable extent on three further variants of the classical Heisenberg model (1). In addition to model (i) with *uniform* exchange, $J_{i,i+1}=J$, discussed previously, we consider the model (ii) with *alternating* exchange, $J_{i,i+1}=(-1)^iJ$, and two models with *random* exchange: model (iii) has $J_{i,i+1}=\pm J$ with equal probabilities and model (iv) has $|J_{i,i+1}|\leq\sqrt{3}J$ with a rectangular probability distribution.[8] The results of this investigation are displayed in Figs. 2–4 for models (ii)–(iv) in exactly the same representation as those of model (i) exhibited in Fig. 1. The outcome is a bit surprising. It seems that long-time tails display no less individuality than, say, people's fingerprints.[9]

Among the four models considered here, the one with alternating exchange alone appears to exhibit completely normal spin diffusive behavior. Its slope function $\tilde{\alpha}$, displayed in Fig. 2, tends to extrapolate on a fairly direct path toward $\alpha_{SD}=0.5$. The data invite no suspicion of any anomaly. The strong wiggles at small t are not statistical fluctuations but originate from oscillations in $C_0(t)$, which persist to longer times in this model than in any of the other three.

The slope function $\tilde{\alpha}$ of the random-exchange model (iii) is shown in Fig. 3. Unlike in the previous two cases, it has an increasing trend for increasing t up to $\tilde{\alpha}\approx0.53$ at the tail end of the data, where it seems to level off. While a limiting value of $\alpha_{SD}=0.5$ cannot be ruled out, the data do not show any tendency to extrapolate to that value.

Changing the distribution of random exchange constants from (iii) to (iv) produces a quite different slope function as can be observed in Fig. 4. It starts out at a much smaller

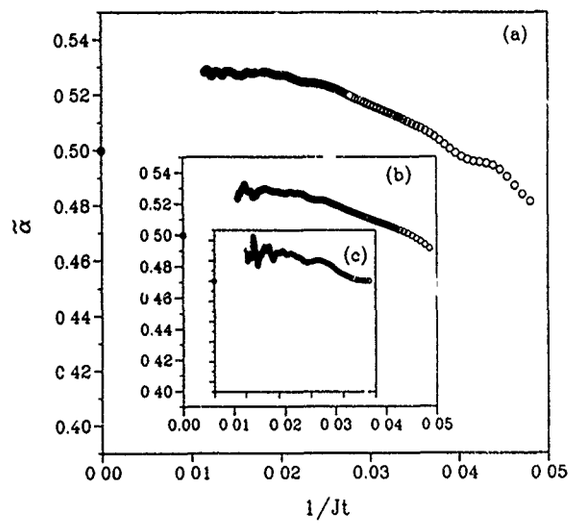

FIG. 3. Slope function $\tilde{\alpha}(t)$ for the 1D classical Heisenberg model (1) with random exchange, $J_{i,i+1}=\pm J$, produced by the same method as that of Fig. 1. The number of integrations with randomly chosen initial conditions was 409 600 for this case. For each initial configuration, the exchange constants were randomly chosen as well.

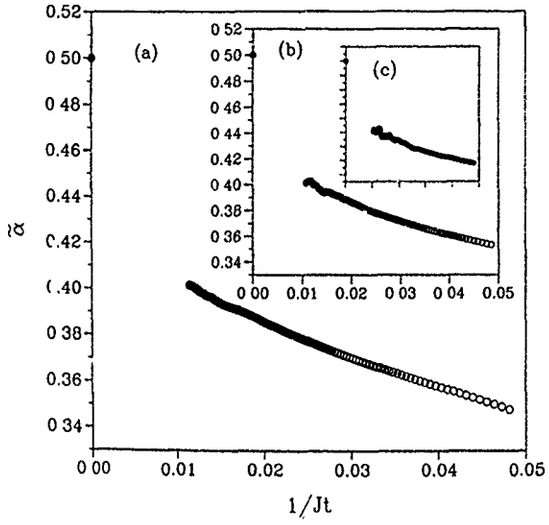

FIG. 4. Slope function $\tilde{\alpha}(t)$ for the 1D classical Heisenberg model (1) with random exchange, $|J_{i,i+1}| \leq \sqrt{3}J$, produced by the same method as that of Fig. 1. The number of integrations with randomly chosen initial condition was 424 960 in this case. For each initial configuration, the exchange constants were randomly chosen as well.

value for short t and reaches $\tilde{\alpha} \simeq 0.4$ at the tail end of the data ($Jt = 102.2$). In some way this slope function looks like the mirror image of that for model (i). It may very well extrapolate to $\alpha_{SD} = 0.5$ or there abouts by some logarithmic law—a modification of Eq. (4). But any such law would have to be motivated by an investigation of q-dependent correlation functions as was done by Bonfim and Reiter[4] for model (i). For the random-exchange model (iii), the anomaly, if it indeed exists, is much weaker than in models (i) and (iv) and will therefore be much harder to identify and analyze in q-dependent correlation functions. These are future projects.

This work was supported by the U.S. National Science Foundation, Grant No. DMR-93-12252. The simulations were run on CM-5 machines at the National Center for Supercomputing Applications, University of Illinois at Urbana-Champaign and at Thinking Machines Corporation.

[6] See Fig. 2 of Ref. 2 (second paper) and Fig. 2 of Ref. 3 for previous interpretations of slope functions based on different simulation data.
[7] The price to be paid in exchange of a smooth slope function is a systematic deviation from the true slope at a given value of Jt for all functions except pure power laws. For a given set of simulation data, if one increases Jt_{av}, one gains smoothness and along with it the ability to extrapolate. Conversely, if one decreases Jt_{av}, the systematic deviations go down, but the statistical fluctuations grow more intense. The three plots in each figure are intended to illustrate that the systematic deviations are negligible except (in some cases) for short times.
[8] The width $2\sqrt{3}J$ of the $J_{i,i+1}$ distribution has been chosen to match the initial curvature of $C_0(t)$ with those of the other three models.
[9] In Ref. 1 (second paper) we have already compared three of the four long-time tails directly and found (ii) and (iii) similar but distinct from (i). The superior statistics of our new data reveals subtle but significant differences between (ii) and (iii) as well.

Theoretical study of magnetostriction in FeTaN thin films

James C. Cates and Chester Alexander, Jr.
Center for Materials for Information Technology and Department of Physics and Astronomy, The University of Alabama, Tuscaloosa, Alabama 35487-0114

Single layer films of FeTaN have been deposited by dc magnetron sputtering, and the relationships between the magnetostriction and film composition have been studied. A linear increase in magnetostriction with nitrogen content has been explained by the dependence of λ_{100} on nitrogen concentration. The form of this dependence has been derived based on a theory developed by De Vries for describing the magnetic after effect in iron films with interstitial nitrogen. At room temperature, the best fit for the experimental magnetostriction data was found for an interstitial interaction constant of $D=4.18\times10^6$ J/m^3. The total magnetic anisotropy energy per grain, U_{110}, has also been calculated as a function of the strain for FeN films with a (110) orientation under a tetragonal deformation. This calculation used the results derived for the dependence of the magnetostriction constant, λ_{100}, on nitrogen concentration. The calculated U_{110} value shows a minimum at a lattice strain value of $\epsilon_{11}=0.0029$, in close agreement with a maximum in permeability at $\Delta d_{110}/d_{110}=0.0028$ previously reported for FeN films.

I. INTRODUCTION

Recent results at The University of Alabama show that FeTaN films deposited by high-growth rate dc magnetron sputtering have suitable soft magne perties for use in recording heads.[1,2] X-ray diffraction rements of these films show a structure containing only the α-Fe phase with a (110) orientation. The addition of tantalum to the FeN films has been shown to improve the incorporation of nitrogen in the films during sputtering while suppressing the formation of iron-nitride phases, such as Fe_4N.

Wang and Kryder have examined the saturation magnetostriction in FeN films deposited by rf sputtering.[3] They attributed the increase in magnetostriction found with increasing nitrogen flow rates during deposition to the existence of higher amounts of γ-Fe_4N which exhibits a positive magnetostriction. Magnetostriction in FeN films deposited by dc magnetron sputtering has been reported by Russak *et al.* to increase linearly with the nitrogen flow rate during deposition.[4] Similar results have been found by Nago, Sakakima, and Ihara for FeTaN films deposited by rf sputtering after annealing at 500 °C.[5]

The relationship between the film composition and magnetostriction in FeN-based films has been difficult to model because the presence of additional iron-nitride phases with various orientations greatly complicates any interpretations of magnetostriction results. One important reason for examining the FeTaN system was that the structure was relatively simple, showing only the α-Fe phase with a (110) orientation. In this system the nitrogen atoms are presumed to primarily occupy interstitial sites in the iron lattice causing a deformation of the lattice from body-centered cubic to body-centered tetragonal. Increases in the nitrogen content in the film corresponded to higher occupation of the interstitial sites. The effects on the magnetostriction constants λ_{100} and λ_{111} of this nitrogen in the interstitial sites have been modeled based on a theory developed by De Vries.[6,7] The resulting expressions have been used to predict the values of the saturation magnetostriction and the total anisotropy energy per grain, U_{110}, for comparison with experimental results.

II. EXPERIMENTAL

The FeTaN films, approximately 4000 Å thick. were deposited on Corning 7059 glass by dc magnetron reactive sputtering in a Vac-Tec model 250 batch side sputtering system. Background pressure during deposition was 4×10^{-7} Torr with the sputtering power at 300 W. The argon flow rate was set at 60 standard cubic centimeters per minute (sccm) while the nitrogen flow rate was varied from 0 to 25 sccm. Targets used for film deposition were FeTa sintered targets with a tantalum content of 5.0 and 10.0 wt %. The composition of films deposited from these targets was measured by x-ray fluorescence and was found to contain 1.8 and 3.2 at. % tantalum, respectively. A high-precision ac magnetostriction tester, based on the design by Tam and Schroeder, was used for magnetrostriction measurements.[8]

III. RESULTS AND ANALYSIS

A. Nitrogen dependence of λ_{100} and λ_{111}

The saturation magnetostriction in the FeTaN samples showed a strong dependence on the nitrogen flow rate during the film deposition. In the range of nitrogen flow rates examined in this study, the flow rate was roughly proportional to the amount of nitrogen present in the FeTaN films. Figure 1 shows the saturation magnetostriction as a function of the nitrogen concentration for films with different tantalum contents. The magnetostriction increased almost linearly with increasing nitrogen concentration. X-ray measurements showed little change in film structure with increasing nitrogen content, other than a decrease in the estimated grain size. The fact that the increase in magnetostriction with nitrogen concentration in these FeTaN samples is not due to the formation of new phases or changes in orientation of α-Fe as seen in other FeN systems should be emphasized.[3,9] That is, in the FeTaN samples the change in magnetostriction with nitrogen content is interpreted as being mainly due to changes in the magnetostriction constants caused by the addition of nitrogen to the α-Fe lattice.

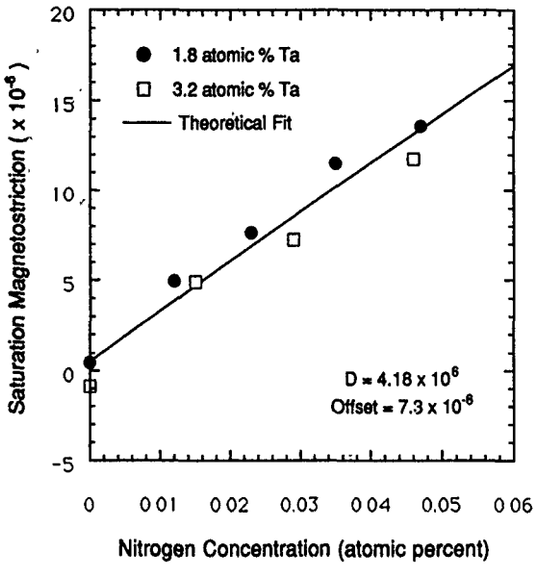

FIG. 1. Experimental values of magnetostriction for FeTaN samples for tantalum contents of 1.8 and 3.2 at. % vs nitrogen concentration. The theoretical line is calculated from Eqs. (3) and (4), using a value of $D=4.18\times10^6$ J/m^3.

This linear increase of the magnetostriction with nitrogen content can be modeled assuming changes in the magnetostriction constant of iron, λ_{100}, when nitrogen is added to interstitial sites in the α-Fe lattice. For this model we have extended the theory developed by De Vries for describing the magnetic after effects in iron films with interstitial nitrogen.[6,7] Our extension included consideration of two important points: (1) the variation of the magnetoelastic constants with nitrogen concentration, and (2) the relaxation time of the distributed nitrogen.

The theory and experiments of De Vries were for iron samples with very low (<0.04 wt %) amounts of nitrogen. For these low concentrations it was assumed that the values of the magnetoelastic coupling parameters, B_1 and B_2, did not depend on the nitrogen concentration. The FeTaN samples of the current research had a nitrogen concentration of up to 6 at. %, and it was found necessary to consider variations of the magnetoelastic coupling constants, B_1 and B_2, with nitrogen concentration in order to have a physically meaningful theoretical description.

It was also necessary to consider the relaxation time of the interstitial nitrogen to compare the current magnetostriction results with the earlier results of De Vries on magnetic after effects. Nitrogen in interstitial sites can diffuse to alternate sites with relaxation times of a few seconds, at 300 K, when the directions of applied magnetic fields are changed. This diffusion causes temporal changes in the magnetoelastic properties of the iron samples, thus producing a magnetic after effect. In the current research the ac-magnetostriction measurements were made in a time which is 25–100 times shorter than the relaxation time of the dissolved nitrogen, and no after effects can be observed. To help make this distinction clear, the magnetostriction constants will be designated as λ^{long} and λ^{short}, depending on whether the measurement time scales were long or short compared to the nitrogen relaxation time.

De Vries modified earlier models of Polder[10] and Néel[11] and postulated the following expression for the free energy per unit volume for a lattice containing interstitial atoms:

$$F-F_0=\frac{1}{2}c_{11}(e_{xx}^2+e_{yy}^2+e_{zz}^2)+\frac{1}{2}c_{44}(e_{xy}^2+e_{yz}^2+e_{zx}^2)+c_{12}(e_{xx}e_{yy}+e_{yy}e_{zz}+e_{zz}e_{xx})+B_1'\left[e_{xx}\left(\alpha_1^2-\frac{1}{3}\right)+e_{yy}\left(\alpha_2^2-\frac{1}{3}\right)\right.$$
$$\left.+e_{zz}\left(\alpha_3^2-\frac{1}{3}\right)\right]+B_2'(\alpha_1\alpha_2e_{xy}+\alpha_2\alpha_3e_{yz}+\alpha_1\alpha_3e_{zx})+\epsilon(C_xe_{xx}+C_ye_{yy}+C_ze_{zz})+\frac{RT}{2VC_0(1-C_0)}(C_x^2+C_y^2+C_z^2)$$
$$+D\left[\left(\alpha_1^2-\frac{1}{3}\right)C_x+\left(\alpha_2^2-\frac{1}{3}\right)C_y+\left(\alpha_3^2-\frac{1}{3}\right)C_z\right]+K_1(\alpha_1^2\alpha_2^2+\alpha_2^2\alpha_3^2+\alpha_3^2\alpha_1^2)+K_2\alpha_1^2\alpha_2^2\alpha_3^2. \quad (1)$$

In this expression, the nitrogen concentration is $3C_0$, the c's are elastic moduli, the e's are lattice strains, the α's are direction cosines of the magnetization with respect to the crystal axes, the C's are deviations of interstitial site occupations from the mean fraction C_0, B_1' and B_2' are the magnetoelastic coupling constants in a nitrogen-containing structure, the K's are the magnetocrystalline anisotropy constants, D is the interstitial interaction constant, ϵ is a strain-interstitial coupling constant. F_0 is the free energy without any effects of strain, interstitials, or magnetization direction, T is the absolute temperature, R is the gas constant, and V is the molar volume of iron.

Equation (1) was used to calculate the effect of the interstitial nitrogen on the magnetostriction constants. The lattice equilibrium was found by minimizing the free energy of Eq. (1) with respect to the strains e_{ij} and the interstitial concentrations C_i. Compared to the De Vries treatment, we have kept higher-order terms involving the nitrogen concentration ($3C_0$), and have allowed for the dependence of B_1 and B_2 on C_0. That is, our treatment allows for the variation of the magnetoelastic coupling constant, B, on the nitrogen concentration. With nitrogen interstitials, these constants are designated B_1' and B_2', and B_1' can be found from an expression for $\lambda_{100}^{\text{long}}$ as

$$B_1' = -\frac{3}{2}\lambda_{100}^{\text{long}}\left(c_{11}-c_{12}-\frac{\epsilon^2 V C_0(1-C_0)}{RT}\right) + \frac{\epsilon D V C_0(1-C_0)}{RT}. \quad (2)$$

The value of B_1' corresponds to the value of the instantaneous magnetostriction constant $\lambda_{100}^{\text{short}}$, and using the well-known relationship between λ_{100} and B_1, the magnetostriction constant, $\lambda_{100}^{\text{short}}$, can be expressed in terms of the nitrogen concentration ($3C_0$). Since the nitrogen atoms will attempt to occupy interstitial sites in planes perpendicular to the direction of the applied magnetic field, the $\lambda_{100}^{\text{long}}$ can be approximated by $\lambda_{100}^{\text{Fe}}$. The value of $\lambda_{100}^{\text{short}}$ will represent the measured value for a FeN film, which is represented as $\lambda_{100}^{\text{FeN}}$. This substitution yields

$$\lambda_{100}^{\text{FeN}} = \lambda_{100}^{\text{Fe}}\left(1-\frac{\epsilon^2 V C_0(1-C_0)}{(c_{11}-c_{12})RT}\right) - \frac{2}{3}\left(\frac{\epsilon D V C_0(1-C_0)}{(c_{11}-c_{12})RT}\right). \quad (3)$$

Following the procedure indicated above for the constant λ_{111} gives the result $\lambda_{111}^{\text{FeN}}=\lambda_{111}^{\text{Fe}}$.

By proper averaging the saturation magnetostriction for a film with a (110) orientation can be shown to be

$$\lambda_s = \frac{11}{32}\lambda_{100} + \frac{21}{32}\lambda_{111}. \quad (4)$$

Using this expression and Eq. (3), the theoretical value of the magnetostriction for a FeN film with a (110) orientation can be calculated, assuming that the nitrogen concentration is uniformly distributed in the film. Two sets of experimental data points and the theoretical fit are shown in Fig. 1. The values of the constants taken from the literature and used in the theoretical fit were $\epsilon=-9.2\times10^{10}$ J/m^3, $c_{11}=2.41\times10^{11}$ and $c_{12}=1.46\times10^{11}$ N/m^2, $T=300$ K, $\lambda_{100}^{\text{Fe}}=20.7\times10^{-6}$, $\lambda_{111}^{\text{Fe}}=-21.2\times10^{-6}$, $R/V=1.17\times10^6$ J/(m^{3}K). This fit describes the increase in magnetostriction with nitrogen content quite well. A vertical shift of the theoretical line was required to fit the experimental data. This could be caused by the presence of intercrystalline material, trace amounts of new phases, or orientations not detectable by x ray, or film contaminants. An average value of $D=4.18\times10^6$ J/m^3 gives a good fit to both sets of experimental points at room temperature. The value of D is roughly 10% less than the value reported by De Vries for his measurements conducted at 225 K. This is consistent with reports of a decrease in D with increase in temperature.[12]

B. Permeability

Measurements of other investigators have shown that the initial permeability along the hard axis of FeN films with a (110) orientation can be correlated with the magnetic anisotropy energy in each grain, calculated for a tetragonal deformation of the iron lattice under the assumption that the magnetocrystalline anisotropy constants, elastic moduli, and magnetostriction constants were the same as those for bulk iron.[13–15] Takahashi and Shimatsu have favorably compared the location of a maximum in the initial permeability for FeN films to the minimum in the total anisotropy energy per grain, U_{110}, of iron that occurs at a lattice strain of 0.0040.[16] The technique for calculating the total anisotropy per grain for an iron film has been described elsewhere.[13–16]

We have recalculated the total anisotropy energy per grain, U_{110}, with allowance for the dependence of λ_{100} on the nitrogen content in FeN films. The amount of lattice strain due to interstitial nitrogen was used to calculate the nitrogen concentration using an expression of Wriedt and Zwell that gives the dependence of the lattice constant of iron on the amount of interstitial nitrogen.[17] The magnetostriction constant, $\lambda_{100}^{\text{FeN}}$, can then be calculated using Eq. (3). In this calculation the total nitrogen concentration was given as $3C_0$ and the experimentally determined room temperature value of $D=4.18\times10^6$ J/m^3 was used. This value of $\lambda_{100}^{\text{FeN}}$ can then be used in the calculation of the total anisotropy energy as a function of the lattice strain. We have done this calculation and find that the energy minimum occurs at a value of lattice strain $\epsilon_{11}=0.0029$ which agrees closely with the experimental maximum in permeability previously reported at $\Delta d_{110}/d_{110}=0.0028$.[16]

ACKNOWLEDGMENTS

We would like to acknowledge the assistance of IBM in the x-ray fluorescence measurements of the tantalum content of the films. The research reported here was partially supported by a grant from the Department of Commerce Advanced Technology Program administered by NSIC. Dependence of the magnetic properties $Gd_{2-x}Ce_xCuO_4$, $0 \leq x \leq 0.15$, on their particle size

$Gd_{2-x}Ce_xCuO_4$, $0 \leq x \leq 0.15$, have been synthesized by the solid state reaction, the sol-gel technique and the water-in-oil microemulsion, in order to vary the particle size. The samples have been characterized by x-ray diffraction, photon correlation spectroscopy and transmission electron microscopy. Magnetization and ac susceptibility measurements were performed between 4 and 300 K. The extrapolated linear part of the inverse magnetization shifts to lower temperatures as the particle size decreases. The internal field associated to the WF of the Cu moments diminishes with the particle diameter. Differences between the zero-field-cooling and the field-cooling magnetization curves were observed for $T < T_N$. These differences depend on the particle size.

Since the discovery of the new family of electron doped superconductors $R_{1.85}M_{0.15}CuO_4$ (with R=Pr, Nd, Sm, Eu, and M=Ce, Th)[1] much attention has been focused on the study of the properties of these materials.[2] Gd_2CuO_4 has been found not to be superconducting when doped with Ce or Th,[3] as contrary to the lighter rare earths compounds. This family crystallizes in the tetragonal Nd_2CuO_4-type structure with the Cu(II) ions ordered antiferromagnetically (AF) at $T_N \approx 270$ K. The interest in Gd_2CuO_4 lies on the possible relationship between its magnetic properties and its no-superconducting behavior. The magnetic properties of this compound have been studied in detail for single crystals and powders.[4] This compound shows a WF component below $T_N \approx 270$ K, possibly due to a distortion of the oxygens surrounding the Cu moment in the T' phase, which occurs for rare earths lighter than Eu(III).

In the present work, we describe the synthesis of $Gd_{2-x}Ce_xCuO_4$ (with $x=0.00$, 0.05, 0.10, and 0.15) using a sol-gel technique and water-in-oil (W/O) microemulsions. Both techniques allow us to obtain polycrystalline powders of controlled size. We performed magnetization measurements in order to study the influence of particle size on the magnetic properties of these materials.

We used three different techniques to obtain particles of different sizes:

(1) Solid state reaction, using a stoichiometric mixture of Gd_2O_3 and CuO as starting materials. The mixture was ground in a ball mill and then annealed first at 800 °C for 24 h with several intermediate grindings followed by a second annealing at 850 °C for 48 h. The resulting powder was used as a reference.

(2) Sol-gel technique, using urea as gelificant agent. As starting materials stoichiometric amounts of nitrate salts were used, due to their high solubility in water. The solvent was evaporated directly on a hot plate with continuous stirring. When cooling a gel is formed, which is decomposed in an oven at 250 °C, yielding the precursor of these samples. After grinding the precursor, it was submitted to several annealings at different temperatures in order to obtain particles of different sizes. More details of this process had been previously reported.[5]

(3) Synthesis of Gd_2CuO_4 was done by means of a W/O microemulsion. We used *n*-heptane as organic phase, Aerosol-OT (bis-2-ethyl hexyl sodium sulfosuccinate) as surfactant and a solution of citric acid and nitrate salts as an aqueous phase. The microemulsion was heated on a hot plate to evaporate part of the organic phase. This gel was washed with *n*-heptane and acetone. The resulting powder was dried yielding to the precursor of these samples. After grinding the precursor, it was subjected to different annealings.

The polycrystalline powders were structurely characterized by x rays. The size distribution was measured by photon correlation spectroscopy (PCS) and transmission electron microscopy (TEM). The magnetic measurements were made between 4 K $\leq T \leq$ 300 K using SQUID and VSM magnetometers in fields up to 5 kOe.

X-ray diffraction of the samples synthesized by the solid state reaction indicates a pure Gd_2CuO_4 phase. Similar data for Gd_2CuO_4, obtained via sol-gel, show almost a pure phase for samples annealed at temperatures as low as 650 °C. The time necessary to obtain this phase decreases considerably when the calcination temperature increases. For example, 72 h are needed at 650 °C but only 3 h at 950 °C. Seven samples between these two temperatures were obtained. $Gd_{2-x}Ce_xCuO_4$ (with $x=0.05$, 0.10, and 0.15) was also prepared via sol-gel. It was observed that when the annealing temperature decreases so does the solubility of Ce in the compound. When $x=0.05$, 0.10, and 0.15 the pure phase is obtained only for temperatures above 700, 750, and 900 °C, respectively. For samples synthesized in W/O microemulsions, the Gd_2CuO_4 phase is obtained at 700 °C. X-ray diffraction shows the presence of ≈10% of Gd_2O_3 as a secondary phase. The amount of this secondary phase is almost independent of the annealing temperature. Five samples were

prepared between 700 and 950 °C using W/O microemulsions.

The particle size of the different samples was measured by PCS. Figure 1 shows the average diameter of the particles as a function of the annealing temperature for samples obtained via sol-gel. As it can be seen the particle size increases with annealing temperature. The particles synthesized by ordinary solid state reaction present high polydispersity, contrary to the obtained by the wet methods, with sizes in the range 0.2–4 μm.

Figure 2 shows two TEM photographs, one for a sample prepared by the solid state reaction [Fig. 2(a)], and the other for a sol-gel sample annealed at 750 °C [Fig. 2(b)]. As it can

be seen, ceramic samples are relatively large ($\approx 1\mu$m), while the sol-gel particles are of the order of $\approx$100 nm. The sizes measured by PCS and TEM agree well.

dc magnetization data show that the WF component found in single crystals and in polycrystalline samples of Gd_2CuO_4 below $\approx$270 K,[4] as shown in Fig. 3(a) for a ceramic sample, is depressed in a sample annealed at 800 °C, as seen in Fig. 3(b). The WF peak in single crystals occurs at the ordering temperature of Cu(II) moments and is due to a distortion from a perfect square of the CuO_2 plane, because of the displacement of oxygen atoms along the normal to the Cu—O bond. Such a distortion results in spin-canted antiferromagnetic domains ("canted" AF ordering of the Cu moments). This property is better appreciated when plotting the χ^{-1} vs T, as done for sol-gel Gd_2CuO_4 samples in Fig. 4. If we associate the extrapolated temperature of the linear part of χ^{-1} with the onset of WF, we observe that the transition temperature seems to be reduced with the particle size. ac susceptibility measurements done in the same samples held similar results. In Fig. 5 it is shown the extrapolated temperature, T_{extr}, obtained by ac and dc measurements. The disappearance of the internal field could be explained if the size of the particles becomes comparable with the correlation length of the Cu(II) antiferromagnetic order. Another explanation could be due to the surface effects which become more important for smaller particles and such effects could slightly modify the lattice parameters, which are determinant in the onset of WF.[2] It is worth mentioning that besides the effects on this peak, other features observed are the decrease of the absolute magnetization values and differences between field cooling (FC) and zero field cooling (ZFC) magnetization curves.

In Fig. 6 the evolution of the internal field, H_i, extrapolated from the paramagnetic part of M vs H measurements at high field as a function of the temperature for sol-gel is presented. Values for ceramic and single crystal samples are also included. It is clear that the internal field diminishes with the particle size.

For the sol-gel $Gd_{2-x}Ce_xCuO_4$ samples, H_i decreases with the annealing temperature and cerium doping as seen in Fig. 7. The internal field is more sensitive to the thermal annealing than to cerium doping.

Magnetic properties of materials in the $CaO-P_2O_5-Fe_2O_3$ system

Binod Kumar and Christina H. Chen
University of Dayton Research Institute, Dayton, Ohio 45469-0170

The magnetic properties of numerous compositions in the ternary $CaO-P_2O_5-Fe_2O_3$ system have been studied. A relatively wide glass formation region is located around the P_2O_5 corner of the system. The Fe_2O_3-containing glasses exhibit paramagnetic behavior. The specimens inside the composition range $Fe_2O_3 \geq 30\%$ consist of both paramagnetic and ferrimagnetic phases.

Glass formation in the $CaO-P_2O_5-Fe_2O_3$ system has been known and studied for over two decades.[1–4] The system provides a wide range of glass specimens for optical and magnetic studies. However, the motivation for early studies was primarily academic. The phosphate glass-forming system has recently attracted considerable attention as potential biomaterials.[5–7] The $CaO-P_2O_5-Fe_2O_3$ system has also been of considerable interest in steel making.[8]

In $CaO-P_2O_5-Fe_2O_3$ glasses and slags, iron exists in primarily two oxidation states, the Fe^{2+} and Fe^{3+} states, which give rise to well documented characteristic optical and magnetic phenomena. The magnetic susceptibility of a few compositions in the $CaO-P_2O_5-Fe_2O_3$ system has been measured and reported by Sanad *et al.*.[9] However, a complete understanding of the basic mechanisms leading to variations in magnetic properties in a wide range of compositions is lacking. Thus, the purpose of this study is to conduct a limited but systematic study of the magnetic properties in the $CaO-P_2O_5-Fe_2O_3$ system.

The compositions used in this investigation are shown in Table I. The details for sample preparation were reported earlier.[4] After casting, the materials were annealed at 500 °C in air. Two were further heat treated before being characterized for magnetic properties. Magnetic susceptibility was measured using a Princeton Vibrating Sample Magnetometer Model 151 from 20 to 500 °C. A few specimens were also characterized for microstructures using optical microscopy, SEM, and energy dispersive x-ray analysis.

Figure 1, a ternary diagram, shows the locations of the synthesized compositions. General observations on these compositions are presented in Table I. Based on these observations and magnetic measurements, the $CaO-P_2O_5-Fe_2O_3$ system is divided into three regions: glass-forming region, refractory region ($T_m > 1400$ °C), and ferrimagnetic region.

The glass-forming region has a relatively wide composition range around the P_2O_5 corner. In this region, specimens were melted easily in the temperature range of 1000–1400 °C and retained their vitreous character during the casting and heat treatment processes. Some compositions inside the ferrimagnetic region also melted with relative ease; however, they crystallized during the casting and heat treatment processes. Compositions with $(CaO+Fe_2O_3) > 60\%$ exhibited significant refractoriness, and three (Nos. 8, 11, and 12) did not melt.

Figure 2 shows magnetic susceptibility, χ, as a function of temperature for three specimens: Nos. 17, 18, and 19. These compositions are located in the glass-forming region. The calcium phosphate glass, No. 19, alone exhibits diamagnetic behavior with a negative χ, which is relatively independent of temperature. When iron is introduced to the binary phosphate glass, it gives rise to paramagnetic behavior, the degree of which is directly related to the iron concentration. Paramagnetism originates from the presence of permanent magnetic dipole moments in the materials. Both oxidation states of iron, Fe^{2+} and Fe^{3+}, lead to permanent dipole moments. The magnetic moment of Fe^{3+}, with five unpaired electrons, is higher than that of F^{2+}, which has only four. It has recently been reported that the melting atmosphere has a major influence on the relative proportion of Fe^{2+} and Fe^{3+} states in these glasses.[10] In general, the oxidizing atmosphere increases the proportion of Fe^{3+}. The melting atmosphere-induced redox state also affects the resulting physical and chemical properties of the glasses.[7] The paramagnetism of Nos. 17 and 18 exhibit significant temperature dependence. Specimen No. 17 is a weaker paramagnetic material whose magnetic susceptibility is close to zero at elevated temperature. In general, paramagnetic susceptibility decreases with increasing temperature.

Paramagnetic materials show a linear relationship between applied magnetic field, H, and specific magnetization, σ. Ferrimagnetism yields a nonlinear relationship between H and σ and also results in a hysteresis effect. The bulk specimens 5, 6, 7, 9, and 10 located in the ferrimagnetic region

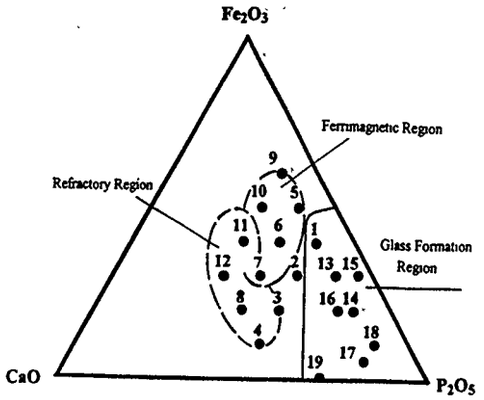

FIG. 1. Synthesized compositions in the CaO-P_2O_5-Fe_2O_3 system.

contain both paramagnetic and ferrimagnetic phases. Magnetic properties of these bulk specimens are comprised of contributions from both phases. Figure 3(a) shows a σ vs H plot of bulk No. 6 heat treated at 700 °C. The bulk magnetic response is resolved into ferrimagnetic and paramagnetic contributions as shown in Figs. 3(b) and 3(c).

Magnetic parameters ${}_MH_c$, σ_s, σ_r, and χ of specimens 2, 5, 6, 7, 9, and 10 are presented in Table II. It is interesting that the paramagnetic contributions remain constant at $\sim 6\times10^{-5}$ emu/(g Oe) for all the specimens in the ferrimagnetic region. The paramagnetic phase is believed to be a vitreous phase containing Fe_2O_3, whereas the ferrimagnetic phase is a crystalline phase containing mostly P_2O_5 and Fe_2O_3. Specimen 10 ($20CaO\cdot40P_2O_5\cdot50Fe_2O_3$) has the highest saturation $\sigma_s \approx 26.0$ emu/g. Optical microscopy of specimen 10 revealed three phases. The volume fraction of the ferrimagnetic phase as determined from optical microscopy is about 83%. From this data, the σ_s for a single ferrimagnetic phase is estimated to be 31 emu/g which is higher than that for cubic ferrites $MgO\cdot Fe_2O_3$ and $CuO\cdot Fe_2O_3$.

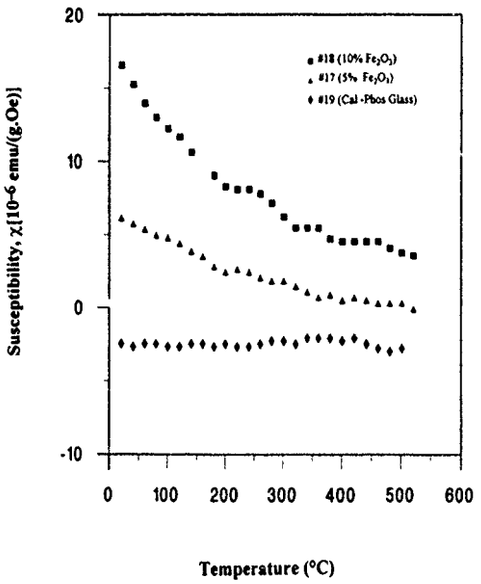

FIG. 2 Magnetic susceptibility χ vs temperature of Nos. 17, 18, and 19.

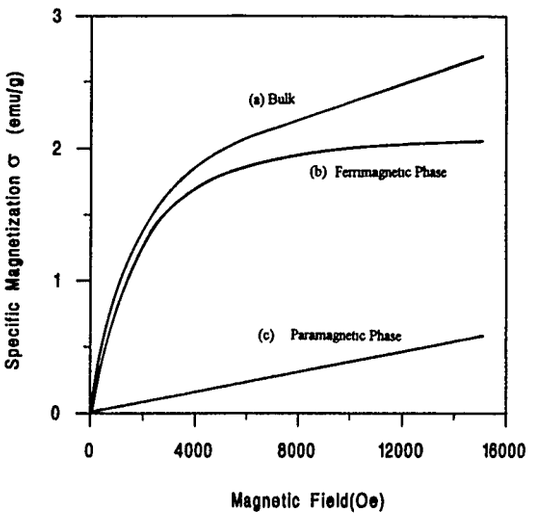

FIG. 3. Magnetization curve of No. 6 heat treated at 700 °C. (a) Bulk, (b) ferrimagnetic phase, (c) paramagnetic phase.

The magnetization curves of No. 5 are shown in Fig. 4. After annealing at 500 °C, No. 5 displays ferrimagnetic behavior with a large hysteresis loop: remanent magnetization $B_r=29.5$ G ($\sigma_r=0.3$ emu/g) and intrinsic coercivity ${}_MH_c=450$ Oe. The specimen was further heat treated at 600, 700, 750, and 850 °C for 24 h. The higher the heat treatment temperature, the lower the degree of ferrimagnetism, and it vanishes at 850 °C. Specimen No. 6 exhibited similar behavior. Table III presents a comparison of the magnetic properties of Nos. 5 and 6 for similar heat treatments. It is apparent that No. 6 possesses ferrimagnetism superior to that of No. 5, in spite of the fact that No. 6 has a lower iron concentration. However, additional heat treatments have a negative effect on the ferrimagnetic behavior of both specimens.

In an attempt to characterize the ferrimagnetic phase, specimen No. 5 was examined using scanning electron microscopy and energy dispersive x-ray analysis. The scanning electron micrographs for the 500 °C annealed and 850 °C heat-treated specimens are shown in Fig. 5. The microstructures of the specimens consist of three phases: dark gray, gray, and light gray. For the specimen after 850 °C/24 h heat treatment, its dark-gray and light-gray phases increase from 26% and 15% to 36% and 42%, respectively, and its gray

TABLE II. Ferrimagnetic paramagnetic properties of the compositions in the ferrimagnetic region at room temperature.[a]

Sample No.	Ferrimagnetism of bulk specimen ${}_MH_c$ (Oe)	σ_s (emu/g)	σ_r (emu/g)	Ferrimagnetic phase	Paramagnetism $\chi=M/H$ (emu/g Oe)

9	~80	~0.01	<0.01		6.2×10^{-5}
10	110	26.0	3.1	83%	6.7×10^{-5}

[a]All the specimens were heat treated at 500 °C but No. 6 was heat treated at 700 °C.

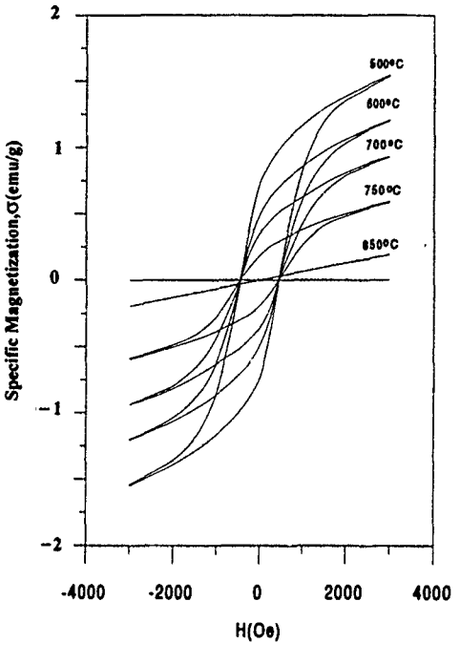

FIG. 4. Magnetization vs magnetic field of No. 5 as a function of heat treatment temperatures.

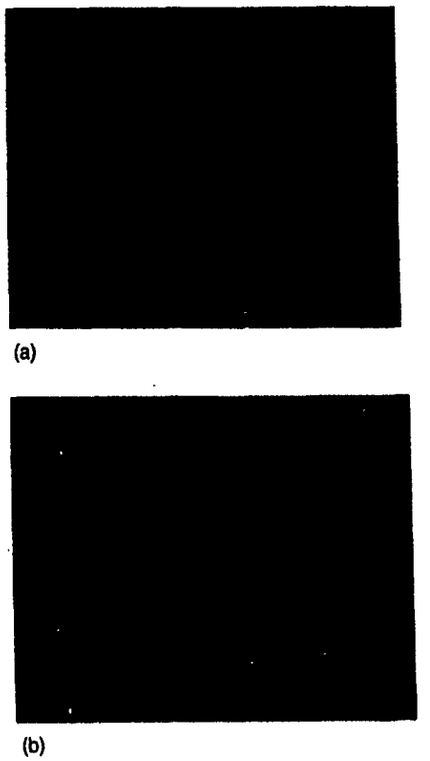

FIG. 5. Microstructures of No. 5 ($10CaO \cdot 40P_2O_5 \cdot 50Fe_2O_3$, wt %). (a) After 500 °C annealing, (b) after 850 °C/24 h heat treatment.

phase diminishes from 59% to 22%. Thus, we believe that this gray phase is responsible for the observed ferrimagnetism. The energy dispersive analysis reveals a composition of this phase to be approximately $3Fe_2O_3 \cdot P_2O_5$.

The lack of phase equilibrium and crystallographic data in the CaO-P_2O_5-Fe_2O_3 system has limited our ability to analyze and identify the ferrimagnetic phase in the system. However, it is interesting to note that a ferrimagnetic compound exists in the CaO-P_2O_5-Fe_2O_3 system. The phosphate-based magnetic materials may potentially have some application in the field of biomedical engineering.

Three regions have been found in the CaO-P_2O_5-Fe_2O_3 system. A wide glass-forming region is located around the P_2O_5 corner, in which bulk specimens could be prepared using a normal casting procedure and cooling rate. The calcium phosphate glass exhibits temperature independent diamagnetism. Adding iron to the calcium phosphate system leads to paramagnetic behavior. A ferrimagnetic region is located in the composition range with 10%–30% CaO, 30%–40% P_2O_5, and $\geq$30% Fe_2O_3. Samples inside the region contain both paramagnetic and ferrimagnetic phases. Subsequent heat treatments at 600–850 °C reduces or destroys the ferrimagnetism.

Magnetic properties of $Y_{3-x-y}Pr_xLu_yFe_5O_{12}$ garnet films

A. Azevedo, C. Cinbis, and M. H. Kryder
Data Storage Systems Center, Carnegie–Mellon University, Pittsburgh, Pennsylvania 15213

In this work we report on the magnetic and low-field ferromagnetic resonance properties of iron garnet films of general composition $Y_{3-x-y}Pr_xLu_yFe_5O_{12}$ for $0 \leq x \leq 0.3$ and $0 \leq y \leq 0.7$. The films were grown onto [111] gadolinium gallium garnet substrates by liquid phase epitaxy. Both growth-induced and cubic anisotropies were investigated by means of torque magnetometry and ferromagnetic resonance at room temperature. The growth-induced anisotropy constant K_u and the first order magnetocrystalline cubic constant K_1 exhibit a linear dependence with the praseodymium content. The addition of Lu with Pr enhances both K_u and K_1 dependence on the doping, yielding $\Delta K_u/x \sim -2.4\times10^5$ erg/cm^3 and $\Delta K_1/x \sim -1.1\times10^5$ erg/cm^3. The addition of praseodymium in the garnet films significantly improves the soft magnetic properties. In-plane coercivity is about 0.1 Oe and there is a negligible anisotropy in the plane of the film. The effect of the doping by praseodymium and lutetium on the saturation magnetization is insignificant at room temperature.

I. INTRODUCTION

Magnetic garnets exhibiting growth induced uniaxial anisotropy have been intensely studied.[1] Many epitaxially grown garnet films exhibit a positive uniaxial anisotropy, and thus the easy or preferred axis of magnetization is perpendicular to the film plane. In contrast, praseodymium-substituted iron garnet films exhibit an in-plane growth-induced anisotropy.[2]

The purpose of this paper is to present the magnetic and low-field ferromagnetic resonance properties of praseodymium-doped iron garnet films as a function of the doping content. Films of general composition $Y_{3-x-y}Pr_xLu_yFe_5O_{12}$ for $0 \leq x \leq 0.3$ and $0 \leq y \leq 0.7$, were grown by liquid phase epitaxy (LPE) onto [111]-oriented gadolinium gallium garnet (GGG) substrates. Lutetium was added, along with praseodymium to compensate for the lattice mismatch which would be produced due to the addition of large praseodymium ions, alone, into the garnet lattice. The uniaxial anisotropy constant K_u and the saturation magnetization $4\pi M_s$ were measured by torque and vibrating sample magnetometry respectively. The first order cubic anisotropy constant K_1 and the gyromagnetic ratio γ were obtained by low-field ferromagnetic resonance (FMR) measurements. Using a hysteresis loop tracer we have also measured the coercivity.

II. EXPERIMENTAL RESULTS

All films have been grown in super-saturated solutions using PbO-B_2O_3 based flux by the horizontal dipping technique. The films were grown isothermally using a continuous rotation rate of 100 rpm for typically 3 min. The growth rate varied between 1 and 3 μm/min. The film thickness ranges between 1 and 12 μm. The growth temperature ranged between 1000 and 1050 °C using supercooling ΔT between 5 and 50 °C. The initial molar fluxed melt composition used was: 333.119 g of PbO, 14.587 g of B_2O_3, 47.366 g of Fe_2O_3, and 4.927 g of Y_2O_3. The effects of praseodymium doping were then investigated by adding praseodymium and lutetium oxide in small increments.

The chemical composition and the thickness of the films were measured using a x-ray fluorescence spectrometer. The saturation magnetization was measured with a vibrating sample magnetometer in fields up to 6 kOe at room temperature. Care was taken to extrapolate the magnetization data to zero field to avoid the large paramagnetic susceptibility of the GGG substrate. The $4\pi M_s$ values indicate that the effect of praseodymium is negligible at room temperature, in agreement with Hansen *et al.*.[2]

The hysteresis loop traces were performed with the applied field parallel to the direction $[11\bar{2}]$ at 10 Hz. There was a very small sixfold in-plane anisotropy, which only affected the rapidity of the approach to saturation, but not the coercivity of the hysteresis loops in different directions. This anisotropy is believed to be due to the magnetocrystalline anisotropy arising from the [111] orientation of the cubic garnet single crystal lattice. Two hysteresis loop traces for two different doping concentrations are shown in Fig. 1. A hysteresis loop for a pure YIG (yttrium iron garnet) film, which exhibits a coercivity of about 2.2 Oe is shown in Fig. 1(a). The hysteresis loop trace shows that the direction $[11\bar{2}]$ is a hard axis with an anisotropy field of about 55 Oe. A hysteresis loop trace for a $Y_{2.25}Pr_{0.25}Lu_{0.5}Fe_5O_{12}$ film, which exhibits a coercivity of 0.094 Oe and is saturated at about 0.94 Oe is shown in Fig. 1(b). The anisotropy of the pure YIG film is completely removed as a result of the praseodymium doping. A plot of coercivity as a function of Pr content, x, is shown in Fig. 2. It is seen that for $x > 0.14$ the coercivity reaches a minimum value of about 0.1 Oe.

We used the torque curve measurements to investigate the influence of the praseodymium content on the uniaxial anisotropy constant K_u. The torque per unit volume from a (111)-growth plane with the applied field in the $(\bar{1}10)$ plane is given by, $L = -\partial E/\partial\alpha \simeq -(K_u - 2\pi M^2)\sin 2\alpha$. Where E is the free energy per unit volume and α is the angle between the magnetization and the easy direction. Here we have neglected the contribution from K_1 and from the Zeeman energy, since the applied field was sufficiently high ($H = 11.5$ kOe) to suppose that **M** and **H** were essentially parallel. The concentration dependence of the uniaxial anisotropy constant K_u is shown in Fig. 3(a). The plot indicates a strong negative contribution to K_u from the praseodymium content. An approximately linear dependence of K_u on x of the form $\Delta K_u/x \sim -2.4\times10^5$ erg/cm^3, was found.

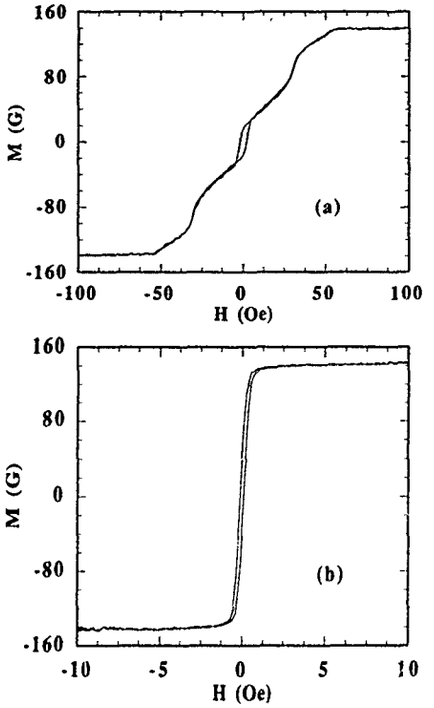

FIG. 1. In-plane hysteresis loop traces (a) for a pure YIG film and (b) for the film $Y_{2.25}Pr_{0.25}Lu_{0.5}Fe_5O_{12}$. The praseodymium-doped iron garnet film has a coercivity of 0.094 Oe and is saturated for fields around 1.0 Oe. The anisotropy of the pure YIG was eliminated, as seen in (a).

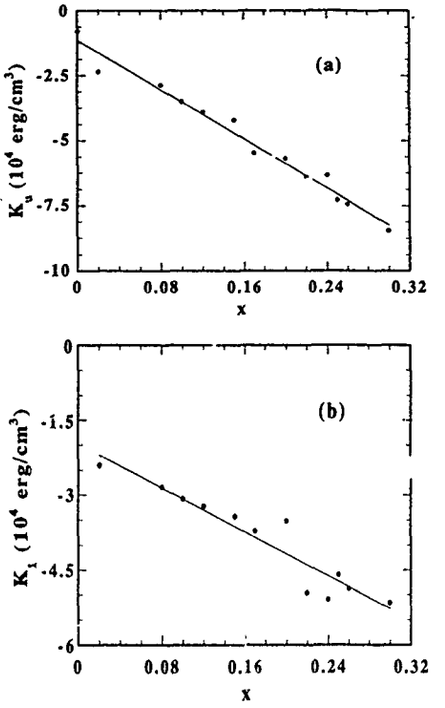

FIG. 3. Concentration dependence of the growth-induced anisotropy constant K_u (a) and the first order magnetocrystalline cubic constant K_1 (b) as a function of the praseodymium content. The negative linear dependences are given approximately by $\Delta K_u/x \sim -2.4\times10^5$ erg/cm^3 and $\Delta K_1/x \sim -1.1\times10^5$ erg/cm^3.

Low-field FMR measurements were performed on the films using a microwave microstrip transmition line, with the in-plane dc field parallel to the $[11\bar{2}]$ direction. The FMR spectra, for low magnetic in-plane fields ($H<20$ Oe) present a strong single mode absorption peak. The dc magnetic field was varied from 20 to 1000 Oe and the FMR frequency was measured for each value of H. Thus, the FMR frequency was plotted as a function of H for each sample. To interpret the low-field FMR measurements, we have derived an equation taking into account the noncollinearity between **H** and **M** on the $(\bar{1}10)$ plane.[3] The resonance condition is given by

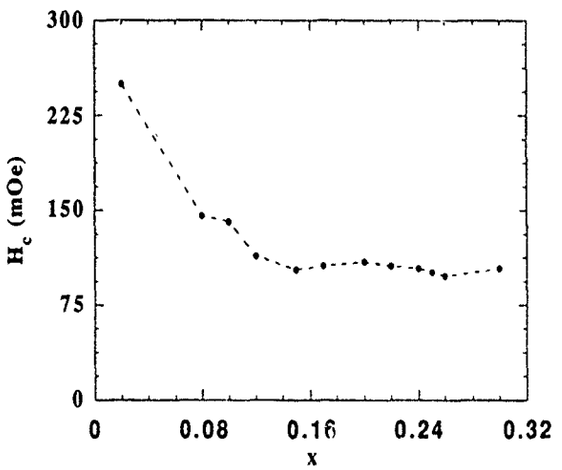

FIG. 2. Dependence of the coercivity on the praseodymium doping. The magnetic field was applied along the direction $[11\bar{2}]$.

$$\left(\frac{\omega}{\gamma}\right)^2=\frac{1}{M^2}\left[HM-2K'+K_1\left(-1+\frac{10\sqrt{2}}{3}\,\epsilon\right)\right]\times(HM+3\sqrt{2}K_1\epsilon) \quad (1)$$

where, $\epsilon\simeq-\sqrt{2}K_1/6K'$ is the small angle between $\bar{H}$ and $\bar{M}$, $K'=K_u-2\pi M^2$, K_1 is the first order magnetocrystalline cubic anisotropy constant, γ is the gyromagnetic ratio, and ω is the resonance frequency. The equation above is corrected to second order in K_1. For $\epsilon=0$, it reduces to the usual equation given by Sturge *et al.*.[4]

Using the measured values of K_u and $4\pi M_s$, Eq. (1) was fitted to the FMR data, yielding the values of K_1 and γ. The dependence of the first order magnetocrystalline cubic anisotropy constant K_1 on the praseodymium content obtained in this manner is shown in Fig. 3(b). The linear dependence of K_1 with x yields, $\Delta K_1/x \sim -1.1\times10^5$ erg/cm^3. Negative values of K_1 were already reported for bulk praseodymium-substituted garnet materials.[5]

III. CONCLUSION

We have investigated the influence of praseodymium and lutetium on the properties of garnet films. The praseodymium and lutetium doping give rise to a strong in-plane anisotropy and improves the soft-magnetic properties of the films. The microwave absorption spectra, for low magnetic in-plane fields ($H<20$ Oe) present a strong single mode resonance line characteristic of single-domain samples. The results reveal a strong dependence of both the first order

magnetocrystaline anisotropy constant K_1 and the uniaxial anisotropy constant K_u on the doping content. The linear dependence of K_u and K_1 on x is approximately $\Delta K_u/x \sim -2.4\times10^5$ erg/cm^3 and $\Delta K_1/x \sim -1.1\times10^5$ erg/cm^3. The influence of the doping on the saturation magnetization is negligible at room temperature, in agreement with prior results.[2]

$Cr_{100-x}Fe_x$ amorphous alloys have been prepared through two different routes: thermal coevaporation and mechanical milling. The Mössbauer measurements on the materials show that the amorphization leads to a dramatic reduction of Fe magnetic moment as compared to the crystalline bulk samples. On the other hand, the magnetic ac susceptibility and the magnetization measurements indicate a dominant ferromagnetic intracluster interaction with a competing intercluster interaction. Such a competition could give rise to a spin-glass-like behavior.

I. INTRODUCTION

To obtain an amorphous binary alloy by the melt-quenching technique, either the constituents of the alloy should have a considerable difference in atomic sizes (usually larger than 15%) or some metalloid elements must be included. Therefore binary alloy systems composed of constituents with similar atomic radii are considered to be difficult for amorphization. Recently, we have succeeded in obtaining amorphous Fe–Cr alloys through mechanical milling[1] and thermal evaporation.[2]

The magnetism of the crystalline Cr–Fe alloys and Fe–Cr–M amorphous state stabilized by the addition of some amount of metalloid metal M have been a subject of intensive study in the past decades.[3–8] Differing from the crystalline alloys, the Curie temperature, and the magnetic moment of the glassy $Fe_{100-x}Cr_xM_y$ alloys have been found to fall much more rapidly with increasing x. The magnetic order disappears around $x=30$.

It would be interesting to know if the amorphous Cr–Fe alloys maintain the same magnetic properties as the Cr–Fe–M amorphous alloys and how the magnetism behaves. In this work, the magnetic behaviors of the Cr–Fe amorphous state are investigated through the analyses of the Mössbauer spectra, the ac susceptibility, and the magnetization measurements.

II. EXPERIMENTAL DETAILS

$Cr_{100-x}Fe_x$ films were prepared by thermal coevaporation from pure Cr and Fe metals, deposited onto kapton substrates held at room temperature (RT). During the depositions, the vacuum was about 3×10^{-7} Torr. A quartz crystal oscillator was used to control the deposition rate, which was about 25 Å min for all the films and also to monitor the compositions, which were conformed by energy dispersive analysis (EDS). All the films have a thickness of about 3000 Å. The x-ray diffraction (XRD) patterns of the obtained films show a prominent amorphous phase in the range $25<x<60$, and a BCC phase appears out of this range.

The mechanically milled powder was obtained through ball milling of $Cr_{72}Fe_{28}$ solid solution at RT performed in a vibrating frame using a hardened steel vial and 16 balls, 5 with a diameter of 1.5 cm and 11 with a diameter of 1 cm. During the milling process, the sample was sealed in a vial filled with argon gas. The XRD patterns indicate a formation of an amorphous phase after 200 hs milling. The compositions analysis by EDS for the powder milled for 200 hs shows an increase of Fe concentration from 28% to 35%, and little amount of Ni (less than 0.4%), which was due to the contamination from the milling tools.

The Mössbauer effect was measured at 4.2 K for all the samples, using a ^{57}Co source in the Rh matrix. ac susceptibility was measured in a cryostat by a mutual inductance method operating at 128 Hz. The magnetization measurements were performed by a vibration sample magnetometer.

III. RESULTS AND DISCUSSION

Figures 1(a) and 1(b), respectively, show the RT and 4.2 K Mössbauer spectra of the $Cr_{72}Fe_{28}$ BCC bulk alloy, $Cr_{65}Fe_{35}$ amorphous powder and $Cr_{50}Fe_{50}$ amorphous alloy film. Due to the disordered structure, which leads a quadrupole splitting distribution, the RT Mössbauer spectra of the

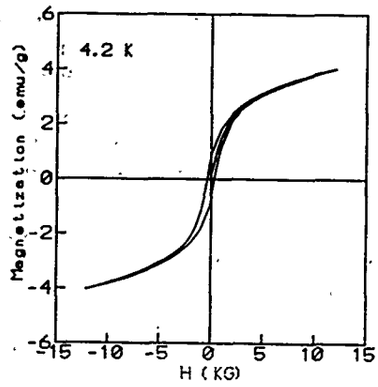

FIG. 2. Magnetization curve of $Cr_{65}Fe_{35}$ mechanically milled amorphous alloy measured at 4.2 K.

two amorphous alloys exhibit a broad absorption line and the more negative isomer shifts, as compared with the crystalline one. As the samples are cooled down to 4.2 K, unlike the crystalline alloy, the amorphous samples still maintain the unsplitted spectra, although they are more concentrated in Fe. Such behavior looks like $Fe_{85-x}Cr_xB_{15}$ amorphous alloys with $x>30$, above which the alloys were considered to be paramagnetic.[7] However, one dose sees a magnetic broadening for the film sample by comparing the 4.2 spectrum with the RT one. For the amorphous powder, on the other hand, the spectrum broadening is not as pronounced as that of the film, therefore, the Fe may not have or carry a very small magnetic moment. The magnetization curve measured at 4.2 K in Fig. 2 for the powder, however, indeed shows a magnetic order. Taking into account the magnitude of the saturation magnetization (Fig. 2), it may be clear that the Cr in the sample carries the magnetic moment, which cannot be detected by Mössbauer spectroscopy.

The ac susceptibilities χ'_{ac} and $1/\chi'_{ac}$ [Figs. 3(a) and 3(b)] exhibit an interesting magnetic feature. Differing from Cr–Fe BCC crystalline samples, the results for both of the amorphous alloys indicate the absence of a long range ferromagnetic ordering. The results show a Curie–Weiss paramagnetic behavior above about $T=100$ K for an amorphous $Cr_{65}Fe_{35}$ powder alloy and 230 K for a $Cr_{50}Fe_{50}$ film alloy [the arrows in Fig. 3(b)], with positive Curie–Weiss temperatures. Below these temperatures, a competing interaction between ferromagnetism and antiferromagnetism is suggested by the maximums [Fig. 3(a)]. The temperature at which $\partial\chi'_{ac}/\partial T$ reaches the maximum is found to be $T=33$ K for the powder and 50 K for the film [the arrows in Fig. 3(a)], which coincide with the maximum values of χ''_{ac}.

The above magnetic behavior may be related to the feature that is similar to the systems where the magnetic properties are dominated by finite cluster effects. The ferromagnetic intracluster ordering occurs at higher temperature, while the competing intercluster interaction leads to a spin-glass-like behavior, and the clusters are frozen at the temperatures (defined as the maximum of $\partial\chi'_{ac}/\partial T$) of 33 K for the powder and 50 K for the film.

The temperature dependence of magnetization for $Cr_{35}Fe_{65}$ amorphous powder was measured with an applied

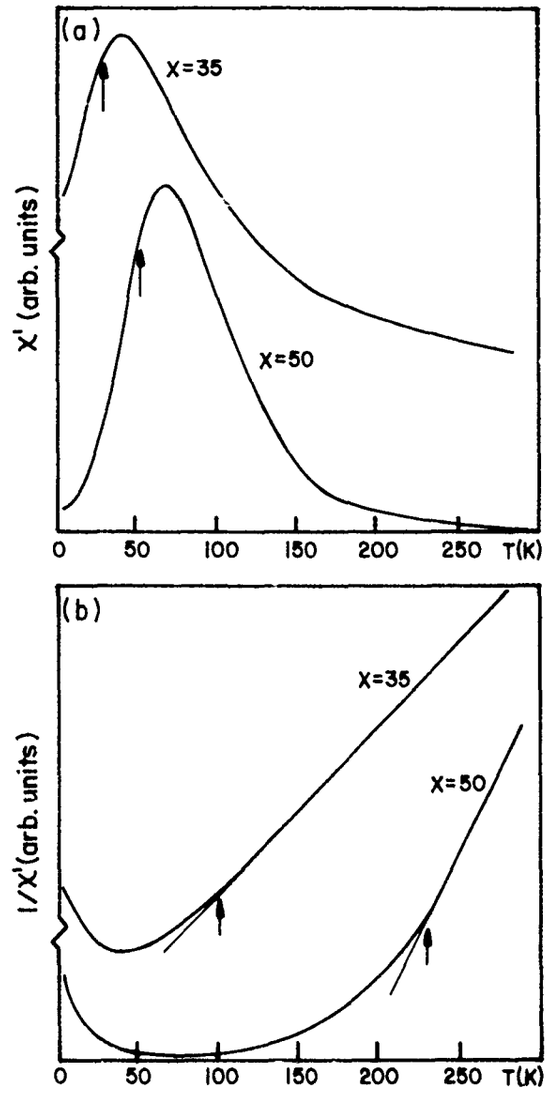

FIG. 3. (a) ac susceptibilities, χ', of $Cr_{65}Fe_{35}$ mechanically milled amorphous powder and $Cr_{50}Fe_{50}$ thermal evaporated amorphous film and (b) the $1/\chi'$ curves for these two samples.

field of 100 G, as shown in Fig. 4. By comparing with the result of ac susceptibility, the maximum on the zero field cooled (ZFC) curve can be related to the cluster freezing. Since the ZFC curve (in Fig. 4) can be taken as a zero frequency susceptibility, one expects a lower blocking temperature than that obtained by ac susceptibility, which can be seen by comparing the two corresponding curves. Figure 4 also shows that the field cooled (FC) magnetization curve deviates from the ZFC values, even above the maximum of the ZFC curve. This may be explained by a distribution of cluster size, which may, in turn, lead to distribution of blocking temperature. The maximum on the ZFC curve may be related to the most probable blocking temperature.

The cluster-like magnetic character for both of the amorphous materials may be associated with the formation of finite size granular structure in our specimens. In an earlier work, we observed a cluster-like behavior by using Möss-

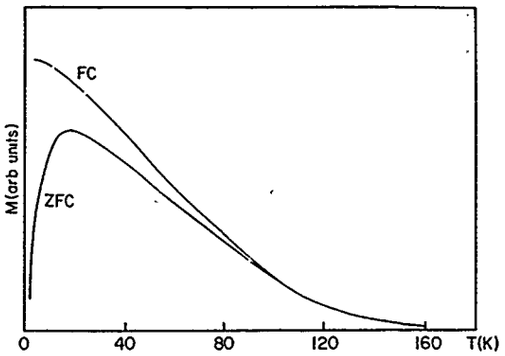

FIG. 4. Temperature dependence of zero field cooled (ZFC) and field cooled (FC) magnetization with applied field of 100 G for $Cr_{65}Fe_{35}$ mechanically milled amorphous powder.

bauer spectroscopy and ac susceptibility on Fe–Ag and Fe–Au film alloys prepared by the same evaporator, and the results suggested that the formation of the clusters is due to the inhomogeneity in atomic density in the films rather than the inhomogeneity in composition.[9,10] Therefore, a similar structural character may also be present in the studied Cr–Fe films. The x-ray diffraction patterns of these films indeed showed a broad diffracted linewidth, even for the films with crystalline structure,[2] which indicates the formation of small size particles. The Mössbauer spectrum of the film shown in Fig. 1 ruled out the possibility of the formation of Fe-rich and Cr-rich two-phase, α-α'. While for the powder, the mechanical milling leads to a continuous reduction of particle size, and a granular system is finally formed. Because of the finite size of the granular system, the spin correlation length is strictly limited by the size of these granules, and therefore long range ferromagnetic ordering cannot be sustained, even in the samples with high Fe concentration.

The above results reveal a dissimilar behavior in magnetism between Fe–Cr–M and the present Fe–Cr amorphous alloys. For example, in $Fe_{100-x}Cr_xB_{15}$ amorphous, the alloys became nonmagnetic when $x>30$, while in the present work, one sees that the Cr–Fe amorphous materials exhibit magnetic order, even for the samples with high Cr concentration. Since the metalloid element, boron, plays no crucial part in destroying the Fe moment,[11] we are forced to conclude that the difference in microstructure between the present Cr–Fe and the melt-spun Fe–Cr–B amorphous alloys may lead to different magnetism. This may be attributed to the more loose-packed structure in the present amorphous samples[12] as compared with metallic glass obtained by melt spinning.

In conclusion, the magnetic properties have been studied on the amorphous Cr–Fe film and powder alloys obtained by thermal evaporation and mechanical milling, respectively. The amorphization dramatically reduces the local Fe magnetic moment in the alloys. Differing from the metalloid contained Cr–Fe amorphous alloys, the studied amorphous materials show magnetic orders, even in the samples with higher Cr concentration. Both of the film and powder amorphous alloys exhibit a cluster-type magnetic behavior, which can be attributed to the granular structure of the materials. The magnetic interaction can be described by spin-glass-type intercluster interaction with a dominated ferromagnetic intracluster interaction.

Magnetostriction in RE-Co amorphous alloy films (abstract)

S. Uchiyama, S. Yoshino, H. Takahashi, K. Tomi-ita, T. Mori, A. Itakura, S. Iwata, and S. Tsunashima
School of Engineering, Nagoya University, Nagoya 464-01, Japan

Rare earth-transition metal (RE-TM) amorphous films have been used as magneto-optical recording media. One of the most important properties is the perpendicular magnetic anisotropy, the main origin of which is explained by one ion anisotropy of rare earth ion. However, it is also noted that the anisotropy contribution due to the magnetostriction depends in a very similar manner on the RE species as in the case of the main anisotropy. Thus it was suggested that the main origin of the magnetostriction might be the one ion anisotropy of RE.[1] The present work reports the saturation magnetostriction constant λ_s of various RE-Co amorphous alloy films with RE=Y, La, Ce, Pr, Nd, Sm, Gd, Tb, Dy, Ho, Er in the range of RE concentration of 0%–40%. In most cases, λ_s increases with RE concentration, then decreases after showing a peak and disappears altogether with ferromagnetism. For an RE species with a small one ion anisotropy, λ_s is small with a value of less than 2×10^{-5}, and is found to be contributed primarily from Co. For RE with larger one ion anisotropy, namely for RE=Sm, Pr, Tb, and Dy, λ_s has values of the order of 10^{-4} and is estimated to be contributed mainly from RE one ion anisotropy.

A model for the Barkhausen noise power as a function of applied field and stress (abstract)

M. J. Sablik
Southwest Research Institute, P. O. Drawer 28510, San Antonio, Texas 78228-0510

The model of Alessandro *et al.*[1] is used to derive the Barkhausen noise power in terms of permeability μ, which is really the irreversible permeability, since the Barkhausen noise is produced by the irreversible motion of domain walls. From the model expression, it is shown that the peak in the Barkhausen noise power as a function of applied field coincides with the peak in the irreversible permeability. From the magnetomechanical hysteresis model,[2] an expression for the irreversible permeability is found and shown to peak at a higher magnetic field than the total permeability. Using the magnetomechanical hysteresis model and the derived expression from the Alessandro model, the Barkhausen noise power peak value is computed and found to increase almost linearly from negative (compressive) to positive (tensile) stress, with slightly decreased slope at high positive and negative values of stress, in agreement with trends in experimental observations.[3,4] Dependence of the Barkhausen noise power on $\dot{H}$, the time rate of increase in the linearly increasing ramp function used for H, is also investigated and found to increase moderately sharply for intermediate ranges of $\dot{H}$ and to saturate at larger $\dot{H}$.

The effects of closure domains on flux conduction in thin film recording head

Zhenzhou Guo and Edward Della Torre
Institute for Magnetics Research, George Washington University, Washington, DC 20052

The magnetic flux conductivity in the tip of a recording head was examined for various applied field and closure domain configurations using a two-dimensional micromagnetic model developed to obtain the domain patterns in soft magnetic thin films. A permalloy thin film sample was selected to simulate a monopole head configuration, and an external field was applied to various closure domain ground states that had zero net remanence magnetization. It was found that for small fields the magnetization process is linear and reversible, and both the susceptibility and the effective track width increase as the size of the closure domains is reduced. For large fields, however, the variation of the flux conduction is much less sensitive to the size of the zero-field closure domains, since the sample is nearly saturated. Small jumps were observed in the magnetization curves corresponding to the domain wall nucleation and annihilation, which can be a source of head noise. It was also observed that the effective center of magnetic pole shifts with increasing field.

The magnetization of a thin film of permalloy with an in-plane magnetic easy axis generally has 90° domain walls. Such a patterned structure is widely used in thin film recording heads. Magnetic flux along the hard axis is conducted by both magnetization rotations and domain wall motions. This wall motion besides being slow, and a source of noise due to Barkhausen jumps, destroys the symmetry of the ground state and introduces a unidirectional shift that is a source of overwrite problems in high-density recording head system which has relatively larger side domains. In other words, when one is trying to magnetize the media, the center of the flux shifts one direction when one is trying to magnetize the medium in one direction, and in the other direction when one is trying to magnetize it the other way. In order to reduce these effects, it is necessary to understand how the domain patterns behave in the recording process. In the past, domain level calculations have analyzed both the domain rotation and the wall-displacement modes of magnetic response.[1,2] Using our two-dimensional micromagnetic model[3] that obtains the domain patterns in thin films, this paper attempts to address these questions.

In this paper, using this micromagnetic model, we tracked the magnetization and domain wall motion for various applied fields and for various ground-state configurations to observe their influence on the magnetic flux. It was seen that the expansion and contraction of the oppositely directed closure domains destroys the symmetry of the ground state and thus application of a field shifts the magnetic center of the flux from the physical center of the head. For high-density recording this could cause serious overwrite prob-

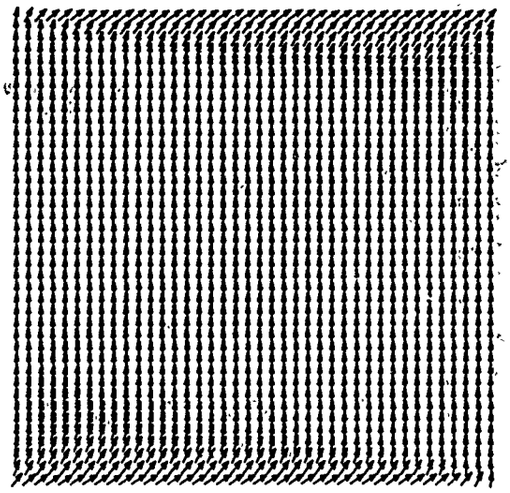

FIG. 3. Near-saturation state.

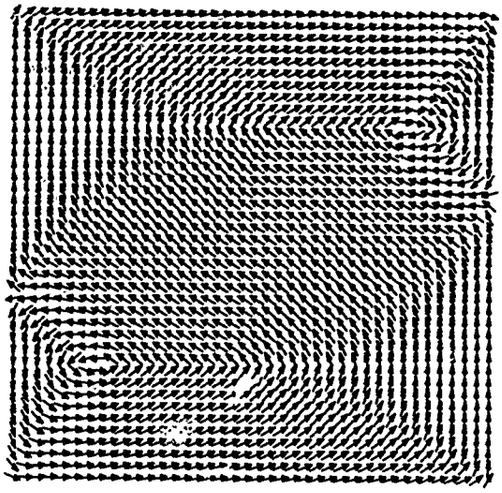

FIG. 5. Corresponding domain pattern when 1200-A/m magnetic field is applied to the 7-domain state along the vertical direction.

lems, since the tracks are narrow and the shift is unidirectional.

A laminated head structure with hollow cross section has been suggested as a means of eliminating the closure domain.[4] In that case, the magnetization flux can close itself around the hollow canter so that no free poles exist. Such a structure would then have no domain walls and magnetic flux conduction occurs entirely through magnetization rotation. Since unlaminated heads are easier to fabricate they continue to dominate the market. The use of a single-layer head whose sides are serrated has been suggested as a means of reducing this problem in an unlaminated head. It will be shown that this new geometry does reduce the effects of closure domains. The track shifting problem is also reduced and the available flux is less dependent upon the ground-state domain configuration.

A square piece of permalloy thin film with 4 μm×4 μm×10 nm dimensions is selected to simulate the head tip. The geometry chosen is corresponding to the high-density recording head that is being considered for heads to reach densities of 10^9 bits/in.^{2}. This head is discretized into an array of 40×40 square elements with the following parameters: the saturation magnetization is 800 kA/m, the uniaxial anisotropy constant is 160 J/m^3 with its easy axis along the transverse direction, and the exchange constant is 10 pJ/m. The termination criterion for the program is set at a maximum rotation in all elements of less than 0.01°.

Two ground states are considered as shown in Fig. 1, a seven-domain state, and Fig. 2, a 13-domain state. Both patterns are equilibrium states relaxed from different initial guess.[3] The seven-domain state has larger closure domains and narrower transverse domains than the 13-domain state. External fields are then applied to both pattern in increments of 250 A/m. The samples respond with both magnetization rotation and domain wall motion. With external field of 3500 A/m, they both approach the same near-saturation state shown in Fig. 3. It is seen that the top and bottom of the sample are still not saturated due to the demagnetizing field even when the external field is as much as an order of magnitude larger than the anisotropy field. The components of the magnetization along the external field are integrated throughout the sample to obtain the average susceptibility for each field. In Fig. 4, it is shown that for small fields, even though the magnetizing process is linear and reversible, the 13-domain state will have more flux than 7-domain state due to the latter's larger closure domains. As the fields become

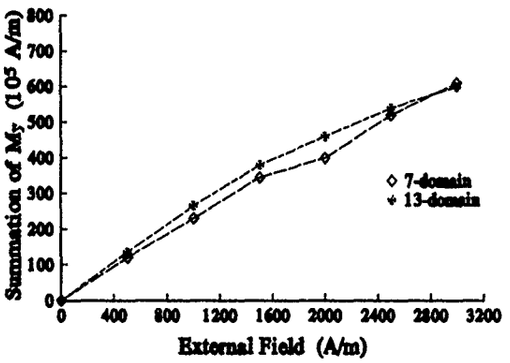

FIG. 4. M-H_0 curves of different domain patterns on the same sample.

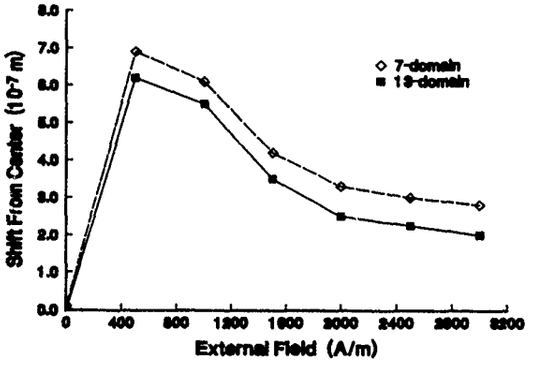

FIG 6. Magnetic pole shift under external field.

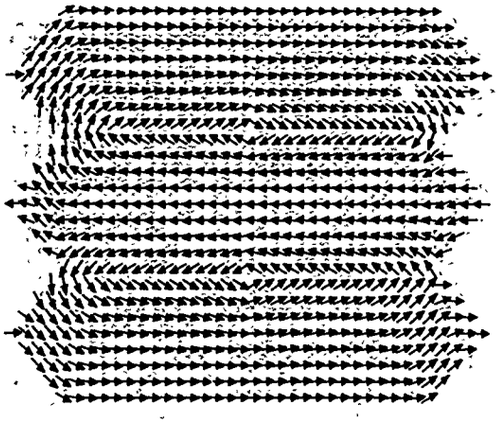

FIG. 7. Head tip with serrated sides.

larger, when the domain walls disappear only some local magnetization variations exist, which eventually go to zero. Certain jumps in the curve occurred at the moment when some closure domain walls were annihilated.

When domain wall motion is responsible for the change in the magnetization of the head, the field of the head causes one closure domain to grow at the expense of the other, as shown in Fig. 5. This causes a deviation in the flux stream from the center of the head. The deviation of the average position of the flux can be calculated as follows:

$$\delta x = \int x|M_y|dx \Big/ \int |M_y|dx. \tag{1}$$

The integration is carried out along the bottom edge of the sample. A plot of δx as a function of H_0 is given in Fig. 6 for the two domain patterns. As the field increases, the shift increases, reaches a maximum, and then decreases as the sample saturates. With the applied field at 800 A/m, the shift for the seven-domain state gets the maximum of 30%. Although there is no flux shift for a saturated head, it is undesirable to record at this point since, among other things, the effective gap length increases at saturation. Thus even at 75% saturation state (i.e., for a field of about 2500 A/m), this

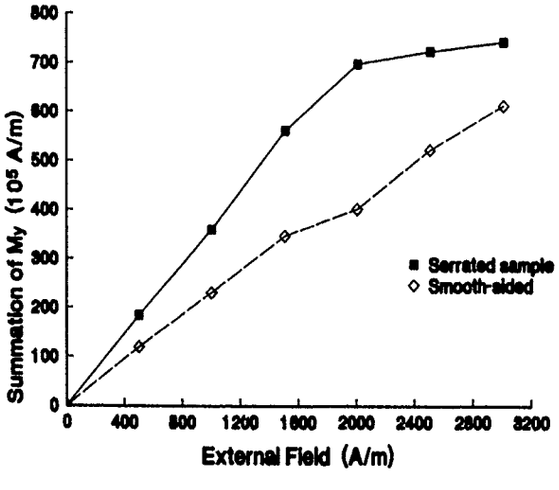

FIG. 8. Flux conduction for sample with smoothed and serrated sides.

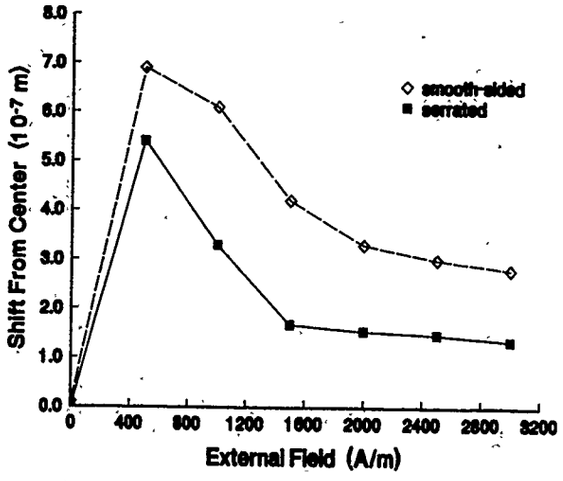

FIG. 9. Pole shift for samples with smoothed and serrated sides.

shift can still be as large as 15%. During the read process the fields involved are rather small, so this effect may be negligible in some cases.

The 13-domain state always has smaller deviations than the 7-domain state. Thus when one is trying to magnetize the media in one direction, the track effectively moves one direction, and in the opposite direction as the magnetization is reversed. This effect depends upon the magnetization history of the sample.

To try to reduce this effect, a head with serrated sides was analyzed, as shown in Fig. 7 in the ground state. This new geometry effectively reduces the closure domain due to the boundary restrictions. Figures 8 and 9, illustrate the flux conductivity and pole shift, respectively, with that for a head with smooth sides. It is seen that the flux conduction is dramatically increased for the new geometry in the linear region. The M-H curve for serrated head is also smoother. The pole shift is also reduced, but not as significantly as the flux. The asymmetry still exists. Overall, we expect that the serrated head will have a slightly better performance. Although a laminated head should be superior from these points of view, from manufacturing point of view, this serration is easier to make. Thus this could be a compromise solution. Besides the shape effects, there are other ways to stabilize the domains such as using the inclusions to pin the domain walls.[5] However, these aspects are beyond the goal of this paper.

Effect of recorded transition shape on spatial noise distributions and correlations

T. C. Arnoldussen
IBM Corporation, SSD, San Jose, California 95193

J. G. Zhu
University of Minnesota, EE Department, Minneapolis, Minnesota 55455

Improved error rate models require better understanding of noise distributions and correlations in magnetization reversals. An analytical model is described for micromagnetic transition noise. Magnetic charge conservation is the basis for the model. The noise distribution is shown to be dependent primarily on the average transition shape. While magnetic charge variance is always peaked at the center of the transition, readback voltage noise may peak at the center for arctangent transitions or may show leading and trailing edge peaks for hyperbolic tangent or error-function transitions. Moreover, noise in the voltage derivative shows yet different distributions. Principal noise eigenfunction modes are determined for the contrasting transition shapes studied. Analytical and full micromagnetic modeling results are compared.

I. NOISE MODEL

Noise associated with thin-film magnetic recording media is concentrated in the written magnetic transitions. Error-rate modeling often treats all noise as additive, Gaussian, white, and stationary. Transition noise does not fit this picture and one desires better characterization of spatial noise distributions and correlations. Bertram and Che presented an analytical model for noise correlation in a longitudinally oriented medium.[1] Here we present a similar model which is based on magnetic charge distribution and conservation of charge in a magnetization reversal. This formulation need not assume a specific orientation of the medium.

The readback voltage for an inductive head is

$$e(x)=K\int_{-\infty}^{\infty}dx'\int_{d}^{d+\delta}dy'\int_{-W/2}^{W/2}dz'\ h_x(x',y')\times[-\nabla\cdot\mathbf{M}(x'-x,y',z')], \tag{1}$$

where $K=N\epsilon v\mu_0$, the product of the number of turns on the head, its efficiency, the disk/head relative velocity, and free space permeability. $\mathbf{M}$ is the vector magnetization pattern written on the disk and h_x is the longitudinal component of head read sensitivity. Although this derivation assumes inductive readback, analogous equations and similar results could be written for a magnetoresistive read head. The negative divergence of $\mathbf{M}$ is the magnetic charge density, $\rho(x,y,z)$. W is the track width, d the head-to-medium spacing, and δ the recording film thickness. Track edge effects are ignored and therefore h_x is assumed to be independent of transverse position z. The charge density can include full three-dimensional divergence $\mathbf{M}$ effects. We only assume that for an isolated transition in "saturation" recording the integral of ρ over all x is $2M_r$, twice the longitudinal remanent magnetization. Noise between transitions caused by magnetization ripple (nonsaturation) is neglected. Thus the charge associated with a transition is constant. Media noise redistributes the charge in a transition, but total charge is conserved. Within a transition, average charge is distributed according to a probability density function[2]

$$p(x)=\langle\rho(x,y,z)\rangle/2M_r=\langle\rho(x)\rangle/2M_r,$$

where $\langle\cdots\rangle$ denotes an ensemble average. The integral of $p(x)$ from $-\infty$ to ∞ is unity.

Building on Eq. (1), the voltage noise may be expressed in terms of $[\rho(x,y,z)-\langle\rho(x)\rangle]$ as in

$$e_n(x)=K\int_{-\infty}^{\infty}dx'\int_{d}^{d+\delta}dy'\int_{-W/2}^{W/2}dz'\ h_x(x',y')\times[\rho(x'-x,y',z')-\langle\rho(x'-x)\rangle]. \tag{2}$$

To simplify we assume that the media film is thin and that magnetization and magnetic charge density are uniform throughout its thickness. The integration over y' is effectively replaced by δ, the media thickness, and $h_x(x',y')$ is evaluated at an effective y spacing d_f, $h_x(x',d_f)$. The autocovariance of the noise voltage is defined by $\mathrm{ac}(x_a,x_b)=e_n(x_a)e_n(x_b)$ and is written out in

$$\mathrm{ac}(x_a,x_b)=K^2\delta^2\int_{-\infty}^{\infty}dx'\int_{-W/2}^{W/2}dz'\ h_x(x',d_f)[\rho(x'-x_a,z')-\langle\rho(x'-x_a)\rangle]\int_{-\infty}^{\infty}dx''\int_{-W/2}^{W/2}dz''\ h_x(x'',d_f)\times[\rho(x''-x_b,z'')-\langle\rho(x''-x_b)\rangle]. \tag{3}$$

Because the terms in square brackets represent noise, the two integrations over the transverse position parameter z',z'' are replaced by the factors W and W_c, where W_c is the transverse noise correlation width.[3] The result is

$$\mathrm{ac}(x_a,x_b)=K^2\delta^2WW_c\int_{-\infty}^{\infty}dx'\ h_x(x',d_f)[\rho(x'-x_a)-\langle\rho(x'-x_a)\rangle]\int_{-\infty}^{\infty}dx''\ h_x(x'',d_f)\times[\rho(x''-x_b)-\langle\rho(x''-x_b)\rangle]. \tag{4}$$

Note: $\rho(x'-x_a)$ and $\rho(x''-x_b)$ are values averaged over track width on a particular transition, not ensemble averages.

 0021-8979/94/75(10)/6773/3/$6.00 © 1994 American Institute of Physics

Charge conservation implies that noise may be introduced by adding excess positive and negative charges (in equal numbers) to the ensemble average charge distribution, provided the variance of these excess charges, at any value of x, is the same as the population variance at the same point. The excess positive and negative charges individually must be distributed according to the same probability density function $p(x)$ as the ensemble average. This is like ping-pong balls dropped into bins to form a distribution. Even if some balls are colored green (+) and some red (−), they follow the same distribution statistics, but carry different labels. Zero-sum excess charge means the independent noise sources[3] are dipoles, correlated pairs of charges.

We can evaluate the voltage noise autocovariance for a single dipole pair of charges of strength q with charges located at generalized locations x_1 and x_2. For accounting convenience we assume the positive pole is located at the smaller of x_1 and x_2, and the negative pole at the larger value. The opposite convention could as well be used, but not both simultaneously, because a positive and negative dipole with identical x_1, x_2 values are correlated and therefore cancel. Thus, the single noise dipole is given by $q[\delta(x-x_1)-\delta(x-x_2)]$ for $x_1<x_2$, and $q[\delta(x-x_2)-\delta(x-x_1)]$ for $x_2<x_1$. $\delta(x)$ is a Dirac delta function. When these charge dipoles are substituted for the square-bracketed terms in Eq. (4), the dipole response is

$$\begin{aligned}\mathrm{ac}(x_a,x_b,x_1,x_2)=K^2\delta^2WW_cq^2[&h_x(x_1+x_a,d_f)\\&-h_x(x_2+x_a,d_f)][h_x(x_1+x_b,d_f)\\&-h_x(x_2+x_b,d_f)]\quad\text{for } x_1<x_2,\end{aligned}\tag{5}$$

$$\begin{aligned}\mathrm{ac}(x_a,x_b,x_1,x_2)=K^2\delta^2WW_cq^2[&h_x(x_2+x_a,d_f)\\&-h_x(x_1+x_a,d_f)][h_x(x_2+x_b,d_f)\\&-h_x(x_1+x_b,d_f)]\quad\text{for } x_2<x_1.\end{aligned}$$

The ensemble average charge in any incremental region Δx is $(2M_r)p(x)\Delta x$. The variance is $(q^2N_T)p(x)\Delta x$, where the total charge is composed of N_T incremental charge units $q=2M_r/N_T$, distributed according to $p(x)$. The total number of excess (noise) positive charges equals the number of excess negative charges, N_q. The average of the excess charge is zero, but the variance is the sum of variances of excess positive and negative charges, i.e., $2q^2N_qp(x)\Delta x$. Therefore, $N_q=N_T/2$, and $N_qq=M_r$. The total voltage noise autocovariance is obtained by multiplying Eq. (5) by $N_q^2p(x_1)dx_1\,p(x_2)dx_2$ and integrating over all x_1 and x_2. The final result is given in Eq. (6), which is equivalent to the Bertram and Che expression,[1] but simpler because of the charge conservation formulation:

$$\frac{\mathrm{ac}(x_a,x_b)}{K^2\delta^2WW_cM_r^2}=\left\{\begin{aligned}&\int_{-\infty}^{\infty}dx'[-m'(x')]h_x(x'+x_a,d_f)h_x(x'+x_b,d_f)\\&-\tfrac{1}{2}\int_{-\infty}^{\infty}dx'[-m'(x')]h_x(x'+x_a)\int_{-\infty}^{\infty}dx''[-m'(x'')]h_x(x''+x_b)\end{aligned}\right\}\tag{6}$$

where

$$[-m'(x)]=-(1/M_r)\langle dM/dx\rangle=\langle\rho(x)\rangle/M_r=2p(x).$$

Equation (6) represents the autocovariance of noise in the readback voltage. This is the form of interest for sampled-voltage detection. For peak detection, the readback voltage is differentiated and fed into a zero-crossing detector. In this case, the autocovariance of noise in the derivative of the readback voltage is of interest, and may be calculated by replacing the $h(x,d_f)$ functions in Eq. (6) by their derivatives $h'(x,d_f)$. When $x=x_a=x_b$ Eq. (6) is simply the voltage noise variance distribution.

II. RESULTS AND DISCUSSION

We assume the same set of conditions used in Bertram and Che,[1] namely $[-m(x)]=\tanh(2x/\pi a)$, $a=1.5d_f$, and $d_f=g/2$, $g/4$, and $g/8$. An inductive readback head (Karlqvist form), with gap length g, was assumed. The resulting voltage variance distribution, normalized by the factor $(NEvu_0M_r\delta/g)^2WW_c$, is shown in Fig. 1(a). Apart from an apparent difference in normalizing constant, the noise distribution is identical to that shown in Ref. 1. Notably, the voltage variance peaks just to either side of the transition center. However, assuming the same conditions except that $[-m(x)]=(2/\pi)\tan^{-1}(x/a)$, which has the same central

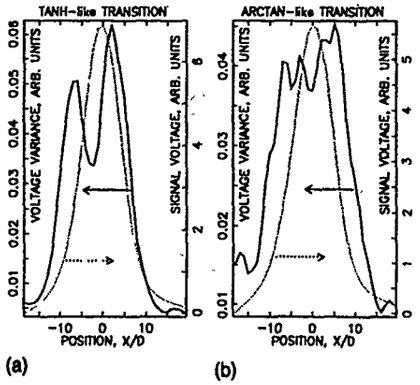

FIG. 2. Voltage variance and average readback pulses for (a) tanh-like and (b) arctan-like transitions. Longitudinal position x is normalized by crystallite diameter D. $g=12D$, $d_f=2D$, $\delta=D$.

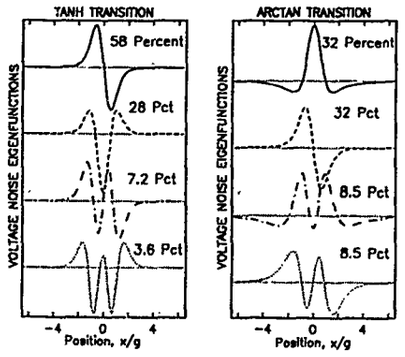

FIG. 4. First four noise voltage eigenfunction modes corresponding to conditions of Fig. 1, with $d=g/4$. Percent contributions are indicated.

slope as the tanh form, Fig. 1(b) gives a quite different voltage noise variance distribution. For an arctangent transition, the side noise peaks do not occur except at the very closest head/media spacing. Figure 1 indicates that the presence or absence of side noise peaks is due mainly to the functional shape of the magnetization transition, not the derivative of the head sensitivity function.[1]

To verify this analytical result, the readback voltage noise variance was computed for two magnetization transitions simulated by micromagnetic modeling.[4] One of these showed a more arctangentlike behavior while the other a more hyperbolic tangent form (error-function forms behave much like hyperbolic tangents). Figures 2(a) and 2(b) show the voltage noise variance of these two micromagnetically computed transitions. Like the analytical calculation, we see that the tanh-like transition shows noise peaks to either side of the transition center, while the arctan-like transition does not. Again, the same head was assumed for both.

We also used the analytical formulation to explore the variance of the readback voltage derivative. Figures 3(a) and 3(b) show this variance, using the same set of conditions as

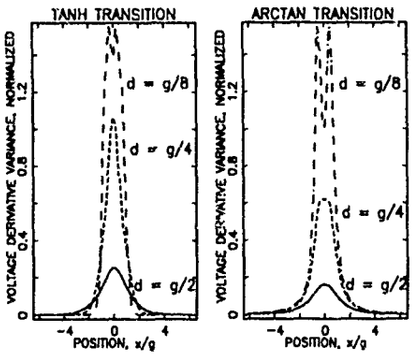

FIG. 3. Voltage derivative variance corresponding to Fig. 1 conditions.

in Fig. 1. For this type of noise, the arctangent transition shows a greater tendency than the tanh transition to exhibit noise peaks on either side of the transition center. As is the case for the voltage variance, side peaks become visible or prominent as head/media spacing decreases.

Equation (6), viewed as a square matrix with elements $AC_{mn}=ac(x_m,x_n)$, can be diagonalized to obtain the noise eigenfunctions and eigenvalues in order of descending contribution using the Karhunen–Loeve theorem outlined and applied by Yuan and Bertram.[5] The first four eigenfunctions and percent contribution to total voltage noise variance are shown in Figs. 4(a) and 4(b), for the tanh and arctan transitions treated above using $a=1.5d_f$ and $d_f=g/4$. We see that the eigenfunctions are qualitatively the same for the tanh and the arctan transitions (and this similarity remains true for the additional, less-important eigenfunctions not shown here). However, the relative contributions of corresponding eigenmodes are different for the tanh and arctan transitions. For the arctan, the eigenmodes occur in pairs of equal weight modes—one symmetric and one antisymmetric. For the tanh, the modes monotonically decrease in weight. In both cases the first two modes resemble pulse shifting (antisymmetric) and a pulsewidth-amplitude fluctuation (symmetric). While not explicitly shown here, the noise at the leading and trailing edges of a transition is negatively correlated, regardless of the transition shape or whether the noise variance exhibits leading and trailing peaks. This is a fundamental result of magnetic charge conservation.

Mean interaction field in magnetic recording media

Ikuya Tagawa, Akihiko Takeo, and Yoshihisa Nakamura
Research Institute of Electrical Communication, Tohoku University, 2-1-1 Katahira, Aoba-ku, Sendai 980, Japan

The mean interaction field was calculated for geometrical arrangements of isolated particles representing a longitudinally oriented Ba-ferrite and metal particulate medium. The effective demagnetizing factor was also calculated for a perpendicular Co-Cr recording medium. A positive mean field was obtained for the Ba-ferrite medium because the distance between particles placed in series to the magnetization direction is much shorter than that between parallel particles. When the orientation distribution became broad, the mean interaction field decreased because the location of magnetic particles changed. On the other hand, a negative mean field was obtained for the metal particulate medium. The results suggested that a positive mean field may act in the perpendicular Co-Cr medium.

I. INTRODUCTION

In magnetic recording media, the magnetic interaction between magnetic crystalline particles influences the recording and the reproducing performances.[1,2] The Henkel plots and delta M plots are also changed by the interparticle interaction. A new medium model based on magnetization curling and a mean-field interaction theory[3] was developed to analyze the interparticle interaction. By using a computer simulation of this medium model, the relationship between the Henkel plot and the mean field became clear. It was also shown that the high-density recording characteristics is influenced strongly by the mean interaction field in perpendicular magnetic recording.[4]

In this article we have investigated the relationship between the mean interaction field and both the packing density of crystalline particles and the particle orientation distribution in the medium.

II. INFLUENCE OF PACKING DENSITY

In particulate media in which magnetic crystalline grains are segregated, the magnetostatic interaction is much larger than the exchange interaction between magnetic particles. Therefore, we have investigated the magnetostatic interaction field which is the mean interaction field.

We have assumed a particulate medium model in which rectangular prismatic particles were arranged in a three-dimensional lattice shape with proper separations as shown in Fig. 1. To remove the effect of the demagnetizing field, the particles were arranged so that the arrangement configuration became a rectangular column whose aspect ratio was 1:10. The magnetization in each prismatic particle was replaced by magnetic charges at the particle surface to calculate the magnetic field. When all of the magnetizations were in the easy-axis direction such as the up direction, the magnetic field at the center particle of the particle arrangement, that is the mean interaction field, was calculated. The separation spaces between particles were decreased to decrease the packing density. The spaces were the same in the x, y, and z directions. The total number of particles was over 1 000 000.

Figure 1 shows the mean-field constant calculated for Ba-ferrite particulate media with the various packing densities. The mean field constant α was obtained by dividing the mean interaction field (Oe) by $4\pi M$, where M is the mean magnetization (emu/cm^3) of the medium. Here the flat rectangular prisms with aspect ratio of 3.5:1 were used for the Ba-ferrite particles. We have obtained a positive mean field and it became larger as the packing density increased. Since the packing density of actual media is about 30%, the mean-field constant is estimated at around 0.43.

Figure 2 shows the mean-field constant characteristics for metal particulate media. The aspect ratio was assumed at 1:7 for the metal elongated particles. The mean field at a packing density of 100% was slightly positive because the Lorentz field never becomes negative. However, a negative mean field was obtained when the packing density was under 90%, and a minimum value was observed at a packing density of around 5%. This result is because the distance between magnetic particles placed in parallel to the magnetization direction is much shorter than that between particles in series, and so the negative interaction field brought by particles in parallel is stronger than the positive field from particles in series. The mean-field constant is estimated to be around -0.07 for the metal particulate medium when the packing density is about 30%.

III. INFLUENCE OF ORIENTATION DISTRIBUTION

The Henkel plots were measured for longitudinally oriented Ba-ferrite particulate media with various particle ori-

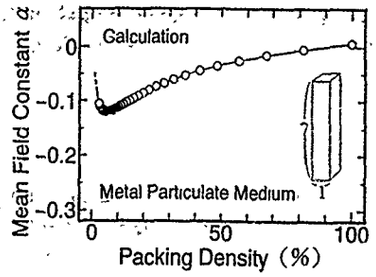

FIG. 2. Mean-field constant vs the packing density characteristics for a metal particulate medium with elongated particles.

entation distributions. The saturation magnetization and the coercive force were 145 emu/cm^3 and 1300 Oe, respectively. If there is no interaction between magnetic particles, the Henkel plot will become a straight line from an upper-left-hand corner to a lower-right-hand corner. However, the measured Henkel plots exhibited a positive interaction as shown in Fig. 3, and it was also suggested that the interparticle interaction became larger as the squareness increased.

If a compensating field to cancel the interaction field is applied in an opposite direction to external field, the Henkel plot will become straight. To estimate the mean interaction field in these Ba-ferrite media, we have measured many Henkel plots with applying various compensating fields which are changed in proportion to the mean magnetization in the medium. When a proportional constant was adjusted to 0.12 for the sample whose squareness was 0.8, the Henkel plot became almost straight as shown by open circles in Fig. 3. Therefore, the mean-field constant α was estimated at 0.12 for this Ba-ferrite medium. By this method using the linearization of the Henkel plot,[5] the mean-field constants were also estimated at 0.10 and -0.05 for the other two samples with the squareness of 0.75 and 0.5, respectively. The measured mean-field constants were much smaller than those calculated by the particle arrangement model and they changed with the squareness. This result suggests that the mean field is diminished by the particle orientation distribution.

Figure 4 shows the influence of the orientation distribution on the mean interaction field, calculated by the three-dimensional particle arrangement model for the Ba-ferrite medium. Here we have assumed the configuration of the particle arrangement as a cubic so that the demagnetizing factor became the same in the x, y, and z directions. The easy axes of particles were given using random numbers and the mean-field constant was decided by taking an average of 100 time calculations. In the case of the perfectly oriented model as shown in Fig. 4(a), the distance between the centers of particles placed in a horizontal direction is much longer than that of particles arrayed vertically. However, for the random orientation of Fig. 4(c), the particles were arranged so that the distances between the particle centers were identical in the horizontal and the vertical directions. The squareness was calculated by the medium magnetization model including the mean-field interaction.[4,6]

The calculated mean-field constant was 0.29 for the perfect orientation of Fig. 4(a) but it decreased as the orientation became poor. The tendency to change by the orientation distribution corresponds very well with the squareness dependency of the Henkel plot as described in Fig. 3. On the other hand, as shown in Fig. 4(d), we have assumed another model in which the easy axes of particles were given uniformly but the centers of particles were located at the same positions as in the random orientation of Fig. 4(c). The mean-field constant for the model of Fig. 4(d) was -0.05 which was nearly equal to the random orientation model of Fig. 4(c). Consequently we can conclude that the mean interaction field is influenced mainly by the location of magnetic particles and not by the particle orientation.

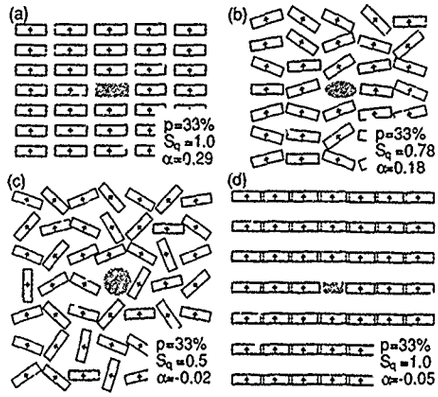

FIG. 4. Influence of the orientation distribution in the Ba-ferrite medium, calculated for (a) the perfect orientation, (b) the orientation with the squareness 0.78, (c) the random orientation, and (d) the uniform orientation but the centers of particles are located at the same positions as (c).

IV. PERPENDICULAR Co-Cr MEDIUM

A perpendicularly anisotropic Co-Cr film medium is considered to be particulate from its noise characteristics[7] and a columnar structure is proposed.[8] Moreover, it is well known that the demagnetizing factor in the perpendicular direction is smaller than 1 mks and is roughly 0.8, in general.

The effective demagnetizing factor was investigated by the particle arrangement model. As shown in Fig. 5, many

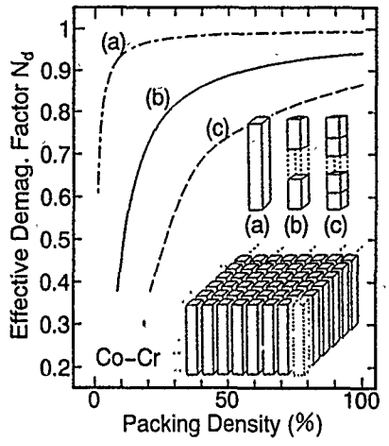

FIG. 5. Effective demagnetizing factor for a Co-Cr film medium, calculated when each column is (a) a single domain, and divided into (b) three and (c) five grains.

rectangular columnar particles whose aspect ratio was 1:10 were arrayed in rows, and the spaces between particles were changed according to the packing density. When each columnar particle was supposed as a single domain, that is by model 5(a), the effective demagnetizing factor decreased suddenly as the packing density became smaller than 10%. However, when the packing density was larger than 20%, the demagnetizing factor was larger than 0.96. Consequently, the effective demagnetizing factor is regarded as about 1 in a Co-Cr perpendicular medium with a columnar structure.

Since it is not clear why the demagnetizing factor is smaller than 1, we have assumed that a positive mean interaction field acted in the perpendicular direction of a medium and it diminished the demagnetizing field effectively. The mean field was calculated by the two different models in which each columnar particle was divided into (b) three and (c) five smaller crystalline grains as shown in Fig. 5. The effective demagnetizing factor was obtained by subtracting the mean field constant from 1. From Fig. 5, if the packing density of the magnetic grains was about 30%, each columnar crystal is supposed to be composed of about three grains separated magnetically because the effective demagnetizing factor is roughly 0.8.

V. CONCLUSIONS

A positive mean field was obtained for a longitudinally oriented Ba-ferrite medium and it increased according to the increase of the packing density. On the other hand, a negative mean field was obtained for the metal particulate medium. This result is because the distance between magnetic particles placed in parallel to the magnetization direction is much shorter than that between particles in series, and so the negative interaction field brought by parallel particles is stronger than the positive field from series particles.

By the linearization of the Henkel plot and by calculation, it was shown that the mean field was changed by the squareness of the Ba-ferrite media. This result is because the distance between particles in series increased and decreased in parallel particles. In the case of a Co-Cr perpendicular medium, each columnar particle was supposed to be composed of three or four grains separated magnetically when the positive mean field acted in the medium.

The interparticle magnetic interaction is strongly influenced by the stacking of particles which was neglected in this article. The relationship between the interaction and the stacking have to be studied as well as the influence of interparticle interaction on recording density and noise characteristics.

Micromagnetic studies of medium noise mechanisms

Xiaodong Che
Quantum Corporation, 500 McCarthy Boulevard, Milpitas, California 95035

H. Neal Bertram
Center for Magnetic Recording Research, U.C. San Diego, La Jolla, California 92093

For a granular thin-film medium, the total noise is determined by intergranular interactions and local anisotropy fields. Among these two factors, the effect of local anisotropy on medium noise is relatively less clear. A micromagnetic model is used to study four kinds of media with different anisotropy distributions. Perpendicular anisotropy is examined in two of the four media: One has a uniform perpendicular component for all grains, the other has some perpendicular grains randomly distributed. It is found that if exchange coupling is absent, the medium with the most uniformly distributed crystalline anisotropy has the lowest noise. Otherwise, the medium with the most nonuniformly distributed anisotropy yields the lowest noise.

I. INTRODUCTION

Medium noise originates from local magnetic-field (anisotropy) fluctuations and interactions between grains that include exchange coupling and magnetostatic interactions. The effect of exchange coupling on the medium noise was studied numerically indicating that a strong intergranular exchange enhances medium noise significantly due to collective magnetic behavior.[1] Therefore, to achieve a medium with the lowest noise, exchange coupling must be eliminated. Medium noise with different anisotropy distributions was studied experimentally by using torque measurement.[2] Based on this experiment, media with perpendicular anisotropy component have lower noise than those without a perpendicular component. Since the torque measurement cannot reveal the micromagnetic structure, a numerical model comparing media with a 2D and a 3D distribution of anisotropy was utilized to understand the noise reduction mechanism.[3] The numerical model found that these two kinds of media had a similar medium noise level. Therefore, the reason for this noise reduction observed in the experiment is still not fully understood.

In this article, a micromagnetic model is utilized to systematically study media noise with different anisotropy distributions. The purpose of this study is to further understand noise mechanisms and to explore optimal anisotropy distributions that offer very low media noise even when exchange coupling exists.

II. MODEL AND MEDIA SELECTION

The model used for this study is a standard micromagnetic model in which a portion of magnetic thin film medium is represented by a 64×64 hexagonal grains.[4] The magnetostatic and exchange interactions between these grains are characterized by two normalized parameters hm and he defined as[5] $hm=M_s/H_k$, $he=A^*/KD^2$, where M_S is the saturation magnetization, H_k is the crystalline anisotropy field, A^* is a phenomenological intergranular exchange coupling, D is the train size, and K is the granular crystalline anisotropy energy.

Four media with different anisotropy distribution are investigated. The anisotropy distributions of these media are listed in Table I.

For each type of medium, 20 different 64×64 arrays are generated to obtain track average fluctuations. For each array, the magnetization is first saturated in one direction and then an isolated transition is recorded by a Karlquist head field. By obtaining 20 different magnetic transition patterns from these arrays, the magnetic fluctuation at down-track position x, $dm(x)$, is calculated by the following formula:

$$dm(x)^2=\frac{1}{20-1}\sum_{i=1}^{20}[m_i(x)-\bar{m}(x)]^2 \tag{1}$$

where $m_i(x)$ is the cross-track magnetization average of the ith medium, and $\bar{m}(x)$ is the average of $m_i(x)$. In the following discussion, $dm(x)$ is treated as the medium noise at position x, although in a practical point of view, it is the medium noise deconvolved with the playback head function.

III. FLUCTUATIONS IN CRYSTALLINE ANISOTROPY AMPLITUDE

Medium A and medium B have the same angular distribution in the crystalline anisotropy, but medium A has a constant H_k value, and medium B has a uniform distribution in H_k from 0.5 to 1.5. In Fig. 1(a) magnetization cross track averages $\bar{m}(x)$ for medium A and medium B with $hm=0.2$, $he=0.05$ are plotted. In Fig. 1(b), the fluctuation function $dm(x)^2$ is also plotted. It is noticed that the medium fluctuation always reaches a maximum at the transition center. This

TABLE I. The anisotropy distributions of these media.

ID	Amplitude of anisotropy	Direction of anisotropy
Medium A	$H_k=1.0$	2D random (planer)
Medium B	H_k varies from 0.5 to 1.5	2D random (planer)
Medium C	$H_k=1.0$	2D random but with 10% grains having perpendicular crystalline anisotropy.
Medium D	$H_k=1.0$	Almost 2D random but with a small vertical component which varies from 0 to 0.2.

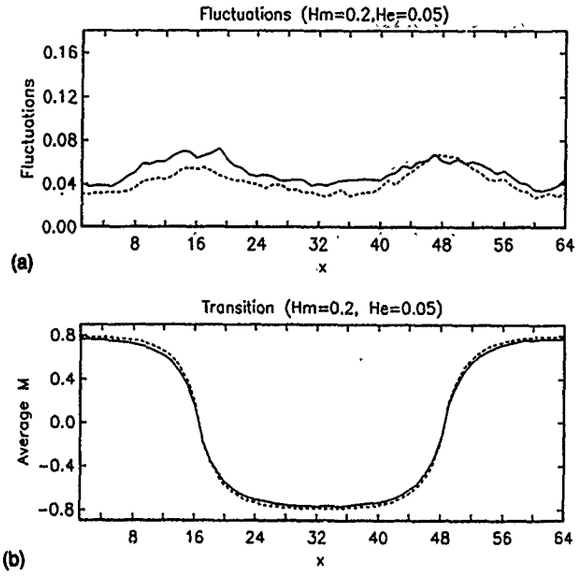

FIG. 1. (a) Magnetic transition profiles and (b) medium fluctuation for medium A (solid lines) and medium B (dashed lines) with $hm=0.2$ and $he=0.05$.

can be qualitatively understood based on a simple statistic argument: Assuming that the magnetization in each grain can only have two values: m_r or $-m_r$, it can be proven that the cross track average fluctuation is proportional to $(m_r^2-\bar{m}^2)^{1/2}$ where $\bar{m}$ is the magnetization average. By comparing the noise levels of these two media, one can find that the medium with a constant H_k has a higher noise level than the other in both transition region and saturation region. This indicates that the cross-track coupling in grains is reduced with a fluctuation in H_k.

In Fig. 2, the total medium fluctuation by taking the summation of $dm(x)^2$ over x is plotted versus magnetostatic interaction parameter *hm* with zero exchange coupling. The *hm* value varies from zero to 0.2 and he is equal to 0.0. When $hm=0.0$, grains in both medium A and medium B have no interactions. Therefore, the two media have the same total

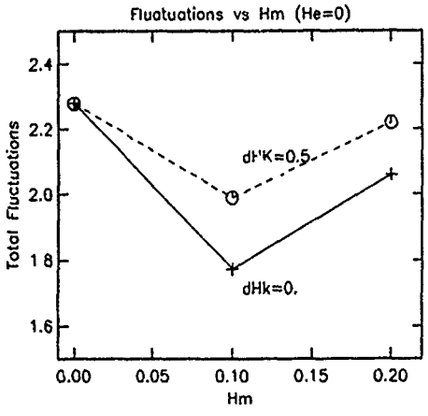

FIG. 2. The total medium fluctuation vs *hm* at $he=0.0$ for medium A (solid line) and medium B (dashed line).

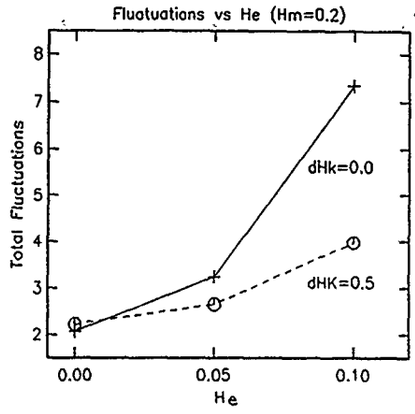

FIG. 3. The total medium fluctuation vs *he* at $hm=0.2$, for medium A (solid line) and medium B (dashed line).

medium fluctuation value. As *hm* increases, the total fluctuation first decreases and then increases. The reduction of the total fluctuation initially is due to magnetostatic interaction which offers an antiparallel interaction across the track. This reduces cross-track coupling. On the other hand, the magnetostatic interaction also lines up magnetization of each grain in the down-track direction. This reduces medium noise in the saturation region. As *hm* increases even further, medium fluctuations increase significantly in the transition region due to a broader transition. This results in a higher total noise. Both medium A and medium B show the same trend for the total medium noise; however, medium A always has a lower fluctuation value than medium B due to its constant H_k value.

In Fig. 3, the total medium fluctuation versus exchange coupling parameter *he* is plotted with $hm=0.2$. For both medium A and medium B, the total medium fluctuation increases monotonically with *he*. However, for medium B the noise fluctuation increases much more slower than that for medium A. This can be explained by the following argument: Analytically, it can be proven that the total fluctuation is proportional to the cross track correlation length.[6] Exchange coupling links the magnetization between adjacent grains and makes the correlation length longer. Medium B which has a fluctuation in the local anisotropy amplitude reduces the cross-track correlation that is developed by the exchange. This argument will also used to explain the noise reduction in medium C.

Although medium B has slightly more noise than medium A without exchange coupling, its noise increases very slowly with increasing exchange coupling. This is a significant advantage when exchange coupling cannot be fully eliminated.

IV. PERPENDICULAR CRYSTALLINE ANISOTROPY

Both medium C and medium D have a perpendicular anisotropy component either from individual grains (medium C) or from all grains (medium D). In our study, 10% of the grains of medium C have their crystalline anisotropy directed perpendicularly. In medium D, the crystalline anisotropy in

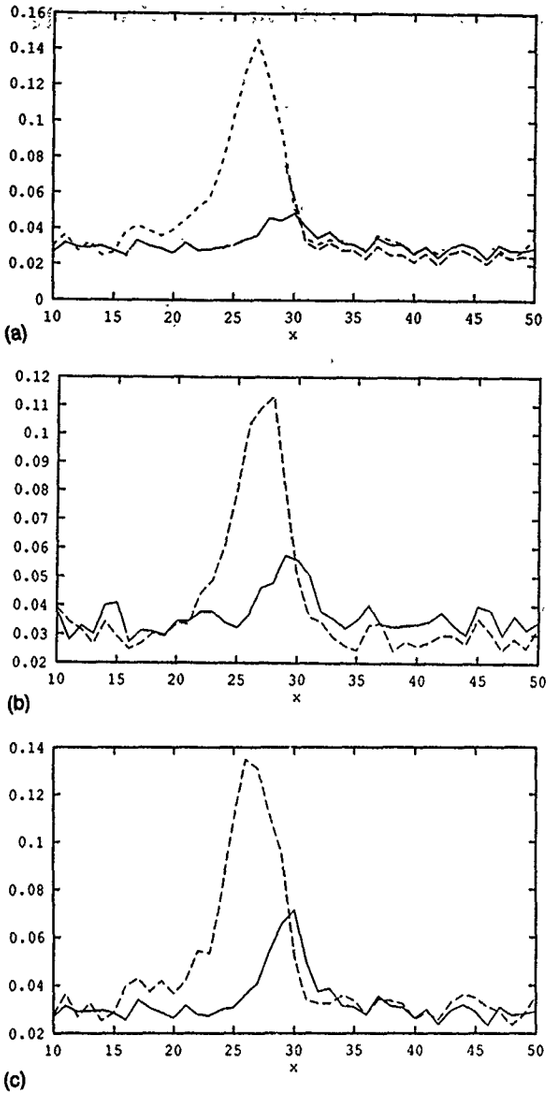

FIG. 4. (a) medium fluctuations for medium A, (b) medium fluctuations for medium C, (c) medium fluctuations for medium D. The solid lines are for $hm=0.1$, $he=0.0$, the dashed lines are for $hm=0.1$, $he=0.1$.

each grain has a perpendicular component varying from 0 to 0.2. Therefore, medium C and medium D have the same perpendicular anisotropy component with an average of 0.10.

In Figs. 4(a), 4(b), and 4(c), $dm(x)^2$ curves for medium A, C, and D are plotted, respectively. The solid curves are for $hm=0.1$ and $he=0.0$ and the dashed lines are for $hm=0.1$, and $he=0.1$. When the exchange coupling is small, the fluctuation is very small for all three media. In the transition region, medium D has the highest medium fluctuation followed by medium C. When the exchange coupling exists ($he=0.1$), the fluctuation increases significantly in the transition region, however no fluctuation increase is observed in the saturation region. By comparing these three media, we find that medium A and medium D have a similar fluctuation level. Medium C has a lower fluctuation level than that of the other media. This indicates that medium D in which crystalline anisotropy is tilted perpendicularly slightly has the same cross-track correlation length as that of medium A. This result agrees with the previous micromagnetic study discussed in Sec. I.[3] Only the perpendicular grains in medium C have sufficient strength to reduce the correlation length developed by exchange coupling. Therefore, in order to reduce exchange coupling effect, fluctuations in anisotropy fields have to be sufficiently large especially between adjacent grains.

It is more likely that the experimental results were obtained on media which have a structure similar to medium C. Since medium C and medium D have the same average perpendicular anisotropy component, the torque measurement cannot distinguish one from the other. As discussed, medium D has a lower medium noise than medium C and A. Therefore, torque measurement can not always be directly correlated with medium noise.

V. CONCLUSIONS

By utilizing a micromagnetic simulation, four idealized media with different crystalline anisotropy distributions are investigated. It is found that, when exchange coupling is absent, medium noise is determined by the local crystalline anisotropy fluctuation. The total medium noise power is low for all four media. Relatively, medium A, with the most uniform anisotropy distribution, has the lowest noise. When exchange coupling is strong, medium noise is determined by the collective magnetization behavior. Under this circumstance, a medium with a structure eliminating the exchange coupling effect has a low noise level. To achieve this kind of structure, fluctuations in the crystalline anisotropy have to be sufficiently large. In the four medium structures we tested, medium B and medium C yield a slower noise increase as exchange coupling rising. Therefore, when exchange coupling cannot be totally eliminated, a medium with a structure similar to medium B or medium C is recommended.

ACKNOWLEDGMENTS

The authors would like to thank Tadashi Yogi for his suggestion of modeling sprinkling perpendicular granular medium (medium C). This work was supported in part by the Center for Magnetic Recording Research, an IBM research grant, and NSF Grant No. DMR90-10908.

Ferrite MiG heads intended for narrow track ($\lesssim 10$ μm) digital recording were recently investigated in the critical pole-tip region at the air-bearing-surface using micro-ellipsometry, Kerr microscopy, and electron back-scatter diffraction from individual grains,[1] and using magnetic force microscopy to detect air-gap remanent fields.[2] Comparison of these direct observations with readback-after-write waveforms from written test tracks, and consideration of granularity influences on bulk permeability and domain size, indicate that waveform instability and asymmetry from *polycrystalline* ferrite (PCF) heads would be diminished by suitable size and orientation of the grains.[1] The use of *single-crystal* ferrite[3] (SCF) for advanced laser enhanced etch definition[3] of narrow pole MiGs can avoid this type of distortion. However, secondary signals[4] often appear as weak pulses separated in time from the main gap pulse. We have associated this effect with a zig-zag shaped wall seen nucleated and propagated from the pole tips by a write pulse.[4] This wall and its underlying domains lie remanent in the stressed ABS material and evidently react to the bit fields during the read cycle. The secondary read-back response, though similar to the pseudo-gap effect, differs in origin. Its timing depends on the distance of the zig-zag wall to the gap, not the fixed position of the sendust-ferrite interface. Our results indicate that suitable grain oriented ferrite would reduce PCF MiG head read-back asymmetry and instability. For SCF heads, a method for *electrically* removing zig-zag walls is possible and secondary pulse removal has now been demonstrated on a spin test strand.

Magneto-optical (MO) polar Kerr rotation and ellipticity (PKR and PKE, respectively) of Co rich Au(111)/Co(0001) multilayers grown by molecular beam epitaxy on GaAs(110) substrates are reported. The individual layer thicknesses, t_{Au} and t_{Co} were t_{Au}/t_{Co}=2.6/3.2, 1.0/1.5, and 0.65/0.8 nm. The samples displayed perpendicular magnetic anisotropy smaller than demagnetization energy. PKR and PKE were measured at photon energies between 1.5 and 5.2 eV. In the multilayer with t_{Co}=1.5 nm, PKR at 3.1 eV reached a value of −0.34°, remarkably higher than that reported on Au rich multilayers. The spectra were compared with theory. A satisfactory agreement was obtained only for the sample with the largest bilayer thickness, $t_{Au}+t_{Co}$=5.8 nm. This indicates that when t_{Au} and t_{Co} are reduced to a few atomic monolayers the role of interfaces is increased. The effects of strain, defects, and atomic mixing at Au-Co interfaces become more important. Both the magnetic and optical properties are modified.

I. INTRODUCTION

Several interesting phenomena have been demonstrated in ultrathin 3D ferromagnetic metal/noble metal film structures, among them perpendicular magnetic anisotropy (PMA), enhancement of magneto-optical (MO) effects, oscillating interlayer exchange coupling, etc.[1–5] This article reports on MO polar Kerr rotation and ellipticity (PKR and PKE) in molecular beam epitaxy (MBE) grown Au/Co multilayers in which the individual layer thicknesses of t_{Au} were chosen smaller than those of t_{Co}. The previous MO studies[2–4] were all focused on the multilayers characterized by $t_{Au}>t_{Co}$.

II. SAMPLES AND EXPERIMENTAL METHODS

The Au/Co multilayers were grown by MBE onto (110) oriented GaAs substrates.[6] First, a 50-nm-thick buffer layer of Ge(110) and a (110) Co layer, followed by the first Au(111) layer, were deposited and on which the Au(111)/Co(0001) multilayer structure was grown. In this way, the first and topmost layers in the multilayer systems were always gold. Three samples with individual Au and Co layer thicknesses, $(t_{Au}/t_{Co})^n$=$(2.6/3.2)^{20}$, $(1.0/1.5)^{40}$, and $(0.65/0.8)^{80}$ were selected for the present study. Here n denotes the number of Au-Co bilayers grown on the Au(111)/Co(110)/Ge(110) buffer system. The sample periodicity was checked by x-ray diffraction (XRD) PKR and PKE were measured at 300 K in a photon energy range from 1.5 to 5.2 eV. Use was made of the azimuth modulation and self-compensation technique.[7] The angle of incidence was 6°. As a first step, the PKR hysteresis loops were taken at a photon energy of 3.1 eV, which provided a value of the saturation magnetic field.

III. RESULTS AND DISCUSSION

The XRD pattern indicated a good periodicity and sharp interfaces in the $(2.6/3.2)^{20}$ and $(1.0/1.5)^{40}$ multilayers, as illustrated in Fig. 1 for the latter sample. In the $(0.65/0.8)^{80}$ sample broader peaks revealed a large amount of Au-Co mixing. The results of the PKR magnetometry are shown in Fig. 2. The saturation of PKR below 0.8 T in the $(2.6/3.2)^{20}$

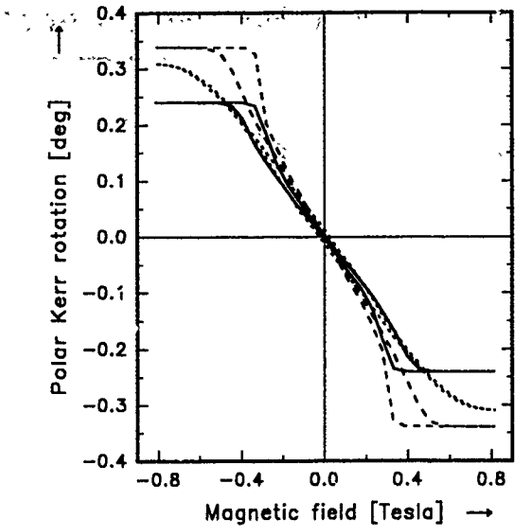

FIG. 2. Magneto-optical polar Kerr rotation hysteresis loops measured at a photon energy of 3.1 eV in [Au(2.6 nm)/Co(3.2 nm)]^{20} (short dash), [Au(1.0 nm)/Co(1.5 nm)]^{40} (long dash), and [Au(0.65 nm)/Co(0.8 nm)]^{80} (solid line) multilayers.

multilayer and the MO hysteresis loops, displaying low remanence and constriction in the other samples, are typical for the case when the PMA is smaller than demagnetization energy.[8] The anisotropy is due to the magnetoelastic effect originating from larger lattice spacing in gold than in cobalt and its magnitude is sensitive to the distribution of Au and Co atoms at the interface,[9] void concentration in Au and, possibly, to Au layer thickness when t_{Au} is reduced to a few atomic monolayers (a reduced strain effect of the Au layer in Co rich Au/Co multilayers). Note that, in Au(5 nm)/Co(t_{Co})/Au(25 nm) sandwiches, the energy of the perpendicular magnetic anisotropy dominates the demagnetization energy up to about t_{Co}=1.5 nm.[10,11] This critical thickness is generally smaller in multilayers where sharp, steplike Au-Co interfaces are more difficult to achieve.[12,13]

Figure 3 displays PKR and PKE spectra of the multilayers. In thicker samples the splitting of the major peak is observed. The structure is mainly of Au origin. Particularly, the peak arising from the plasma edge in gold situated near 2.5 eV is clearly discernible in the (2.6/3.2)^{20} multilayer. Here PKR reaches −0.33°. This value is considerably higher than that observed in Au rich multilayers.[2–4] In the (1.0/1.5)^{40} multilayer the PKR amplitude is even higher (−0.34°), while the peak broadens and shifts to 3 eV. The peak is remarkably reduced in the (0.65/0.8)^{80} where the nominal t_{Au} and t_{Co} are less than 3 and 4 ML, respectively, and large Au-Co mixing at the interfaces was difficult to avoid.

Several formalisms based on Maxwell's theory have been developed to describe the optical interactions in magnetic multilayers.[14–18] We modeled the spectra using the model given elsewhere[14] and the bulk optical (for Au and Co) and MO (for Co) data.[19–25] This approach was shown to be successful in the case of Au/Co/Au sandwiches where the composition profile can be made nearly ideally rectangular.[19] The computed spectra in the multilayers are all similar in

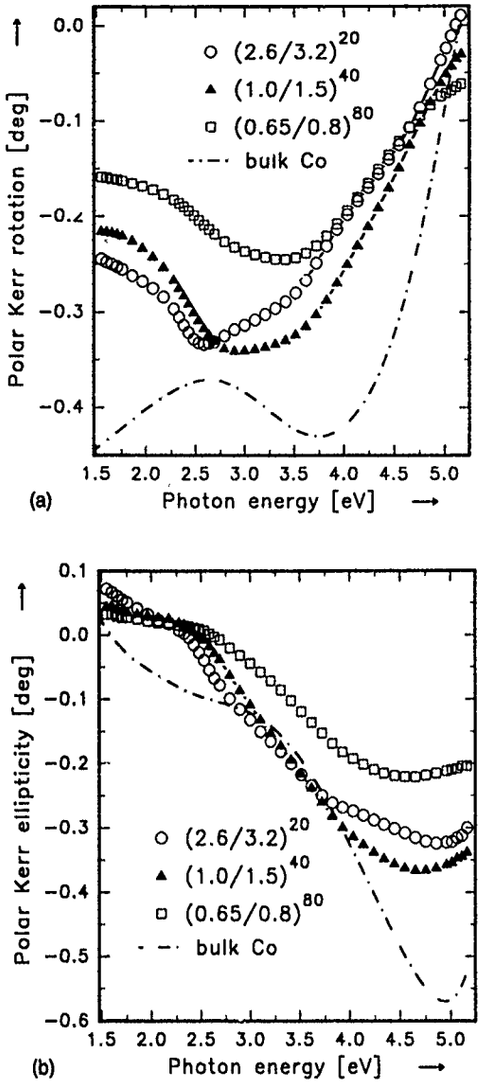

FIG. 3. Magneto-optical polar Kerr effect in Au/Co multilayers and bulk Co of (a) rotations and (b) ellipticities.

shape, displaying a moderate increase in amplitude as $t_{Au}+t_{Co}$ and the thickness of the topmost layer simultaneously decrease. However, the experimentally observed spectra do not follow this simple trend. A satisfactory agreement between the measured and computed spectra is obtained only for the thickest $t_{Co}+t_{Au}$ bilayer (Fig. 4). In this case all structures in the computed spectra can be correlated with the experiment. Nevertheless, the measured spectra show broader linewidths and the peak assigned to the plasma edge in gold[2] occurs at slightly higher photon energy.

To explain the observed differences we have to consider the following effects: (1) Amplitude reduction of the interband transition contributing to the absorption edge in gold[20,25] due to structural defects (e.g., voids) and the lack of long range order. These defects are likely to occur in our Au ultrathin films which were grown under a compressive stress induced by adjacent Co. (2) Increase of the Au-Co mixing at the interfaces with number of bilayers. This reduces not only the interface perpendicular anisotropy but also the magnetization and, consequently, the PKR and PKE because a part of

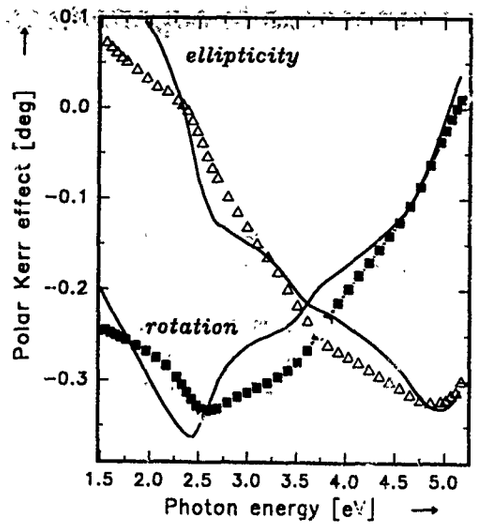

FIG. 4. Polar Kerr effect in [Au(2.6 nm)/Co(3.2 nm)][20] multilayer. Experimental data of rotation (squares) and ellipticity (triangles); computed using the optical constants of the bulk Au (solid lines).

the Co atoms at the interfaces are not ferromagnetically coupled to each other. (3) Larger Drude (free carrier) linewidth in ultrathin gold is produced by the scattering at Au-Co interfaces. (4) Effect of electronic coupling between spin-polarized Co and Au.[5,11,13] As a result, a contribution from spin-polarized Au to the total magneto-optical activity, especially in the region of the Au plasma edge,[26] cannot completely be ruled out.

An inspection of the XRD pattern in Fig. 2 proves a high degree of perfection of the [Au(1.0 nm)/Co(1.5 nm)][40] multilayer. The sample displays a rather high PKR and PKE. The thickness of the Au spacer, t_{Au}, is smaller than 5 ML and the adjacent Co layers can be considered as coupled.[13] The shift of the main peak towards higher photon energies is due to the changes of Au permittivity in the ultrathin film limit and partially due to a weak MO contribution of the spin-polarized gold monolayer at Au-Co interface.[11] The effect of Au-Co mixing at the interfaces dominates the spectra of the [Au(0.65 nm)/Co(0.8 nm)][80] multilayer. This makes the ferromagnetically ordered Co layer thinner by about 1 ML per period[12] and, consequently, attenuates MO amplitudes in this sample.

IV. SUMMARY

In conclusion, we have presented polar Kerr effect spectra in Co rich MBE grown Au/Co multilayers. In the multilayer with t_{Co}=1.5 nm PKR at 3.1 eV reached a value of −0.34°, remarkably higher than that reported in Au rich multilayers. The spectra were compared with theory. The modeling has shown that magneto-optical Kerr spectra in Au/Co multilayers, especially in the Au plasma edge region near 2.5 eV, strongly depend on the optical constants of gold.[19] In this spectral region the constants are very sensitive to Au layer perfection.[20,25] A satisfactory agreement using bulk Au optical constants was obtained only for the sample with the thickest bilayer, $t_{Au}+t_{Co}$=5.8 nm. This indicates that, at t_{Au} and t_{Co} reduced to a few atomic monolayers, the role of interfaces is increased. The effect of strain and defects as well as that of atomic mixing at Au-Co interfaces become more important. Both the magnetic and optical properties are modified: surface perpendicular magnetic anisotropy induced by the mismatch between the lattice parameters of Au and Co, oscillator strenghts for the Au interband electronic transitions, free electron scattering in Au, etc. Also, spin polarization in Au induced by exchange coupled Co atoms at Au-Co interfaces should be taken into account.

ACKNOWLEDGMENTS

The authors are grateful to Professor D. Greig of Leeds University for the preparation of the samples. The helpful discussions with Dr. P. Široký are acknowledged. Spin-reorientation processes in anisotropic magnetic superlattices (SLs) with antiferromagnetic interfacial coupling are theoretically analyzed. Results provide magnetic phase diagrams of the kind "external field–relative magnetic moment," as well as equations for the lines of the phase transitions. The influence of possible inhomogeneous magnetization in SLs is considered phenomenologically for the normal-incidence polar Kerr magneto-optical effect assuming the Q parameter to be a function of distance along the normal to the interface. A simple approach to the solution of this problem is outlined.

INTRODUCTION

Studying magnetic superlattices (SLs) is of great importance with regard to our understanding of the influence of surfaces and interfaces on their physical properties. This is particularly true for MO media. Magnetization processes in SLs are now under comprehensive investigation.[1,2] However, the existing theoretical models of SLs either operate with an infinite medium or involve numerical methods and thus do not explain completely the behavior of the magnetic structures in an external magnetic field. In particular, there has been little research into how bulk or surface magnetic anisotropy and the outer surfaces affect the magnetic phase transitions and the reorientation processes. Inhomogeneous magnetization can presumably occur. To ascertain whether this may affect the MO properties of SLs the normal incidence polar Kerr effect, being important for applications, should be studied for the case where the inhomogeneity is along the normal to the plane of the medium. Consequently, the MO Q parameter becomes a function of the distance z from the surface. As far as we are aware this problem has not been solved before except for the special case of homogeneous multilayered thick films.[3] Although we have treated rigorously the most general case, which will be reported on in due course, the solution here is, for brevity, given in terms of the differential reflectance approach.[4]

FIELD INDUCED SPIN-REORIENTATION PROCESSES IN SLs

We consider SLs with the two layers periodically repeated. One of them is to be isotropic and the other to possess uniaxial anisotropy (e.g., Gd/Co). The SL is subjected to an external field **H** in the plane of the films. In the first instance the magnetization is assumed to be homogeneous in each layer. Their total number $N+1$ is odd, so the first and last layer are identical. To find the phase diagrams at the temperatures far below the Curie point we use the thermodynamic potential

$$F=-\sum_{i=1}^{N/2+1} h\cos\theta_{2i-1}-\sum_{i=1}^{N/2}(h/\mu-K/2\cos\theta_{2i})\times\cos\theta_2+\sum_{i=1}^{N}\cos(\theta_i-\theta_{i+1}), \quad (1)$$

where θ_i is the angle between **H** and the magnetization in the ith layer. In (1) $\mu=d_1M_1/d_2M_2$, $h=Hd_1/\lambda M_2$, $K=\tilde{K}/\lambda M_1M_2$ are, respectively, the relative magnetic moment of the SL unit cell, the reduced external field, and the anisotropy constant. All these are defined through the thicknesses d_1, d_2, the magnitudes of the magnetization M_1, M_2 of the layers, the positive quantity λ proportional to the interface exchange constant, and the second-order anisotropy constant $\tilde{K}$. The potential (1) has been written as if the isotropic layer is the first one of the SL. That for the anisotropic layer has been considered in Ref. 5. The equilibrium magnetic phases are found from the conditions: $\partial F/\partial\theta_i=0$ and the matrix $\|\partial^2F/\partial\theta_i\partial\theta_j\|$ is positive-definite.[5] To simplify the analysis and gain analytical results we put $N\to\infty$. Since the sign of K essentially changes the phase diagrams, they will be considered separately for both signs.

For $K>0$ and **H** perpendicular to the anisotropy axis the phase diagram of Fig. 1 consists of the following five phases:

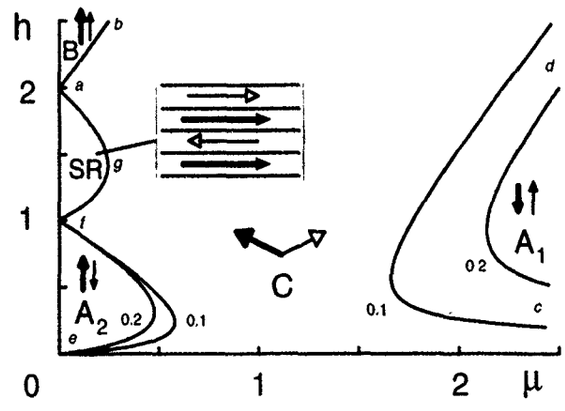

FIG. 1. Phase diagram of the ferrimagnetic SL for $K=0.1$ and 0.2. The field **H** is perpendicular to the easy axis.

 0021-8979/94/75(10)/6786/3/$6.00 © 1994 American Institute of Physics

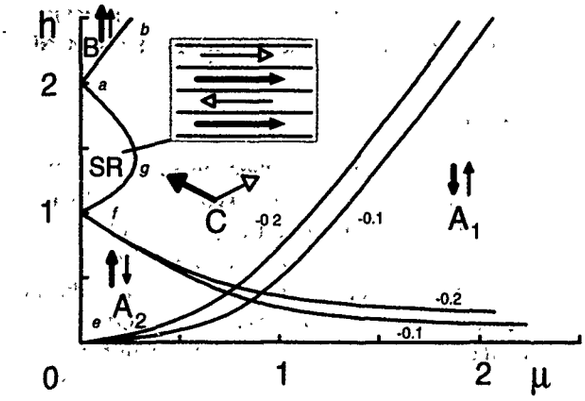

FIG. 2. Phase diagram of the ferrimagnetic SL for $K=-0.1$ and -0.2. The field **H** is parallel to the easy axis.

(1) "Ferromagnetic" B, above the line $ab(\theta_i=0)$,

$$h>2, \quad \mu<\frac{h(h-2)}{h(2+K)-2K}. \tag{2}$$

(2) "Ferrimagnetic" A_1, at the right of the line $cd(\theta_1=\theta_3=\ldots=0,\ \theta_2=\theta_4=\ldots=\pi)$,

$$h>\frac{2K}{2-K}, \quad \mu<\frac{h(h+2)}{h(2-K)-2K}. \tag{3}$$

(3) "Ferrimagnetic" A_2, at the left of the line $fe(\theta_1=\theta_3=\ldots=\pi,\ \theta_2=\theta_4=\ldots=0)$,

$$h<1, \quad \mu<\frac{h(1-h)}{h(1-K)+K}. \tag{4}$$

(4) "Surface-reoriented" (SR), at the left of the line $af(\theta_1=0,\ \theta_3=\theta_5=\ldots=\pi,\ \theta_2=\theta_4=\ldots=0)$

$$h>3/2, \quad \mu<\frac{h(2-h)}{h(2-K)+2K}, \tag{5}$$

$$h<3/2, \quad \mu<\frac{h(h-1)[1-2(h-1)^2]}{h+K(h-1)(2-h)}. \tag{6}$$

The magnetization in the boundary layers is oriented parallel to **H** while the structure of the ferrimagnetic phase A_2 persists in the interior of the SL.

(5) "Canted" (C) between ab, af, fe, and cd lines. The magnetic moments make various angles with **H**. The "surface-twist" phase[6] exists in C for small μ in the area limited by the lines eg, fe and it turns into C phase on the line defined from (5). In this phase the maximum deviation from the collinear orientation (being inherent to the both phases A_1 and A_2) takes place near the surface. This deviation vanishes with distance into the interior of SL. So the magnetization process in the SL is seen to be sophisticated if $\mu<1$. For even $N+1$, surface phases arise though these exist near either the top surface or the bottom one.

For $K<0$ and **H** directed along the anisotropy axis the second phase diagram, shown in Fig. 2, includes the same phases as in Fig. 1 although there are some important differences in the critical field lines. The stability conditions are given by Eqs. (2)–(6) with changing K to $-K$. The phases A_1 and A_2 overlap each other. This means the existence of the first kind of phase transition between A_1 and A_2. The equation of its line is $\mu=1$ at $h\to 0$. At the point where the instability lines of the collinear phases A_1 and A_2 intersect each other the first order transitions between the phases C and $A_{1,2}$ take place. The region of such transitions expands with increasing value of K. Similar behavior occurs in bulk ferrimagnets.[7]

The magnetization in the layers can be inhomogeneous. This is expected to be valid particularly for SLs including rare-earth elements and transition metals. From our recent investigation of how the inhomogeneities change the critical fields we can conclude that the critical fields of the transitions $B\leftrightarrow C$, $A_1\leftrightarrow C$ (the lines ab and cd in Figs. 1 and 2) increase but those of $A_2\leftrightarrow C$ decrease (the line ef), that is, the region of the phase C expands.

MO POLAR KERR EFFECT OF INHOMOGENEOUS SLs

It is clear from the forgoing work that inhomogeneities in magnetization can occur in SL structures. Consequently we turn to the problem of how much inhomogeneities affect MO properties of SLs. Though the above analysis is applicable to in-plane magnetization we present, in the first instance, a consideration of the polar Kerr effect, since this is of particular interest for magneto-optic recording and can be dealt with rather easily in certain situations.

The simple differential reflectance approach for dealing with this can be applied in the specific case where the isotropic refractive index n is constant throughout the whole SL, having a total thickness d, but the MO parameter $Q(z)$ varies arbitrarily with z. Our aim is to find the Kerr rotation θ and ellipticity η (state of polarization of reflected plane wave) provided the incident wave is linearly polarized. To begin with, one considers an elemental layer of thickness δz ($\ll\lambda/2\pi|n|$), buried to a depth z in the SL. In the first instance we need only consider the MO effect of this element and do so by assuming that the rest of the medium is nonmagnetic.[8] It may be shown that the elemental Kerr component δk resulting from this buried layer is given by

$$\delta k=B_0\alpha Q(z)(e^{\alpha z}+B_1e^{-\alpha z}+B_2)\delta z, \tag{7}$$

where $\alpha=2ik_0n$, $k_0=2\pi/\lambda$, $B_1=r_s^2e^{2\alpha d}$, $B_2=2r_se^{\alpha d}$, $B_0=in[(1+n)(1+r_0r_se^{\alpha d})]^{-2}$, r_0 and r_s are the isotropic Fresnel amplitude reflection coefficients at the air/film and film/substrate interfaces, respectively. At this point we invoke the general principle of superposition which applies to first-order MO effects.[8] This principle states that the magneto-optically induced electric field components resulting from an interaction of the wave with a magnetic multilayered system are a linear superposition of the complex MO electromagnetic field components due to individual magnetic elements in the system, where the fields associated with each element are calculated on the basis that the rest of the system is non-magnetic. It therefore follows that the Kerr component for the whole SL is given by

$$k=\alpha B_0\int_0^d Q(z)(e^{\alpha z}+B_1e^{-\alpha z}+B_2)dz. \tag{8}$$

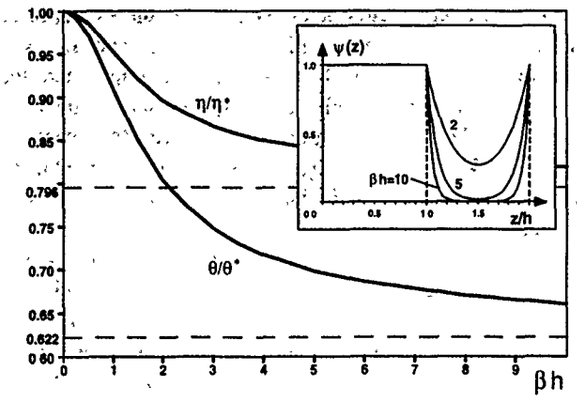

FIG. 3. Normalized Kerr angle θ/θ^* and ellipticity η/η^* vs the parameter βh of the inhomogeneity whose distribution over a period is shown in the inset.

For many functions, $Q(z)$, analytical expressions for k can be easily obtained from (8). Moreover, since $\theta+i\eta=k/r$ ($k\ll r$), where r is the amplitude reflectance of the whole SL and is given by the reiterative reflectance formula,[9] the complex Kerr rotation can be determined.

As an illustration we consider an infinite periodic SL ($d\to\infty$). Each period is a bilayer. Its first layer is homogeneous with $Q_1=Q_0$ and the second is inhomogeneous with $Q_2=Q_0\psi(z)$, where $\psi(z)=\cosh\beta(h-2z)/\cosh\beta h$. The thicknesses are both equal to h and the inhomogeneity factor β determines how rapidly Q_2 varies with distance from the interface. The variation of Q over a period is shown in the inset in Fig. 3. For $\lambda=633$ nm, $h=10$ nm, $n=2+i4$, and $Q_0=-0.008+i0.017$, Fig. 3 shows that the Kerr angle and the ellipticity, normalized respectively to those at $\beta=0$ ($\theta^*+i\eta^*=-0.178+i0.152°$), are sensitive to the inhomogeneity. For $\beta\to\infty$ the second layer becomes homogeneous and the state of polarization tends to $\theta+i\eta=-0.111+i0.121°$, being equivalent to the case where $Q_2=0$. If the latter is assumed beforehand then, for instance, at $\beta h=5$ relative errors in θ and η are seen, from Fig. 3, to be ~11% and ~5%, respectively. At $\beta h=10$, its influence being less, the errors are only ~6% and ~3%. The example given serves as a preliminary illustration to the more general statement that the inhomogeneities may not always be neglected in the study of the polar Kerr effect. This may be particularly important when determining the optical constants of SLs from experimental data.

CONCLUSION

Spin-reorientation phase transitions in anisotropic magnetic superlattices have been studied theoretically within the framework of the new approach. The presence of an outer surface is shown to change magnetization processes and phase diagrams considerably. New surface spin configurations have been found. An anisotropy of the surface layer determines the type of phase transitions into the surface magnetic phases (first or second order). If the external field is applied along the hard axis then these phases are observed only for certain values of the relative magnetic moment μ. For the field applied along the easy axes the surface-twist phase arises in the magnetization process at any μ. Spatial inhomogeneities in the magnetization distribution can influence MO properties of SLs. To show this, the polar Kerr effect has been considered phenomenologically at normal incidence assuming the MO Q parameter is an arbitrary function of the distance from the interface. A simple procedure of computing the state of polarization of the reflected wave has been developed. The results presented allow us to take into account inhomogeneous systems and therefore we have the potential to explain important features in the magnetic and MO properties of superlattices.

The magnetic and magneto-optical properties of Co, Cr, Mn, and Ni substituted barium ferrite films

R. Carey, P. A. Gago-Sandoval, D. M. Newman, and B. W. J. Thomas
Centre for Data Storage Materials, Coventry University, Coventry CV1 5FB, United Kingdom

Using rapid thermal processing (RTP) we recently demonstrated the production of high quality well ordered barium ferrite films in times much shorter than those required by a conventional annealing process. Influence over the magnetic and structural properties developed in annealed samples was also achieved by variation of the RTP heating profile (R. Carey, P. A. Gago-Sandoval, D. M. Newman, and B. W. J. Thomas, presented at Intermag-93, Stockholm, April 13–16, 1993). It is known that the magneto-optic properties of barium ferrite can be enhanced by selective substitution of some of the Fe by Co^{2+} and Ti^{4+} albeit at the expense of reducing the magnetic anisotropy. A multitarget scanning cosputtering process has been used in conjunction with rapid thermal processing to produce a series of barium ferrite films in which Co, Cr, Mn, Ni are selectively introduced to substitute for between 5 and 20 at. % of the Fe. A corresponding percentage of Ti is also added to maintain charge compensation. The magnetic and magneto-optic properties of these films are presented and discussed with reference to their composition and treatment respect to the properties of barium ferrite.

INTRODUCTION

Following a long development period, first generation optical data storage systems using erasable magneto-optic materials based on the rare-earth transition-metal alloys are now available. They have been well tailored with respect to their magnetic, magneto-optical, and recording properties at laser wavelengths around 800 nm. However, both the figure of merit[1] at shorter wavelengths and the long term stability of these materials is less than satisfactory.

With new techniques developed to prepare garnets and ferrite thin films,[2–5] magnetic oxides again become potential candidates for the magneto-optical recording material. While oxide thin films are able to overcome some of the major deficiencies of the rare-earth transition metal alloy films, some properties of these materials, e.g., the uniaxial anisotropy, the coercivity, the grain size, and the high crystallization temperature, require further improvement for the optical recording application.

Our investigation indicates that barium ferrite films have a marked uniaxial anisotropy and good squareness of the in-plane hysteresis loop but the magneto-optical response remains quite poor, especially at laser wavelengths around 650 nm. The use of RTP has already reduced both the grain size and the annealing times to acceptable levels.

It is known that magneto-optical (MO) effects in garnets and ferrite materials for optical recording[6] may be substantially enhanced by ion substitution. In barium ferrite, substitution using Co^{2+} ions has already been the subject of many reports,[7–10] but, so far, non has considered other substitutions using elements with similar ionic radii to iron and the resultant effect on both the magnetic and the magneto-optic properties.

In this paper we present an investigation of the magnetic and magneto-optical properties of barium ferrite with some iron substitution by Co, Cr, Mn, and Ni.

EXPERIMENTAL TECHNIQUES

Films of Co, Cr, Mn, and Ni substituted barium ferrite were prepared by a combination of dc and rf magnetron cosputtering in a multitarget Nordiko 2000 system onto unheated Vycor glass substrates. Each deposition utilized three separate targets: (1) barium ferrite (rf), (2) the substitution ion (Co, Cr, Mn, Ni) (dc), and (3) titanium for charge compensation (dc). The sputtering parameters used followed those already published[11] (see Table I) and depositions were arranged to provide all samples with a thickness close to 200 nm, with the concentration of the substitution element Co, Cr, Mn, or Ni varying between 5 and 20 at. %. The compositions, shown in Table II, were determined using energy dispersive x-ray analysis (PV9160) in a Philips SEM505 scanning electron microscope. A vibrating sample magnetometer and a polar Kerr loop plotter were used to provide the ferrimagnetic and magneto-optical properties.

All the as-deposited samples were essentially nonmagnetic and amorphous. A post deposition heat treatment, using the RTP system,[11] was necessary to develop any ferrimagnetic or magneto-optical properties. Samples were therefore annealed in vacuum, for 3 min and 30 s at 810 °C achieved using a linear heating rate of 35 °C s^{-1} and a constant predetermined duty cycle, intended to avoid any differences in microstructure between samples that might be produced by different heat treatment,[11] followed by slow cooling.

RESULTS

The results of this study are shown in Table II. In general it can be seen that, for most samples, the saturation Kerr rotation at 670 nm is enhanced compared with the rotation produced by a barium ferrite film[12] but that there is only a slight improvement at 825 nm for Mn substitution.

A 5 at. % Co substitution provides the maximum saturation polar Kerr rotation at 670 nm of 0.14°, in good agreement with other authors,[8] while at 825 nm the measured rotation is less than that for the barium ferrite film. When the Co content is increased to 10 at. % the saturation rotation at 670 nm is reduced to −0.071° and becomes −0.063° at 825 nm. Further increase in the Co content leads to a magneto-optic response close to that for a pure cobalt film.

The magnetic properties, as measured by the vibrating sample magnetometer, follow a similar pattern so that a hysteresis loop for the high concentration Co substitution film is very similar to that for a pure cobalt film of similar thickness. For the smaller Co concentrations, hysteresis loops are generally S-shaped with similar loops (and coercivities) being obtained for directions both perpendicular and parallel to the film plane.

There have been several studies of the magnetic properties barium ferrite films with Ni substitution.[13] The magneto-optical results in Table II show a similar behavior to that for Co substitution but with a smaller Kerr rotation at 825 nm compared with that for the pure barium ferrite film. For the 5 at. % Ni substitution the Kerr rotation at 670 nm is again enhanced. The hysteresis loop, and particularly the remanence, seems to be more sensitive to Ni substitution than Co substitution going to a reduced remanence of 15% of the saturation value for only 5 at. % Ni and eventually vanishing at 20 at. % Ni.

For Mn substitution, the saturation Kerr rotations produced are in a similar range to those for Co substitution, but the magnetic hysteresis loops for these samples became quite irregular.

For Cr substitution the saturation Kerr rotation is again small, but the in-plane hysteresis loop showed a surprisingly large remanence and coercivity when the Cr concentration approached 30 at. %.

CONCLUSION

The results presented in this paper indicate that substitution of some of the Fe in barium ferrite thin films by small concentrations (generally about 5 at. %) of elements of the same periodic family can provide a significant enhancement of the saturation polar Kerr rotation at shorter wavelengths. Unfortunately, there is no associated improvement in the magnetic properties of the films and only in those cases where the substitution element has similar magnetic characteristics to iron (e.g., Co, Ni) are the hysteretic properties easily measured. For the cases of Mn and Cr substitution, the smaller magnetic moments produced a generally small signal and therefore noisy hysteresis loops.

With the higher concentrations of Co and Ni, the magnetic properties of the substituted samples became similar to those of thin films of the pure elements.

Magnetization and Faraday rotation measurements at 1152 nm have been performed on $Ho_3Fe_{5-z}Al_zO_{12}$ ($z=0.45$) single crystals as a function of temperature and magnetic field oriented along the 3 crystallographic axes [100], [110], and [111] in both experiments. A strong anisotropy is observed at low temperature ($T<100$ K), although the Faraday susceptibility remains anisotropic until $T_{comp}=185$ K. High field magnetization measurements (H up to 200 kOe) show that the FR anisotropy is mainly of magnetic origin. The results are interpreted on the basis of the Dionne-refined Néel model of ferrimagnetic garnets using a field dependent canting angle.

I. INTRODUCTION

In ferrimagnetic rare earth iron garnet of formula $RE_3Fe_5O_{12}$ (REIG), the magnetic ions are distributed over three crystallographic sites with sublattice magnetizations M_a (octahedral site 16a: [Fe^{3+}]), M_d [tetrahedral site 24d: (Fe^{3+})] and M_c (dodecahedral site 24c: {RE^{3+}}).[1-3] The Fe[a]–Fe(d) superexchange interactions determine the Néel temperature ($T_N=560$ K) for all REIGs. Furthermore, in heavier rare earth garnets, there exists a compensation temperature T_{comp} at which the bulk magnetization vanishes. In pure HoIG, $T_{comp}=137$ K. At low temperatures, when both crystal field and exchange anisotropies become of the same order of magnitude, an onset of noncollinear ordering takes place in the {c} sublattice as shown by neutron diffraction experiments.[4,5]

In REIGs, the near IR Faraday rotation (FR) is the sum of the gyroelectric and gyromagnetic contributions proportional to the three magnetic sublattices magnetizations.[6] As M_c is mainly determined by the molecular field created by the two Fe^{3+} sublattices and the applied magnetic field H, the substitution of Al^{3+} for Fe^{3+} ions allows for the decrease of their contribution to the molecular field on the RE sublattice, thus increasing the influence of the external field on the properties of the compound. The different molecular field coefficients N_{ad}, N_{aa}, and N_{dd} originally determined for YIG are equally suitable for all other REIGs.[7-9] Furthermore, for heavier RE garnets, fits of good quality were obtained by reduction of the net moment in the {c} sublattice using a canting angle φ.[8-10]

In this work we investigated the magnetic and magnetooptic properties of $Ho_3Fe_{5-z}Al_zO_{12}$ ($z=0.45$) single crystals as a function of temperature and magnetic field oriented along the 3 crystallographic axes [100], [110], and [111] in both experiments. Al^{3+} ions are distributed over the [a] and (d) sites and the formula of the garnet can be written: {Ho_3} [$Fe_{2-x}Al_x$] ($Fe_{3-y}Al_y$) O_{12} with $z=x+y$ and $y \gg x$.[3]

II. EXPERIMENT

Single crystals of composition $Ho_3Fe_{5-z}Al_zO_{12}$ were grown by our method of flux growth under 10 bar of oxygen pressure.[11] Three [100], [110], and [111] oriented platelets ~2 mm thick were cut from the same crystal in order to minimize chemical composition differences. They were used "as grown" both for magnetic and FR experiments. Electron microprobe analysis carried out on the platelets gives $z=0.45$ ($\pm 1\%$–2%).

Magnetization (M) measurements were performed from 4.2 to 300 K in a magnetic field up to 200 kOe. Data are expressed in Bohr magnetons, for one formula unit $Ho_3Fe_{5-z}Al_zO_{12}$. FR measurements were obtained at 1152 nm wavelength from 6 K to Curie temperature, with H up to 20 kOe. This wavelength is located on the rise at 300 K, and outside of low temperature, of the $^5I_8 \rightarrow {}^5I_6$ transition[12] indicating that the FR measurements correspond mainly to a dis-

persive effect. In both cases, H was applied parallel to the normal of the platelets. The estimated precision of the magnetization and FR results is ±2%.

III. RESULTS AND DISCUSSION

Low temperature isotherms of magnetization and FR are plotted in Figs. 1 and 2 for the three main crystallographic orientations. For $6<H<20$ kOe, they present a linear variation according to $M=M_s+\chi_M H$ and $\Phi=\Phi_s+\chi_F H$. The spontaneous magnetization M_s and spontaneous FR Φ_s of the crystals and their corresponding susceptibilities χ_M and χ_F are obtained by extrapolating this linear part to $H=0$. The temperature dependencies of $M_s(T)$ and $\Phi_s(T)$ are reported in Figs. 1 and 2, respectively.

We observed that [111] is the easy axis of magnetization and [100] the hard axis as in pure HoIG. At 4.2 K saturation along the [110] axis is attained at $H\sim200$ kOe (Fig. 1) which confirms that it is an intermediate direction. A similar situation is found concerning the FR isotherms. However, below 100 K, the limited magnetic field range does not permit to observe the saturation for [110] and [100] direction. Both properties lead to a compensation temperature $T_{comp}=185$ K (±3 K), whereas $T_N=500$ K (Fig. 2). In the spontaneous state, the anisotropic character of both magnetic and MO properties decreases rapidly with temperature and disappears at about 100 K. However the FR susceptibility is isotropic above T_{comp} only (Fig. 3). It is to be noted that, in comparison to pure HoIG,[13] in a large temperature range, with the exception of the T_{comp} shift, the spontaneous FR values are less affected than the magnetization values by Al substitution: e.g., at 300 K the Φ_s value shows a variation of 60%, whereas M_s value is divided by 2.7.

On the basis of the Dionne refined Néel model,[9] the ferrite magnetization is simply written: $M_{REIG}=|M_d-M_a-M_c|$. The respective sublattice magnetizations are represented by Brillouin functions [Eq. (1) of Ref. 7]. It is noticeable that to reproduce the experimental values of both Fe^{3+} sublattice moments at 0 K, a correction which originates from local canting was introduced [Eq. (6) of Ref 7]. The inter and intra sublattices interactions are represented by the molecular field coefficients previously determined in YIG:Al:

$$N_{aa}=-65(1-0.42y) \quad (\text{mole cm}^{-3}), \tag{1}$$

$$N_{dd}=-30.4(1-0.43x), \tag{2}$$

$$N_{ad}=N_{da}=97(1-0.125x-0.127y). \tag{3}$$

Using Van Erk's thermodynamic model[14] and assuming that the "as grown" samples correspond to a quenching temperature of ~1173 K, $x=0.02$ and $y=0.43$. The $Ho^{3+}-Fe^{3+}$ exchange interactions for $z=0.45$ can be described, in a first approximation, by the molecular field coefficients of pure HoIG:[9] $N_{ac}=N_{ca}=-2.1$; $N_{cd}=N_{dc}=4$; $N_{cc}=0$.

To complete the review of our hypotheses it is important to remark that to take into account the spin canting in the $\{c\}$ sublattice, first the "effective" quantum number of the Brillouin function was choosen equal to $J_c\cos(\varphi)$, second the magnetic moment at 0 K was written:[8]

$$M_c(0)=3g_c\mu_B J_c\cos(\varphi), \tag{4}$$

with $J_c=8$, $\varphi=51.5°$, and $g_c=5/4$ as in pure HoIG.[9]

φ is considered temperature independent.[8] Using this model, the temperature dependences of the magnetic properties of HoIG:Al were calculated using an iterative procedure.[15,16] As shown in Fig. 1, in the spontaneous state, there is a good agreement (maximum difference of 4% at 4.2 K) between theory and our [111] experimental data in the 4.2–300 K temperature range. In contrast, attempts to fit the magnetization curves $M(H)$ for any temperature reveals a large discrepancy with the experimental isotherms. More precisely, the calculated susceptibiilities are twice the observed values (Fig. 3). Above T_{comp}, a very reasonable order of magnitude of M_c can be simply deduced from the difference between M(HoIG:Al) and M(YIG:Al) for the same z,

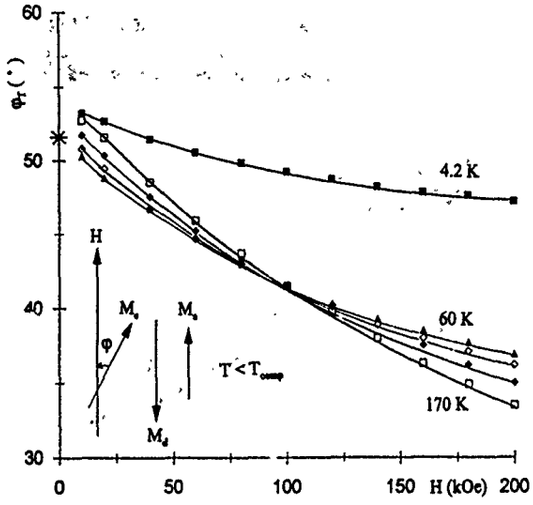

FIG. 4. Isotherms of the field dependence of the canting angle $\varphi_T(H)$ (10–200 kOe) for $T \ll T_{comp}$. Temperature independent $\varphi(H=0)$ of Dionne s model (see Ref. 9) is represented by *.

T, and H conditions. In the 190–300 K temperature range, the M_c contribution tends to zero when H lies within the 75 kOe range. This situation suggests that a canting angle of 90° within the $\{c\}$ sublattice accounts for the zero M_c moment; the extension of this conclusion leads to a field and temperature dependent canting angle $\varphi_T(H)$.

Using the set of molecular field coefficients [Eqs. (1)–(4)], the spin canting angle $\varphi_T(H)$ needed to fit within experimental accuracy any isothermal magnetization curve of the HoIG:Al ferrite was determined. The main role of φ on the calculation of M_c is underscored in the precedent lines. The so-obtained $\varphi_T(H)$ curves shown in Figs. 4 and 5 confirm the strong influence of the applied magnetic field with two different behaviors below and above T_{comp}. Below 185 K, the decrease of φ_T when H increases represents the tendency of M_c to align parallel to the external field. However, even for $H=200$ kOe the φ_T change remains relatively limited (30%). On the contrary, above T_{comp}, an important variation of φ_T which illustrates a progressive rotation of M_c from 51.5° to 130° is evidenced. In both cases when H vanishes towards 0, $\varphi_T \rightarrow \sim 51.5°$ of pure HoIG.[9]

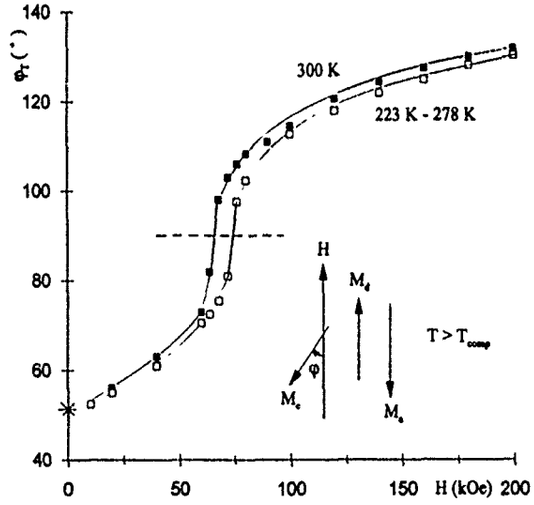

FIG. 5. Isotherms of the field dependence $\varphi_T(H)$ (10–200 kOe) for $T > T_{comp}$.

IV. CONCLUSION

In this paper, the magnetic and FR properties of Al substituted Holmium garnet were studied. At low temperature ($T<100$ K) the spontaneous state of the studied garnet presents a very pronounced anisotropic character. This anisotropy, attributed to Ho^{3+}, persists until $T_{comp}=185$ K for FR susceptibility. Similar results were previously observed for other heavier rare earth garnets like DyIG and ErIG.[17]

To describe the HoIG:Al ferrite magnetization, the Dionne's model was used, with the Ho^{3+}-Fe^{3+} molecular field coefficients of pure HoIG. In the spontaneous state, the properties are explained with a Brillouin function modulated by a spin angle of 51.5° independent of temperature as proposed by Dionne. On the contrary, a field dependent canting angle $\varphi_T(H)$ has to be used to interpret the high field $M(H)$ curves. Two different behaviors of $\varphi_T(H)$ were observed below and above T_{comp}.

Measurement of the Faraday effect of garnet film in alternating magnetic fields

Jia Ouyang, Ying Zhang, and Huahui He
Department of Solid State Electronics, Huazhong University of Science and Technology, Wuhan, Hubei 430074, China

A method of measuring the peak value of the Faraday rotation Φ_F (hereafter referred to as the dynamic Faraday rotation) induced by an alternating magnetic field is described. It requires accurate measurement of the fundamental and the second harmonics of the photodetector currents. The sample is a $(BiPrGdYb)_3(FeAl)_5O_{12}$ magneto-optic garnet film prepared by liquid phase epitaxy. Using the presented method, we successfully measured the dynamic Faraday rotation in the garnet film at the near infrared wavelength 1.55 μm of the light beam. The result shows that Faraday rotation induced by an alternating magnetic field is proportional to ac current and decreases with increasing ac frequency. The method is simple, general, accurate, and can be used at any ac frequency. Experimental errors in our measurement are analyzed and an accuracy better than 2% can be obtained. Finally, some of the factors which may influence the measurement results are discussed.

INTRODUCTION

In recent years, the magneto-optical devices based on magneto-optic garnet film have found wide applications in optical communication and optical processing.[1] When magneto-optic garnet film is placed in an alternating magnetic field, its magnetization varies correspondingly to result in a dynamic Faraday rotation. The Faraday effect in alternating magnetic fields is the basis for modulator[2] and magnetic field sensors.[3] Therefore, it is of great importance to know and understand the magneto-optical characteristics of garnet film in an alternating magnetic field. Although the research on the frequency characteristic of the Faraday rotation in some materials such as FR-5 glass and CdMnTe have been reported,[4,5] few of the research efforts have been focused on garnet films. In this paper, we present a technique for measuring the peak value of Faraday rotation in an alternating magnetic field. The dependence of dynamic Faraday rotation on frequency and current is measured at the near infrared wavelength of the light beam. Finally, the factors influencing the measuring precision are discussed and an approximate formula for evaluating the measurement error is given.

PRINCIPLE OF MEASUREMENT

The configuration of measuring cell is shown in Fig. 1. The magneto-optic garnet film is placed in the coil which provides an alternating magnetic field. Let 0° (reference) and $(90°+\Phi)$ be the polarization directions of the polarizer P and the analyzer A respectively. Neglecting the nonlinear response of dynamic Faraday rotation with respect to the ac field, the polarization rotation induced by the sample in field $H \sin \omega t$ is $\Phi_F \sin \omega t$. According to Malus law, after the light has passed through P. A, the light intensity is given by

$$I=I_0[\cos^2(90°+\Phi+\Phi_F \sin \omega t)], \tag{1}$$

where I_0 is the intensity of input laser beam and Φ_F is the peak value of the dynamic Faraday rotation. When $\theta=2\Phi_F \sin \omega t$, $\sin \theta$ and $\cos \theta$ can be expanded into sums of Bessel function J_n of the first kind[6]

$$\sin \theta=2\sum_{n:\text{odd}} J_n(2\Phi_F)\sin n\omega t, \tag{2}$$

$$\cos \theta=J_0(2\Phi_F)+2\sum_{n:\text{even}} J_n(2\Phi_F)\cos n\omega t. \tag{3}$$

Using Eqs. (2) and (3), it is easy to see that Eq. (1) can be rewritten as

$$\begin{aligned} 2I/I_0=1&-J_0(2\Phi_F)\cos 2\Phi+2J_1(2\Phi_F)\sin 2\Phi \sin \omega t \\ &-2J_2(2\Phi_F)\cos 2\Phi \cos 2\omega t \\ &+J_3(2\Phi_F)\sin 2\Phi \sin 3\omega t\ldots \end{aligned} \tag{4}$$

When $\Phi=0°$, i.e., P and A perpendicular to each other, the first harmonic I_f becomes zero, but the second harmonic I_{2f} reaches maximum. Let λ be the ratio between I_{2f} and I_f. When P and A deviate from perpendicular position,

$$\lambda=I_{2f}/I_f=J_2(2\Phi_F)\cos 2\Phi/J_1(2\Phi_F)\sin 2\Phi. \tag{5}$$

If we measure λ and Φ, Φ_F can be calculated.

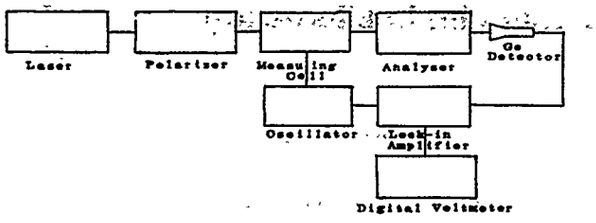

FIG. 2. The experimental apparatus for measuring the dynamic Faraday effect in the $(BiPrGdYb)_3(FeAl)_5O_{12}$ magneto-optic garnet film.

MEASUREMENT AND RESULT

In our experiment, the sample was a magneto-optic garnet film with a $(BiPrGdYb)_3(FeAl)_5O_{12}$ composition grown on (111) oriented gadolinium gallium garnet (GGG) substrate by liquid phase epitaxy (LPE) The coercivity H_a is 3 Oe, and the saturation magnetic field H_s is 320 Oe. The hysteresis loop is close to a straight line.[7] Therefore, only the fundamental harmonic component of dynamic Faraday rotation need be considered. The measurement system is shown in Fig. 2. The light source used for the measurement was a 3 mW stabilized He-Ne laser operating at 1.55 μm. For both the polarizer (P) and the analyzer (A), we chose a Glan–Thompson prism with an extinction ratio $<10^{-6}$. The transmitted light after the analyzer was detected by the Ge detector. The output of the detector was connected to the input of EG&G 128A lock-in amplifier. The reference signal came from the oscillator which also provided the ac current for the coil. The oscillator current and the dc output voltage of the lock-in amplifier were both measured using accurate digital meters. The analyzer is mounted on a rotatable table with a precision of 0.005° for the measurement of Φ.

When the lock-in amplifier reference frequency is set to f by rotating analyzer A until the amplitude of the fundamental component I_f of the transmitted light intensity became zero as indicated by the zero output of the lock-in amplifier, we can determine accurately that P and A are perpendicular to each other. Turning the lock-in amplifier reference frequency to f and 2 f and measuring the output voltage of the lock-in amplifier, respectively, we could determine the fundamental and the second component I_f, I_{2f} of the transmitted light intensity at different angles between P and A away from the perpendicular position. When the frequency and intensity of ac current were kept at 1 kHz and 0.2 A, respectively, and the angle Φ was changed, the results of Φ_F for the $(BiPrGdYb)_3(FeAl)_5O_{12}$ film with a thickness of 20 μm are listed in Table I. These results show good consistency for several values of Φ and suggested the validity of our method. Keeping the current intensity constant and

Φ (deg)	1°	2°	3°	4°
V_f (mV)	1.002	2.017	2.970	4.311
V_{2f} (mV)	0.074	0.076	0.075	0.079
Φ_F (deg)	0.298	0.305	0.303	0.295

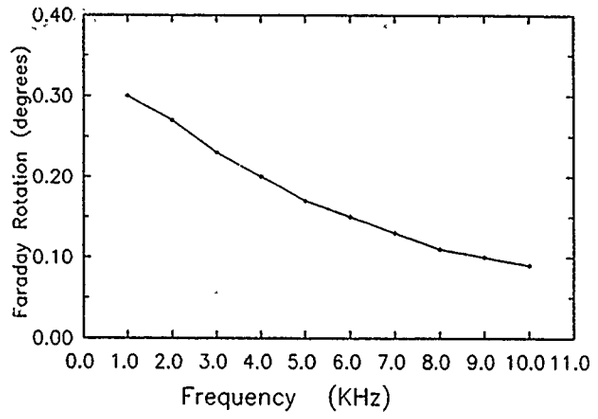

FIG. 3. The dynamic Faraday rotation vs the frequency of an alternating field.

changing the frequency, we measured the dependence of the dynamic Faraday rotation Φ_F on frequency of the ac current and the result is shown in Fig. 3. As the frequency response of dynamic Faraday effect depends on the ability of the induced magnetization to follow the applied alternating field, the relaxation of the magnetization of the garnet film leads to a decrease of the dynamic Faraday rotation when frequency of the ac current increases. This may result from defects impeding the domain-wall motion. The dependence of dynamic Faraday rotation Φ_F on the intensity of the ac current is shown in Fig. 4.

Dynamic Faraday rotation Φ_F is calculated from the given experimental values of λ and Φ. For our sample, the dynamic Faraday rotation Φ_F is much less than 1. By the approximation of the Bessel function, we have

$$J_2(2\Phi_F)/J_1(2\Phi_F)=\Phi_F/2. \tag{6}$$

From Eqs. (5) and (6) we obtain

$$\Phi_F=2\lambda \text{ tg } 2\Phi. \tag{7}$$

Therefore, the relative measurement error of Φ_F is

$$\Delta\Phi_F/\Phi_F=\Delta\lambda/\lambda+4\Delta\Phi/\sin 4\Phi. \tag{8}$$

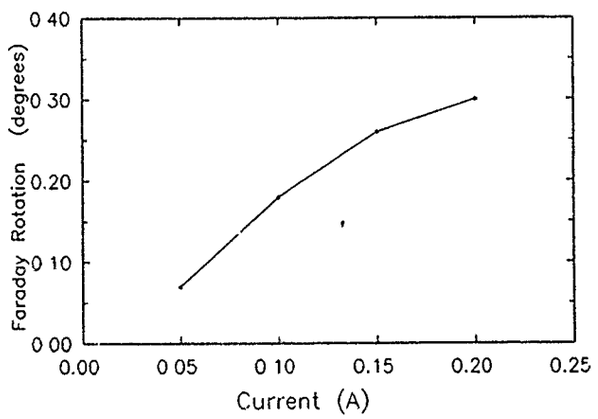

FIG. 4. The dynamic Faraday rotation vs the current intensity.

As the above equation indicates, the accuracy of measurement depends on the accuracy at which λ and Φ can be individually measured. To obtain a high accuracy, we must maintain the ac current stability better than 10^{-4}; I_f and I_{2f} should be measured under the same sensitivities in the f and $2f$ detector channel and a high precision digital voltmeter should be used. Equation (8) also indicates that when $\Phi=22.5°$, the measurement error becomes minimum, but in fact we measured λ at smaller values of Φ to avoid the shot noise. In our measurement, the accuracy of Φ is 0.005°. The I_f and I_{2f} are read on a high precision digital voltmeter which allows the relative error of measurement of λ lower than 10^{-2}. A relative precision better than 2% for Φ_F can be estimated from Eq. (8).

When the hysteresis loop of samples cannot approximate to a straight line, two factors may deteriorate the measurement result, namely the possible nonlinear response of the dynamic Faraday rotation with respect to the ac field and the possible hysteresis to the dynamic Faraday rotation. The first factor will introduce higher harmonics to the dynamic Faraday rotation. The second factor, on the other hand, will introduce retardation of the phase between the dynamic Faraday rotation and the applied field. Therefore, the dynamic Faraday rotation cannot be simply calculated from Eq. (5), and a more complicated analysis is required.

CONCLUSION

In summary, the experimental apparatus for measuring the dynamic Faraday effect is set up. By using the apparatus, we have measured the peak value of the Faraday rotation of the magneto-optic garnet induced by an alternating magnetic field. The dependence of the dynamic Faraday on the frequency and ac current is investigated. The apparatus is simple, accurate, general, and can be used to measure the dynamic magneto-optical characteristic of magneto-optic materials by observing the frequency response of the Faraday rotation.

The calculations of the spontaneous electric Faraday rotation (FR) and the magnetization contributed by Tb^{3+} ions in Tb substituted iron garnets based on the quantum theory are presented. The crystal field (CF) and the superexchange interaction are two crucial factors in determining FR and the magnetization. Every CF splitting level is nondegenerate. But the energy differences between the lowest seven CF split levels of the ground configuration are not very large comparing with the superexchange interaction upon the Tb^{3+} ions, so the strong admixing of these levels by the high-order perturbation of the exchange interaction makes FR and the magnetization not small. Except FR below 150 K, the calculated results are in good agreement with experiments.

I. INTRODUCTION

Many experimental investigations about the magneto-optic (MO) and magnetic properties of various rare-earth substituted garnets (RE:YIG) have been carried out. It has been found that the MO behavior of some RE:YIG is excellent, but the origin of the MO effect induced by the RE ions in such compounds is not well known. In a previous paper we have reported the calculations of the Faraday rotation (FR) at room temperature in some RE:YIG.[1] In this paper, the temperature dependence of the magnetization contributed by the Tb^{3+} ions and that of FR caused by the intra-ionic electric dipole (ED) transitions between the $4f^8$ and $4f^75d$ configurations of the Tb^{3+} ions in terbium substituted garnets (Tb:YIG) has been calculated based on the quantum theory. Except FR below 150 K, the calculated results are in good agreement with experiments.

The temperature dependence of the magnetization depends on the splitting of the ground configuration due to the crystal field (CF) and superexchange interaction upon the Tb ions. While the FR depends not only on the splitting of the ground configuration but also on the splitting of the excited configuration. Therefore, calculating the magnetization and FR at the same time is helpful for studying the origin of the MO effect and the magnetization of the RE ions in such compounds.

II. THE CALCULATION OF THE MAGNETIZATION

To calculate the magnetization contributed by the Tb^{3+} ions, it is necessary to calculate the splitting of the ground configuration of the Tb^{3+} ions. The perturbation Hamiltonian of a Tb^{3+} ion in the crystal is

$$H' = H_{SO} + H_C + H_{ex}, \tag{1}$$

here H_{SO} is the spin-orbit coupling, H_C the CF Hamiltonian, and H_{ex} the superexchange interaction

$$H_{SO} = \lambda \mathbf{LS}, \tag{2}$$

$$H_C = \sum_i \sum_{kq} A_{kq} r_i^k Y_{kq}(\theta_i, \varphi_i), \tag{3}$$

$$H_{ex} = 2\mu_B \mathbf{H}_m \mathbf{S}. \tag{4}$$

Here L and S are the total orbit and the total spin angular momentum operators, respectively, H_m the molecular field, and μ_B the Bohr magneton. The superexchange interaction is less than the spin-orbit coupling and CF, so we carry out the perturbation calculation in the order of priorities: $H_{SO}+H_C$ and H_{ex}. For a free Tb^{3+} ion, the lowest multiplet of the $4f^8$ configuration is $^7F_6$, the first excited multiplet is $^7F_5$. The energy difference between these two multiplets is not very large, so we take these two multiplets together for perturbation calculation. Solving the following secular equation

$$\| \langle JJ_z | H_{SO} + H_C | J'J_z' \rangle \quad E\delta_{JJ'}\delta_{J_zJ_z'} \| = 0 \tag{5}$$

we have obtained the CF split energy levels and wavefunctions. The values of the matrix elements $\langle JJ_z|H_{SO}|J'J_z'\rangle \delta_{JJ'}\delta_{J_zJ_z'}$ are taken from the book by Martin *et al.*[2] The choice of the proper set of the parameters of the CF upon the Tb^{3+} ions is a crucial step. The values obtained with a point charge model are too small to obtain correct results. A similar situation was also found when studying the magnetic properties of some other RE substituted garnets. Nekvasil *et al.*[3] have determined a set of parameters for the CF upon the Sm^{3+} ions in SmIG by fitting the experimental results about the magnetic phase transition in SmIG. In this paper, it is supposed that the CF parameters A_{kq} are the same for the Sm^{3+} ions in SmIG and the Tb^{3+} ions in Tb:YIG. That is, the values of $\langle r^k \rangle A_{kq}$ are determined by the values of the CF parameters for the Sm^{3+} ions in SmIG and the ratio of the values of $\langle r^2 \rangle$, $\langle r^4 \rangle$, and $\langle r^6 \rangle$ of the Sm^{3+} and Tb^{3+} ions. The nonzero parameters are shown in Table I. The energies of the lowest ten CF split levels are -367.5, -355.2,

TABLE I. The values of the parameters of the CF upon the Tb ions (in cm^{-1}).

	$\langle r_2\rangle A_{20}$	$\langle r^2\rangle A_{2\pm2}$	$\langle r^4\rangle A_{40}$	$\langle r^4\rangle A_{4\pm2}$	$\langle r^4\rangle_{4\pm4}$
$4f$	−638	246	−4229	214	980
$5d$	−3063	1180	−67567	3416	14245
	$\langle r^6\rangle A_{60}$	$\langle r^6\rangle A_{6\pm2}$	$\langle r^6\rangle A_{6\pm4}$	$\langle r^6\rangle A_{6\pm6}$	
$4f$	1110	−109	500	49	

−294.5, −254.9, −208.9, −198.4, −108.0, 39.8, 79.2, 191.8 cm^{-1}. Here the energy of the multiplet $(4f^8)^7F_6$ of a free Tb^{3+} ion is taken to be zero. Because the environment of the Tb^{3+} ions in Tb:YIG has D_2 symmetry, every level is nondegenerate.

The nondegenerate states have no contribution to FR. But the energy differences between the lowest seven levels are not very large comparing with the superexchange interaction. So the admixing of these states due to the superexchange interaction is large and the admixed states have contribution to the magnetization and FR. Such admixing is calculated by solving the following secular equation:

$$\|\langle\psi_i|H_{SO}+H_C+H_{ex}|\psi_j\rangle-E_g\delta_{ij}\|=0. \tag{6}$$

In the calculation, the bras and kets include the wavefunctions of the lowest seven CF levels. The values of the matrix elements $\langle\psi_i|H_{SO}+H_C|\psi_j\rangle\delta_{ij}$ are the energy values of these states.

The Zeeman effect of the Tb^{3+} ions depends mainly on the superexchange interaction between the Fe and Tb ions. The resultant magnetization of two Fe sublattices in Tb:YIG is well represented by the magnetization of YIG (M_{YIG}). So, the molecular field H_m acting upon the Tb^{3+} ions can be expressed as

$$H_m=nM_{YIG}. \tag{7}$$

According to the idea of Neel,[4] n is a linear decreasing function of temperature. In a first order it has the form:

$$n=n_0(1+\gamma T). \tag{8}$$

The values of the average magnetic moment of a Tb^{3+} ion at various temperatures have been calculated with the following formula:

$$\bar{m}=-\mu_B\sum_g\langle g|(L_z+2S_z)|g\rangle\rho_g. \tag{9}$$

Here ρ_g is the occupation probability of the state $|g\rangle$,

$$\rho_g=e^{-E_g/kT}\Big/\left(\sum_g e^{-E_g/kT}\right)=\rho_0\,e^{-E_g/kT}, \tag{10}$$

where E_g is the energy of the state $|g\rangle$. They are obtained by solving Eq. (6). The values of M_{YIG} at various temperatures have been obtained by Gonano.[5] n_0 and γ are determined by the self-consistent calculation of $\bar{m}$.

The optimum value of γ is -1.5×10^{-3} K^{-1}. It is near the value obtained by Leycuras *et al.*[6] for Ce^{3+} ions in Ce:YIG. The optimum value of n_0 is 8.0×10^4 Oe/(μ_B/two formula of YIG). The calculated values of $\bar{m}$ are given in Table II. In the table, the measured values obtained by Guillot *et al.*[7] are also given as comparison. It is seen that the calculated values are in good agreement with the measured values.

III. THE CALCULATION OF THE FARADAY ROTATION

The FR per unit length of the medium caused by the intraionic ED transitions is[8]

$$\theta_F=\frac{N\pi}{9\hbar c}\frac{(\bar{n}^2+2)^2}{\bar{n}}\sum_{g,n}\frac{\omega^2}{\omega_{ng}^2-\omega^2}\{|\langle n|V_-|g\rangle|^2-|\langle n|V_+|g|\rangle^2\}\rho_g \tag{11}$$

for each type of ion present in the material, where c is the velocity of the light in vacuum, N the number of ions per unit volume, $\bar{n}$ an average refractive index, ω the angular frequency of the light wave, g runs over the CF and exchange interaction split $4f^8$ states with occupation probability ρ_g, and n runs over the CF split $4f^75d$ states at energy $\hbar\omega_{ng}$ above the ground states. $V_\pm$ are the ED moment operators for right- and left-handed circularly polarized light,

$$V_\pm=\sum_i e[x(i)\pm jy(i)], \tag{12}$$

where Σ_i indicates summing over the ED moments of all $4f$ electrons.

The following formula[9] has been used to calculate transitional matrix elements:

TABLE II. The calculated and measured values of the magnetic moment $\bar{m}$ of the Tb^{3+} ion and the FR θ_F per unit length at 1150 nm wavelength contributed by the intra-ionic electric dipole transitions of the Tb^{3+} ions. $\bar{m}$ in μ_B/ion, θ_F in deg/cm^{-1} per Tb ion, T in K.

[b]M. Guillot, H. Le Gall, A. Marchand, J. M. Desvignes, and M. Artinian, J. Magn. Magn. Mater. **83**, 25 (1990).

$$\langle l_1^n \alpha LSJM_J | r^k Y_{kq} | l_1^{n-1} l_2 (\alpha' L_1 S_1 l_2) L'S'J'M_J' \rangle$$

$$= (-1)^{J+J'+L_1+S+l_1+l_2-M_J} \delta_{SS'} \left(\frac{n}{4\pi} [J,J',L,L',l_1,l_2,k] \right)^{1/2} \begin{pmatrix} J & k & J' \\ -M_J & q & M_J' \end{pmatrix} \begin{pmatrix} l_1 & k & l_2 \\ 0 & 0 & 0 \end{pmatrix} \begin{Bmatrix} L & S & J \\ J' & k & L' \end{Bmatrix}$$

$$\times \begin{Bmatrix} l_1 & L_1 & L \\ L' & k & l_2 \end{Bmatrix} \langle l_1^n \alpha LS \{ | l_1^{n-1} \alpha' S_1 L_1 \rangle \langle l_1 | r^k | l_2 \rangle, \tag{13}$$

where $[J]=2J+1$.

According to Ref. 2, the lowest term of the $4f^7 5d$ configuration of the Tb^{3+} ions is ^9D, the second term is ^7D. The ED transition from the $(4f^8)^7F$ term to $(4f^7 5d)^9D$ term is forbidden. Furthermore, this term cannot be admixed with the ^7D term by CF. The $4f^7 5d$ configuration has many higher energy terms. The transitions from them to the $(4f^8)^7F$ states are allowed. But the values of the energy of these terms are not found. Therefore, when we solve Eq. (5) to calculate the splitting of the $4f^7 5d$ configuration due to FR, only the multiplets $^7D_5$ and $^7D_4$ have been included. In calculating FR, the energies of all other terms are supposed to be equal to the average energy of the $4f^7 5d$ configuration, i.e., 64400 cm^{-1}.[2,10] According to our calculation, the ED transition probabilities between the $(4f^8)$ $^7F_6$ and $^7F_5$ multiplets and these terms are much less than the transition probabilities between the $^7F_6$ and $^7F_5$ multiplets and the $(4f^7 5d)^7D_5$ and $^7D_4$ multiplets. So the error due to the above approximation is small. The effect of the superexchange interaction on the $4f^7 5d$ configuration is neglected. The accurate value of $\langle r \rangle_{4f5d}$ of the Tb^{3+} ion is not found, so it is determined by fitting the measured values of FR and by comparing with the similar values of other RE ions. The value used is 0.187 Å.

The calculated values of FR per unit length per Tb ion are shown in Table II, in which the measured values obtained by Guillot *et al.*[11] are shown as well. It is seen that the calculated values agree with experiments in the temperature range from 150 to 300 K.

IV. DISCUSSION

From the above results, it is seen that except FR below 150 K, the behavior of the magnetization and FR contributed by the Tb^{3+} ions in the garnets is well explained. The CF and superexchange interaction are the two most important factors in determining the magnetic and MO behavior of the Tb^{3+} ions in the garnets. As the splitting of the states due to CF is not large enough, the FR at the near infrared region and the FR at the visible region have the same sign. The admixing of different CF levels of the $4f^8$ configuration by the high-order perturbation of the exchange interaction is large; otherwise, the magnetization and FR contributed by the Tb^{3+} ions will be very small.

The cause of the difference between the calculated and measured values of FR at low temperature is not clear. It can be seen from Table II, the calculated MO coefficient, which equals the ratio of θ_F to $\dot{m}$, is nearly a constant in the whole temperature range studied, in accord with the theory of Crossley *et al.*[8] According to Refs. 12 and 13, the covalency of the $5d$ states with the neighboring ions is large and depends on the electronic structure of the RE ions. Therefore, the assumption that the values of the parameters ($\langle r^2 \rangle A_{20}$ etc.) of CF upon the $5d$ electrons are proportional to the values of $\langle r^2 \rangle$ and $\langle r^4 \rangle$ of the $5d$ shells of different RE ions may be not good. According to our work for Ce:YIG, if the CF splitting of the $4f^{n-1}5d$ configuration is large enough, the MO coefficient will be dependent on the temperature.[14] Therefore, we think that the simple assumption about the CF upon the $5d$ electrons may be one cause for making the theoretical values of FR deviate from the true values at low temperature.

The temperature-dependent sensitivity characteristic in the zeroth-order diffraction beam from the multidomain materials of $Bi_XGd_YY_{3-(X+Y)}Fe_5O_{12}$ films grown by a conventional liquid-phase-epitaxial method are studied. By measuring the variation of the sensitivity with temperature, it was found that films with $X=1.3$ and $Y=0.43$ show the minimum value of $\pm 0.5\%$ between 253 and 353 K. The contribution of the Gd substitution on the improvement of the temperature dependence of the sensitivity was explained by a simple theoretical calculation.

I. INTRODUCTION

With recent developments in optical magnetic field (current) sensors based on Faraday effect, there has been considerable demand for applying these sensors to electric power systems such as power delivery systems to measure current, and to monitor the condition of these lines.[1] Hence high sensitivity, high accuracy in the operating temperature range and high reliability are required for such sensors. It is expected that rare-earth iron garnets, especially Bi-subsutituted iron garnets [hereafter referred as (BiR)IG] have high sensitivity constants because of a large Faraday rotation angle. But recently the attribution of Faraday loops to both the magnetization process (the domain wall displacement or the magnetization rotation) and the light beam diffraction by the stripe magnetic domain structure of garnet films has been made clear.[2]

In this paper we report the experimental results on the sensitivity temperature dependence in detecting only the zeroth-order diffraction beam from (BiR)IG, which takes the boundary displacement process for magnetization reversal. And we also report on Gd-substituted (BiY)IG films with the minimum temperature dependence of the sensitivity and on the available calculation results on the temperature dependence.

II. EXPERIMENTS

(BiR)IG films were grown on (111)-oriented $(GdCa)_3(MgZrGa)_5O_{12}$ substrates by means of a liquid-phase-epitaxial (LPE) dipping technique with a horizontal rotation mode. A $PbO\text{-}Bi_2O_3\text{-}B_2O_3$ system was employed as a solvent and B_2O_3 rich melts were used to obtain highly Bi substituted films.[3] The chemical composition of the prepared films was determined by electron probe micro-analysis.

Sensitivity constants measurements were made in the temperature range of 223–393 K using 850 nm GaAlAs-light-emitting-diode (LED) light which propagates parallel to the external field as shown in Fig. 1. Two Glan–Thompson prisms were used for the polarizer and analyzer and the analyzer is at an angle of 45° with respect to the polarizer.

Figure 2 shows the film thickness dependence of the magnetic domain width measured from Faraday effect patterns and the first-order diffraction angle of the He-Ne laser beam. From these results the first-order diffraction angle of 4.7° was obtained by the calculation at the wavelength of a light source (850 nm). This is too large to condense all of the diffracted beams by a lens (for example the rod lens of NA =0.37 and 2 mm ϕ used to realize compact sensor modules). So the Faraday output signal only in the zeroth-order diffraction beam throughout a pin-hole was measured by a single-ended fixed analyzer method[2] as shown in Fig. 1.

III. RESULTS AND DISCUSSION

Figure 3 shows the measured result of the Faraday output signal and the obvious hysteresis loop was not observed in this measurment. The normalized Faraday output intensity according to the domain wall movement magnetization is given by

$$P=[1+(H/H_s)\tan(\theta_F d)]^2, \tag{1}$$

where, H, H_s, θ_F, and d are external magnetic field, the magnetic saturation field, the Faraday rotation angle, and the film thickness, respectively. The calculated result by Eq. (1) is represented by a solid line in Fig. 3. The measured results are in good agreement with the calculated result and it is confirmed that the boundary displacement is the dominant magnetization process in the (111)-LPE-(BiR)IG film.

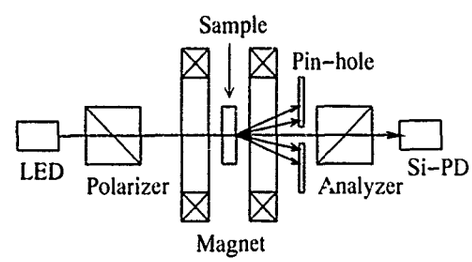

FIG. 1. A schematic diagram of the measuring system for the present study.

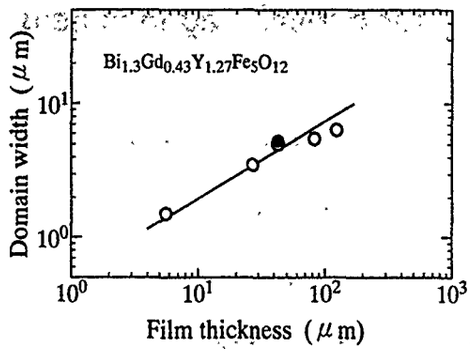

FIG. 2. The film thickness dependence of the domain width: ○ and ● show measured results from Faraday effect patterns and first-order diffraction angle, respectively.

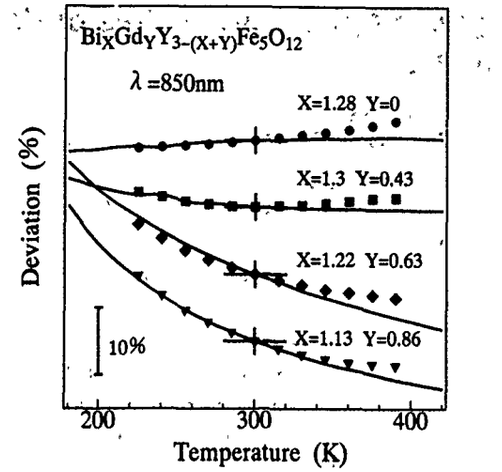

FIG. 4. Temperature dependence of sensitivity for various Gd concentrations. Plotted points show measured results and solid lines shows calculated results by Eqs. (1), (2), and (3).

The temperature dependence of the sensitivity deviation from the value of 300 K in four kinds of compositions is shown in Fig. 4. The results on (BiY)IG (Y=0), which are plotted (●), show a positive dependence and substitution with Gd decreases the gradients of the dependence and the sign of the dependence changes to minus for Y larger than 0.43. The sample of $X=1.3$ and $Y=0.43$ shows a minimum of ±0.5% between 253 and 353 K.

Equation (1), which gives the Faraday output intensity characteristics, contains two temperature dependent physical constants of θ_F and H_s. Hence when the term of $\tan[\theta_F(T)d]/H_s(T)$ in Eq. (1) have no temperature dependence, the sensitivity is unchanged with temperature. And by this consideration the contribution of Gd substitution to the improvement of the temperature dependence of the sensitivity can be explained as follows.

The saturation magnetization and its temperature dependence $M_s(T)$ corresponding to $H_s(T)$ of ferrimagnetic garnets can be well described in terms of the molecular field theory.[4-6] The net magnetic moment per mole is given by

$$M_s(T)=|M_d(T)-M_a(T)-M_c(T)|, \tag{2}$$

where the subscript refers to the particular sublattice. In calculating $M_s(T)$ of (BiGdY)IG modified molecular field coefficients[7,8] were used to account for the linear dependence of T_{comp} and T_c with Bi concentration X. Figure 5 shows the calculated results for various Bi and Gd concentrations. It is obvious that the gradients of the temperature dependence around room temperature decreased steadily with an increase in the Gd concentration.

Figure 6 shows the measured temperature dependence of Faraday rotation angle for various Bi and Gd concentrations and over the temperature range from 300 to 600 K. From these results it is found that the Faraday rotation angle increases in proportion to the Bi concentration and does not depend on the Gd concentration. The gradients of $\theta_F(T)$ around room temperature also do not depend on the Gd concentration. According Crossley model,[9] the value of $\theta_F(T)$ can be calculated in terms of the sublattice magnetization[10,11] and are given as

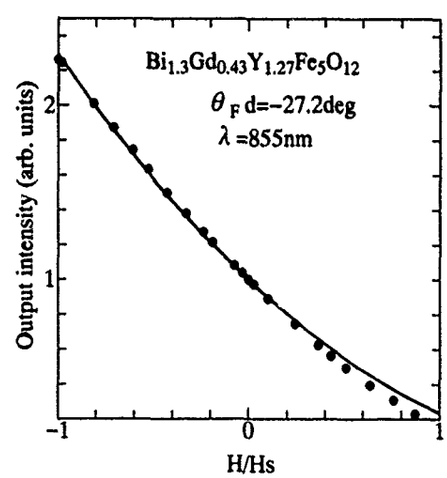

FIG. 3. Sensor output intensity vs applied magnetic field. ● show measured results and solid line show the calculated result by Eq. (1).

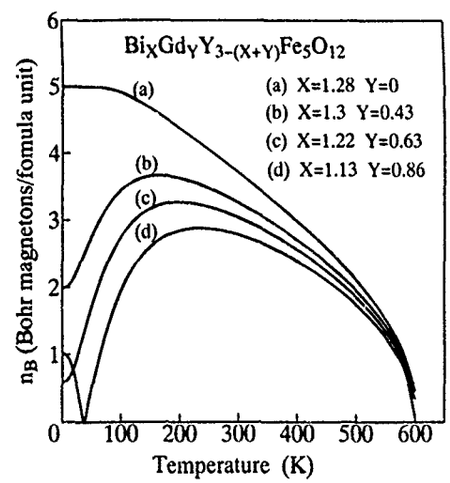

FIG. 5. Calculated results of temperature dependence of magnetization for various Gd concentrations by the molecular field theory (see Refs. 4–6).

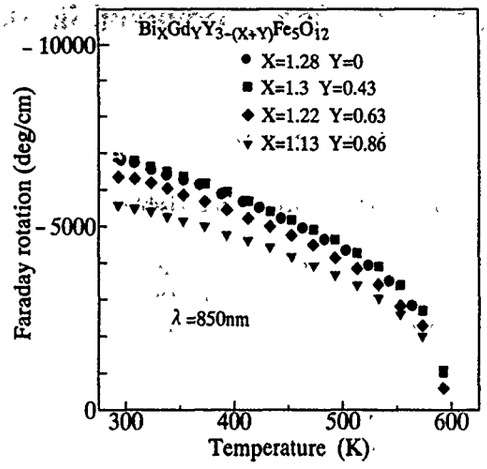

FIG. 6. Temperature dependence of Faraday rotation for various Bi and Gd concentrations.

$$\theta_F(T)=AM_a(T)+DM_d(T)+CM_c(T), \tag{3}$$

where A, D, and C are the magneto-optical coefficients for each site. From the measured results shown in Fig. 6 values of A, D, and C for (BiGdY)IG with five different compositions were determined by the fitting method and $\theta_F(T)$ over the temperature range 180–420 K were calculated by Eq. (3).

Using these calculated results on $M_s(T)$ and $\theta_F(T)$, the temperature dependence of the sensitivity was obtained by Eq. (1) for various Bi and Gd concentrations. The results were shown in Fig. 4 with a solid line. They show good agreement with the experimental results.

IV. CONCLUSION

Bi-substituted rare-earth iron garnet films, $Bi_XGd_YY_{3-(X+Y)}Fe_5O_{12}$ for optical magnetic field sensors were prepared by the LPE method. From sensitivity measurements it was found that in the case of the zeroth-order diffraction detection $Bi_{1.3}Gd_{0.43}Y_{1.27}Fe_5O_{12}$ has the minimum temperature dependence within ±0.5% over the temperature range of 253–353 K. By the calculated results on $\theta_F(T)$, which was calculated in terms of the sublattice magnetizations, and $M_s(T)$ by the molecular field theory, the contribution of the Gd substitution on the improvement of the temperature dependence of the sensitivity can be explained.

Calculated results agree well with the experimental results of the temperature dependence of sensitivity.

Magneto-optical properties of Al and In-substituted CeYIG epitaxial films grown by sputtering (abstract)

M. Gomi and M. Abe[a)]
Department of Materials Science, Japan Advanced Institute of Science and Technology, Asahidai 15, Tatsunokuchi, Ishikawa 923-12, Japan

Cerium substitution to iron garnet strongly enhances magneto-optical (MO) effect in the visible region around $h\nu=1.4$ and 3.1 eV. We have previously proposed a $Ce^{3+}(4f)$-Fe^{3+} (tet.) charge transfer model as an electronic transition inducing the strong MO effect.[1] In this study, we have measured Faraday spectra of CeYIG films in which Fe ions were diluted with Al or In ions. These ions, respectively, are known to preferentially occupy tetrahedral and octrahedral iron sites in the garnet structure, giving us some information on the role of Fe^{3+} in the MO enhancement. The $Y_2Ce_1Fe_{5-x}M_xO_{12}$ (M=Al, In; $x=0-5$) films were epitaxially grown *in situ* on (111)-oriented $Gd_3Ga_5O_{12}$ (GGG) single crystal substrates by conventional rf diode sputtering. With the amounts of substitutions increasing, Faraday rotation and ellipticity of the films at $h\nu=1.4$ eV reduced at nearly the same rates for both ions of Al and In. We found from the analysis using molecular field theory that these reductions are in proportion to the magnetic moment of the tetrahedral iron sublattice. This indicates that the tetrahedral Fe^{3+} contributes to the electronic transition at 1.4 eV, supporting the proposed charge transfer model.

TE/TM polarized light reflection from a multilayer structure containing a magneto-optic (MO) and a metal film is investigated theoretically and experimentally. A metal film is used whose thickness is chosen to support long-range surface polaritons (SP). This is to use their sharp resonance for tuning the whole structure. It was shown that if the MO layer is placed in a multilayer structure consisting of a thin metal film that supports a long-range surface polariton, the resonance couples to the off-diagonal element of the YIG-film dielectric tensor. This means that this process exhibits a nonreciprocal property, as well as a Faraday rotation in the MO film. A combination of these two effects enhances the value of the magneto-optic quality (Faraday rotation divided by the losses incurred by the light) and the nonreciprocity of the light reflection from the structure. Theoretical and experimental optimization of these effects at a wavelength equal to 0.5 μm has been carried out for thin monodomain single crystal YIG films, saturated by a magnetic field of the order 1 Oe. It has enabled the design of a high frequency operation circulator to be developed. These results will be reported in this paper.

Magnetic Davydov splitting in 2D AFM $(CH_2)_2(NH_3)_2MnCl_4$ (abstract)

V. Eremenko, I. Kachur, V. Piryatinskaya, and V. Shapiro
Institute for Low Temperature Physics and Engineering, Academy of Sciences of Ukraine, 47 Lenin Avenue, 310164 Kharkov, Ukraine

Recently it was shown[1] that the light absorption spectrum of $(CH_2)_2(NH_3)_2MnCl_4$ ($EDAMnCl_4$) differs strongly from those of other compounds of this family $(CH_{2/n}(NH_3)_2MnCl_4$. Additional peculiarities in the spectral distributions of two-magnon Raman scattering and the coefficient of exciton-magnon absorption were found.[2] It was also determined that the pure exciton band in the absorption spectrum is of the electric dipole type of polarization. All these peculiarities are out of the framework of the usual tetragonal two-sublattice antiferromagnet model and indicate the inverse center loss and magnetic cell doubling. Results of studying the absorption spectrum of $EDAMnCl_4$ presented in the report show that not less than three Davydov components of the exciton band ${}^{\sigma}A_{1g}({}^{\sigma}S) \rightarrow {}^{4}E_g({}^{4}G)$ optical transition may be detected with confidence in magnetic fields oriented along the c axis. It confirms the four-sublattice magnetic structure of $EDAMnCl_4$. The presence of exciton line splitting at $H=0$ and its nonlinear character at $\mathbf{H} \| \boldsymbol{\alpha}$ (that is practically parallel to $\mathbf{l}$) allows us to make a conclusion about the resonance interaction between ions with antiparallel spins and, probably, about the initial noncollinearity of magnetic structure. Parameters characterizing the magnetic Davydov splitting are determined using comparison of the experimental data and theoretical analysis.

Magnetic neutron scattering (invited)

J. W. Lynn
Reactor Radiation Division, National Institute of Standards and Technology, Gaithersburg, Maryland 20899

The application of neutron scattering techniques to magnetic problems is reviewed. We will first discuss diffraction techniques used to solve magnetic structures, as well as to measure magnetic form factors, order parameters, critical phenomena, and the scattering from low-dimensional systems. We will also discuss inelastic scattering techniques, including polarized beam methods, utilized to determine the spin dynamics of various materials. Information will be provided about the types of spectrometers available at the user-oriented national facilities located at Argonne National Laboratory, Brookhaven National Laboratory, Los Alamos National Laboratory, The National Institute of Standards and Technology, and Oak Ridge National Laboratory, as well as the spectrometers at the Missouri University Research Reactor.

I. INTRODUCTION

Magnetic neutron scattering plays a central role in determining and understanding the microscopic properties of a vast variety of magnetic systems, from the fundamental nature and symmetry of magnetically ordered materials to elucidating the magnetic characteristics essential in applications. One traditional role has been the measurement of magnetic Bragg intensities in the magnetically ordered regime, which can be used to determine not only the spatial arrangement and atomic magnetization density of the magnetic moments, but also the value of the ordered moments as a function of temperature, pressure, and applied magnetic field. These types of measurements can be carried out on single crystals, powders, thin films, and multilayers, and often the information collected can be obtained by no other experimental technique. Small angle neutron scattering (SANS) is a technique to explore the magnetism over longer distances than conventional diffraction, and is ideal to study domain structures and other spatial variations of the magnetization density on length scales from 1–1000 nm. The relatively new technique of neutron reflectometry can be used to explore the magnetization distribution in the near-surface regime of thin films, multilayers, and crystals. In the investigation of the spin dynamics of systems, though, neutrons play a truly unique role. Neutron scattering is the only technique that can directly determine the complete magnetic excitation spectrum, whether it is in the form of the dispersion relations for spin wave excitations, wave vector and energy dependence of critical fluctuations, crystal field excitations, moment fluctuations, etc. In the present article we will briefly discuss some of these possibilities, and present a few examples taken from recent work at NIST. We will also discuss the neutron instrumentation presently available to the magnetism community, and plans for new instrumentation which will take the field into the next decade and beyond.

There are a number of very good sources of detailed information about neutron scattering. The textbook by Lovesey[1] treats the theory of neutron scattering in depth, and the more recent work of Balcar and Lovesey[2] specifically addresses the theory for the case of magnetic neutron as well as x-ray scattering. Bacon's text[3] is more for the experimentalist, treating experimental procedures and the practicalities of taking and analyzing data. Williams' text[4] focuses on the use of polarized neutrons, while Squires' book[5] is more of a graduate introductory text to the subject. An alternative reference is the recent compendium by Price and Sköld,[6] which covers a variety of topics in neutron scattering in the form of chapters by various experts.

II. MAGNETIC DIFFRACTION

The integrated intensity for a magnetic Bragg reflection is given (for a simple collinear magnetic structure) by[1]

$$I_M = C\mathcal{M}_\tau A(\theta_B)\left(\frac{\gamma e^2}{2mc^2}\right)^2 \langle 1-(\hat{\tau}\cdot\hat{M})^2\rangle |F_M|^2, \qquad (1)$$

where the neutron-electron coupling constant in parenthesis is -0.27×10^{-12} cm, $\hat{\tau}$ and $\hat{M}$ are unit vectors in the direction of the reciprocal lattice vector τ and the spin direction, respectively, and the orientation factor $\langle 1-(\hat{\tau}\cdot\hat{M})^2\rangle$ must be calculated for all possible domains. C is an instrumental constant which includes the resolution of the measurement, $A(\theta_B)$ is an angular factor which depends on the method of measurement, and $\mathcal{M}_\tau$ is the multiplicity of the reflection (for powders). The magnetic structure factor F_M is given by

$$F_M = \sum_{j=1}^{N} \langle \mu_z\rangle_j f_j(\tau) e^{-W_j} e^{i\tau\cdot r_j}, \qquad (2)$$

where $\langle \mu_z\rangle_j$ is the thermal average of the aligned magnetic moment of the magnetic ion at the jth site at position $\mathbf{r}_j$, W_j is the Debye Waller factor for the jth atom, $f(\tau)$ is the magnetic form factor (Fourier transform of the magnetization density), and the sum extends over all magnetic atoms in the unit cell. We see from these expressions that neutrons can be used to determine several important quantities; the location of magnetic atoms and the spatial distribution of their magnetic electrons; the temperature, field,... dependence of $\langle \mu_z\rangle$, which is directly related to the order parameter for the phase

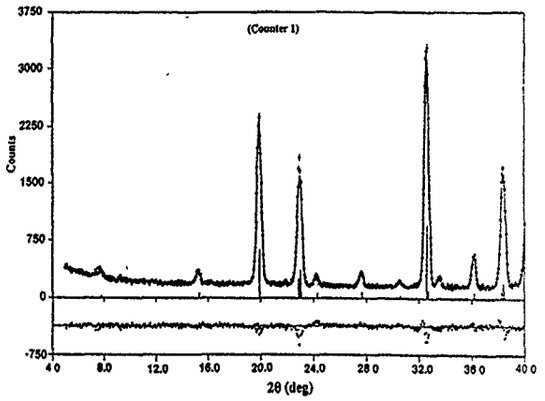

FIG. 1. Calculated (solid curve) and observed intensities for a powder of $YBa_2Fe_3O_8$. The differences between calculated and observed are shown at the bottom (Ref. 7).

transition (e.g., sublattice magnetization). The preferred magnetic axis ($\hat{M}$) also can often be determined from the relative intensities. Finally, the scattering can be put on an absolute scale by internal comparison with the nuclear Bragg intensities from the same sample, whereby the saturated value of the magnetic moment can be obtained.

As an example, a portion of the powder diffraction pattern from a sample of $YBa_2Fe_3O_8$ is shown in Fig. 1.[7] The solid curve is a profile refinement of both the antiferromagnetic and crystallographic structure for the sample. From this type of data we can determine the crystal structure, lattice parameters, site occupancies, etc., as well as the magnetic structure and value of the ordered moment. The results of the analysis are shown in Fig. 2; the crystal structure is identical to the structure for the 1-2-3 superconductor with the Fe replacing the Cu, and the magnetic structure is also the same as has been observed for the Cu spins in the oxygen-reduced (semiconducting) material.

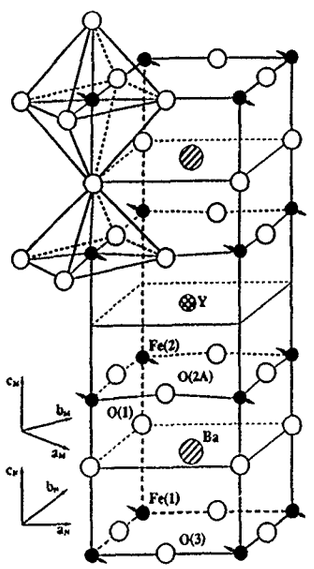

FIG. 2. Crystal and magnetic structure for $YBa_2Fe_3O_8$ (Ref. 7).

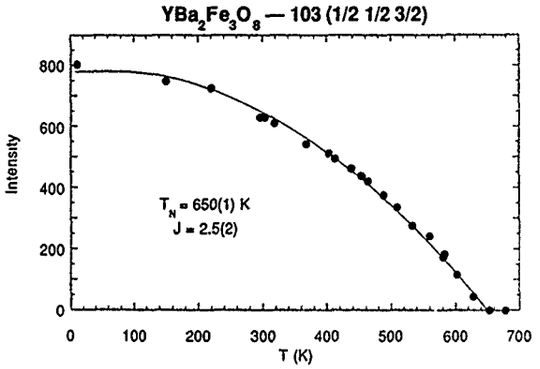

FIG. 3. Temperature dependence of the intensity of the magnetic reflection.

Experimentally we can recognize the magnetic scattering by several characteristics. First, it should be temperature dependent, and the Bragg peaks will vanish above the ordering temperature. Figure 3 shows the temperature dependence of the intensity of the peak at 19.5°, which clearly reveals a phase transition at 650 K. A second characteristic is that the magnetic intensities become weak at high scattering angles (not shown), as $f(\tau)$ typically falls off strongly with increasing angle. A third, more elegant, technique is to use polarized neutrons. The polarization technique can be used at any temperature, and for any material regardless of whether or not it has a crystallographic distortion (e.g., via magnetoelastic interactions) associated with the magnetic transition. It is more involved and time-consuming experimentally, but yields an unambiguous identification and separation of magnetic and nuclear Bragg peaks.

The polarization analysis technique as applied to this problem is in principle straightforward.[8] Nuclear coherent Bragg scattering never causes a reversal, or spin-flip, of the neutron spin direction upon scattering. Thus the nuclear peaks will only be seen in the non-spin-flip [denoted by (++)] scattering geometry. The magnetic cross sections depend on the relative orientation of the neutron polarization **P** and the reciprocal lattice vector transfer τ. In the configuration where $\mathbf{P}\perp\tau$, half the magnetic Bragg scattering involves a reversal of the neutron spin [denoted by the (−+) configuration], and half does not. Thus for the case of a purely magnetic reflection the spin-flip (−+) and non-spin-flip (++) intensities should be equal in intensity. For the case where $\mathbf{P}\parallel\tau$, all the magnetic scattering is spin-flip. Hence for a magnetic Bragg peak the spin-flip scattering should be twice as strong as for the $\mathbf{P}\perp\tau$ configuration, while ideally no non-spin-flip scattering will be observed. Figure 4 shows the polarized beam results for the same two peaks, at scattering angles (for this wavelength) of 30° and 35°; these correspond to the peaks at 19.5° and 23° in Fig. 1. The top section of the figure shows the data for the $\mathbf{P}\perp\tau$ configuration. The peak at 30° has the identical intensity for both spin-flip and non-spin-flip scattering, and hence we conclude that this scattering is purely magnetic in origin as inferred from Fig. 3. The peak at 35°, on the other hand, has strong intensity for (++), while the intensity for (−+) is smaller by a factor of 1/11, the instrumental flipping ratio. Hence this peak is a pure

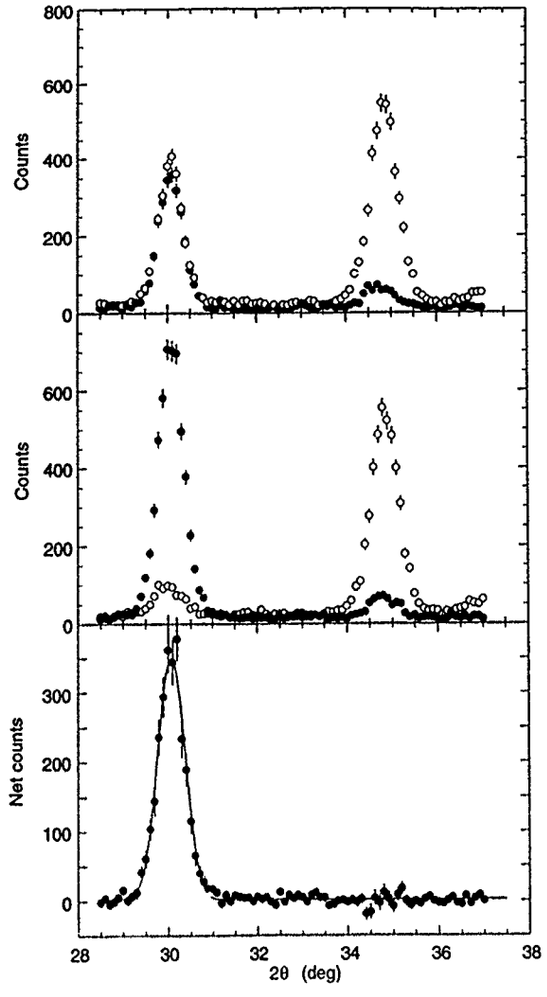

FIG. 4. Polarized neutron scattering. The top portion of the figure is for $\mathbf{P}\perp\tau$, where the open circles ○ show the non-spin-flip scattering and the filled circles ● are the observed scattering in the spin-flip configuration. The low angle peak has equal intensity for both cross sections, and thus is identified as a pure magnetic reflection, while the ratio of the (++) to (−+) scattering for the high angle peak is 11, the instrumental flipping ratio. Hence this is a pure nuclear reflection. The center portion of the figure is for $\mathbf{P}\|\tau$, and the bottom portion is the subtraction of the $\mathbf{P}\|\tau$ spin-flip from the data for $\mathbf{P}\perp\tau$. Note that in the subtraction procedure all background and nuclear cross sections cancel, isolating the magnetic scattering (Ref. 7).

nuclear reflection. The center row shows the same peaks for the $\mathbf{P}\|\tau$ configuration, while the bottom row shows the subtraction of the $\mathbf{P}\perp\tau$ spin-flip scattering from the $\mathbf{P}\|\tau$ spin-flip scattering. In this subtraction procedure instrumental background, as well as all nuclear scattering cross sections, cancel, isolating the magnetic scattering. We see that there is magnetic intensity only for the low angle position, while no intensity survives the subtraction at the 35° peak position. These data unambiguously establish that the 30° peak is purely magnetic, while the 35° peak is purely nuclear. This simple example demonstrates how the technique works; obviously it would play a much more critical role in cases where it is not clear from other means what is the origin of the peaks, such as in regimes where the magnetic and nuclear

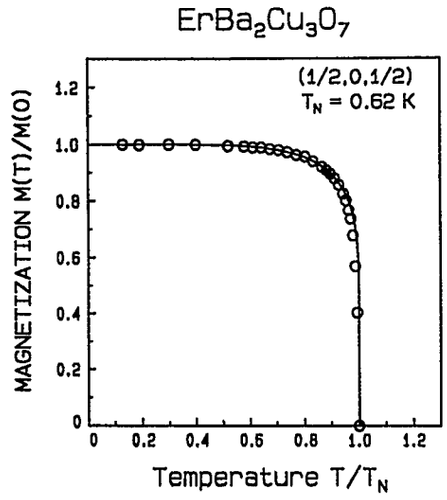

FIG. 5. Temperature dependence of the sublattice magnetization for the Er spins in superconducting $ErBa_2Cu_3O_7$, measured on a single crystal weighing 31 mg. The solid curve is Onsager's exact theory for the two-dimensional, $S=\frac{1}{2}$, Ising model (Ref. 9).

peaks overlap,[7] or in situations where the magnetic transition is accompanied by a structural distortion.

Another example of magnetic diffraction[9] is shown in Fig. 5. Here we show the intensity of a Bragg peak as a function of temperature for the Er ordering in $ErBa_2Cu_3O_7$. The magnetic interactions in this material are highly anisotropic, and this system turns out to be an ideal two-dimensional (planar) Ising antiferromagnet; the solid curve is Onsager's exact solution to the $S=\frac{1}{2}$, 2-D Ising model, and we see that it provides an excellent representation of the experimental data.

A final diffraction example is shown in Fig. 6, where the data for a series of molecular beam epitaxy Fe_3O_4/NiO superlattices are shown.[10] These scans are along the growth direction (Q_z), and we see the (222) fundamental peak (to-

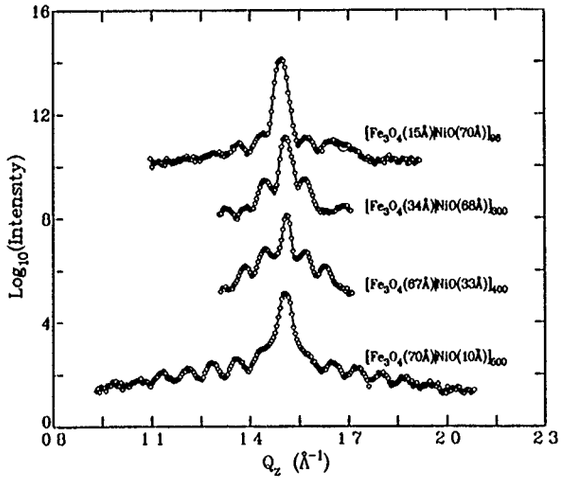

FIG. 6. Observed scattering from a series of Fe_3O_4/NiO multilayers with different layer depths and total thickness. The satellites observed about the fundamental (222) reflection in the center originate from both nuclear and magnetic scattering. The typical weight of these samples is 1 mg (Ref. 10).

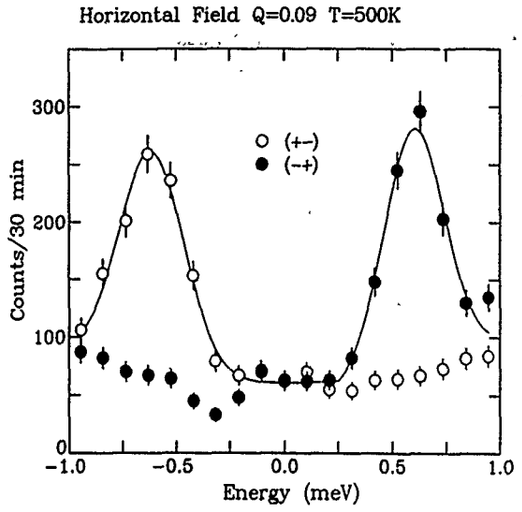

FIG. 7. Spin-flip scattering observed for the amorphous Invar $Fe_{86}B_{14}$ system in the $\hat{P}\|\mathbf{Q}$ configuration. Spin waves are observed for neutron energy gain ($E<0$) in the (+−) cross section, and for neutron energy loss ($E>0$) in the (−+) configuration (Ref. 11).

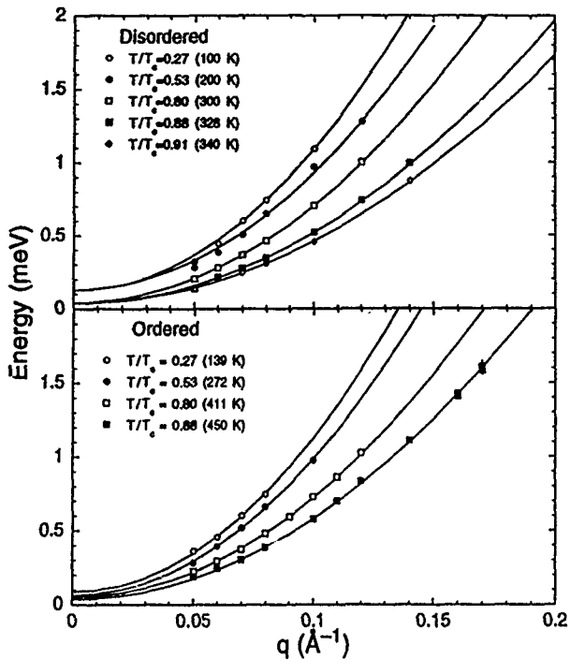

FIG. 8. Measured spin wave dispersion relations for chemically disordered (top) and ordered (bottom) Fe_3Pt (Ref. 12).

gether with a peak from the MgO substrate) along with a series of satellite peaks on either side. The satellite peaks have both nuclear and magnetic contributions, and from such data the crystallographic and magnetic coherence lengths both in and between the layers can be followed as a function of temperature, field, thickness, etc.

It is interesting to compare the type and quality of data that are represented by these three examples. The powder diffraction technique is quite straightforward, both to obtain and analyze data. In this case typical sample sizes are ~5 g, and important and detailed information can be readily obtained with such sample sizes in a few hours of spectrometer time. The temperature dependence of the order parameter in $ErBa_2Cu_3O_7$, on the other hand, was obtained on a single crystal weighing only 31 mg. Note that the quality of the data is much better than for the powder sample even though the sample is more than two orders-of-magnitude smaller. The final example was for Fe_3O_4/NiO multilayers, where the weight of the superlattices that contributes to the scattering ranges from 0.3–1.5 mg. Thus it is clear that interesting and successful diffraction experiments can be carried out on quite small samples.

III. MAGNETIC EXCITATIONS

Inelastic neutron scattering plays a unique role in determining the magnetic excitation spectra in magnetic systems, as it is the only probe that can directly measure the complete magnetic excitation spectrum. Typical examples are spin wave dispersion relations, critical fluctuations, crystal field excitations, and moment/valence fluctuations. Here we give an example of some spin wave measurements utilizing inelastic polarized beam techniques, which is a technique that is finding increasing use. In the long wavelength (small q) regime the spin wave dispersion relation for an isotropic ferromagnet is given by $E_{sw}=D(T)q^2$, where D is the spin wave "stiffness" constant. The general form of the spin wave dispersion relation is the same for all isotropic ferromagnets, while the numerical value of D depends on the details of the magnetic interactions and the nature of the magnetism. One example of a prototypical isotropic ferromagnet is amorphous $Fe_{86}B_{14}$. Figure 7 shows an exampie of polarized beam inelastic neutron scattering data taken on this system.[11] To understand these data we note that spin wave scattering, represented in the Hamiltonian by the raising and lowering operators $S^{\pm}=S^x\pm iS^y$, causes a reversal of the neutron spin. These spin-flip cross sections are denoted by (+−) and (−+). If the neutron polarization $\hat{P}$ is parallel to the momentum transfer $\mathbf{Q}$, $\hat{P}\|\mathbf{Q}$, then we should be able to create a spin wave only in the (−+) configuration, or destroy a spin wave only in the (+−). This is precisely what we see in the data; for the (−+) configuration the spin waves can only be observed for neutron energy loss scattering ($E>0$), while for the (+−) configuration spin waves can only be observed in neutron energy gain ($E<0$). We remark that the cross sections for inelastic scattering are typically several orders-of-magnitude smaller than for elastic Bragg scattering, and thus large samples are required for these types of measurements; the sample in this case weighed ~10 g.

Data like these can be used to measure the renormalization of the spin waves as a function of temperature, as well as determine the lifetimes as a function of wave vector and temperature. An example for the crystalline Invar-type ferromagnet Fe_3Pt is shown[12] in Fig. 8. Here we have determined the wave vector dependence of the dispersion relation at a series of temperatures, both for the chemically ordered and disordered single crystals. These measurements can then be compared with theory as well as other experimental observa-

TABLE I. Neutron scattering spectrometers available for materials research in magnetism at the various neutron scattering centers in the U.S. Brookhaven National Laboratory (BNL) and the National Institute of Standards and Technology (NIST) operate heavy water reactors, while Oak Ridge National Laboratory (ORNL) and the University of Missouri (UM) operate light water reactors. The neutron sources at Argonne National Laboratory (ANL) and Los Alamos National Laboratory (LANL) are pulsed spallation facilities. NA=not applicable; C signifies under construction/development. At ORNL some spectrometers share a beam port and are therefore only available part time.

tions (such as magnetization measurements) which are controlled by such spin wave excitations.

IV. NEUTRON FACILITIES

The neutron scattering facilities available in the U.S. are shown in Table I. The National Laboratories all have ongoing user programs to acquire beam time, while the research at the University of Missouri reactor is done on a collaborative basis only. Brookhaven National Laboratory, Oak Ridge National Laboratory, and the National Institute of Standards and Technology operate research reactors, which provide steady beams of thermal, and in the case of NIST and BNL, cold neutrons. The NIST cold source supports a guide hall facility which can accommodate 15 or more instrumental stations when completed; it is the only project presently under construction. Argonne National Laboratory and Los Alamos National Laboratory have pulsed spallation neutron sources. This technique for producing neutrons in general is complementary to steady-state reactor sources, and the pulsed nature of the sources means that all instruments operate on the time-of-flight principle. The person to contact for more information about these facilities is provided at the bottom of the table.

Neutrons provide a unique tool not only for magnetism, but for broad areas of materials science, physics, chemistry, biology, and nuclear medicine. The reactors that are presently in use have already been operating for a quarter of a century, and there is a detailed plan to build a new research reactor, the advanced neutron source, to replace some of these facilities. The ANS would provide an order-of-magnitude more raw flux, and would also allow dramatic improvements in beam optics for many instruments; a great deal has been learned (and invented) in the last 25 years about how to optimize neutron scattering instrumentation. If authorized for construction next year, the ANS would come on line early next decade, and would allow the U.S. to recapture the lead in the neutron scattering field. There are also plans to develop a design for a new, higher intensity spallation source. If these new facilities become a reality, then neutron scattering in the U.S. will continue to play a vital role in magnetism in particular and condensed matter physics in general, well into the next century.

Soft x-ray synchrotron radiation facilities for the study of magnetic materials (invited) (abstract)

Brian Tonner, W. O'Brien, M. A. Green, H. Höchst, and R. Reininger
Synchrotron Radiation Center, University of Wisconsin-Madison, 3731 Schneider Drive, Stoughton, Wisconsin 53589

Synchrotron radiation sources are used for a variety of measurements of magnetic materials, including photoemission spectroscopy of band-structure (both with and without spin polarization), photoabsorption spectroscopy, and x-ray scattering. Recently, considerable attention has been paid to applications of circularly polarized monochromatic synchrotron radiation to spectroscopy and scattering of magnetic materials. Magnetic x-ray circular dichroism (MXCD), present in both x-ray absorption[1–3] and x-ray photoemission spectra,[4,5] can be used as a site- and element-specific probe of local magnetic moment. With suitable instrumentation, the MXCD effect can be used to image magnetic domain structure of surfaces and buried layers, with element (and potentially chemical-state) specificity.[6] Examples of studies using MXCD with an existing bending-magnet light source will be shown, and used to introduce the performance of a new, undulator-based variable polarization beamline under construction at SRC.

The Synchrotron Radiation Center is supported by the National Science Foundation, Division of Materials Research.

A number of specialized facilities have been developed or are under development throughout the world to support research at high magnetic fields in a broad range of science and technology areas. These facilities provide continuous magnetic fields up to 32–35 T and pulsed fields up to 50–70 T for tens of ms periods with fields beyond 100 T for several μs. During the last several years, new laboratories have been planned and are being developed within the United States and Japan with major expansions of facilities occurring in France, The Netherlands, and other countries. The National High Magnetic Field Laboratory, presently under construction in the United States, will include superconducting magnets ($B \leqslant 20$ T), resistive magnets ($B \leqslant 25-35$ T depending on bore and power), hybrid magnet ($B \leqslant 45-50$ T), and pulsed fields ($B \leqslant 60-70$ T for 100 ms, $B \leqslant 50-70$ T for 10–20 ms and $B \leqslant 250$ T for about 10 μs). These new facilities within the United States and elsewhere will expand the research opportunities at the extremes of parameter space, i.e., magnetic field, ultralow temperatures, and high pressures, for researchers in the life and condensed matter science areas. An overview of the facilities throughout the world will be presented along with a brief discussion of the science opportunities and recent results at the extremes of high magnetic field.

$LiNiO_2$: Quantum liquid or concentrated spin glass?

From the magnetic and Mössbauer spectroscopy study of $LiNi_{1-x}Fe_xO_2$ with $x=0$, 0.01, 0.05, and 0.10 evidence for strong ferromagnetic correlations and spin freezing at low temperatures was found, reminding many characteristic features of spin glass behavior in variance with models describing the ground state of $LiNiO_2$ as a quantum liquid.

The ternary oxide $LiNiO_2$ was widely accepted to be a model compound for the two-dimensional (2D) antiferromagnetic triangular lattice (AFTL) with $S=1/2$ and an Ising-like anisotropy. This material has acquired special interest, since it was suggested that it may have a resonance valence bond (RVB) ground state, and so probably can contribute to the understanding of the mechanism of the high T_c superconductivity.[1] According to the RVB model the ground state has to behave as a quantum liquid with no long-ra. magnetic order, energetically more favorable as a classical antiferromagnetic type of order. Parallel to the theoretical development, a lot of experimental work, including mainly magnetic and specific heat measurements, electron spin resonance (ESR), nuclear magnetic resonance (NMR), neutron scattering, and magnetic relaxation studies, was invested in order to elucidate the main point, namely, the nature of the ground state of $LiNiO_2$ (see for instance the references mentioned in the papers by Kemp *et al.*[2] and Hirota *et al.*[3]).

Because of the still controversial character of many experimental results and their interpretation we decided to extend the study of $LiNiO_2$ especially in order to better understand the influence of the stoichiometry on the magnetic properties and to define the type of magnetic state occurring at lower temperatures. For the latter purpose we used the Mössbauer spectroscopy of $LiNiO_2$ samples doped with ^{57}Fe.

The samples A–F with the intended composition $LiNi_{1-x}Fe_xO_2$ (first column of Table I) were prepared from the intimately mixed (agate mortar) starting materials; LiOH H_2O (alpha), NiO (puratronic, Johnson–Matthey), and ^{57}Fe (medgenix) by firing in corundum crucibles (degussit Al 23) in air at 800 °C ($3\times28h$ with intermediate regrindings for samples with $x=0$) or at 750 °C ($20h$ with several regrindings for the samples with $x=0.01$). X-ray checks (Philips powder diffractometer, Cu $K\alpha$ radiation, Au standard) showed all Ni containing materials to crystallize in the α-$NaFeO_2$ structure (space group R3m). The average oxidation state of Ni, determined by redox titration with $Fe^{2+}/Cr_2O_7^{1-}$ is given in Table I. The extremely large value of 3.70 for the degree of oxidation of sample C was reached after an extra 24-h-long treatment of sample A in SO_4H_2.

The temperature dependence of the magnetic susceptibility measured in a field of 1.5 T and of the reciprocal susceptibility for the samples A, B, and C is shown in Fig. 1. In all cases a behavior similar to that of a spin system which orders or freezes at low temperatures and with strong ferromagnetic correlations was observed. A Curie–Weiss dependence was found above temperatures which depend on composition, starting with about 150 K for sample A. The values of the Curie constants corrected for the core diamagnetism and of the derived values of the asymptotic Curie temperature ϑ_p and of the effective number of Bohr magnetons P_{eff} are given in Table I. One can see that ϑ_p increases with the degree of oxidation and with the Fe content.

A good agreement between the experimental values of the Curie constants and the expectations based on the degree of oxidation of the samples A and C and of the amount of Fe in the samples D, E, and F can be found under the assumption that the Ni^{3+} and Ni^{4+} ions are in the low spin states $(t_{2g})^6(e_g)^1$ and $(t_{2g})^6$ with the spin numbers 1/2 and 0, respectively, and the Fe atoms are present in the Fe^{3+} high spin state $(t_{2g})^3(e_g)^2$ with the spin $S=5/2$. The agreement is ex-

TABLE I. Intended composition, average Ni value determined from the degree of oxidation O_x, molar Curie constant, asymptotic Curie temperature ϑ_p, effective number of Bohr magnetons P_{eff} per transition metal atom of the intended composition and magnetic transition temperature T_c.

Intended compcsition	$\bar{O}_x$	C_m (cm^3 K mol^{-1})	θ_p (K)	P_{eff} (μ_B)	T_c (K)
A $LiNiO_2$	+2.85	0.51	112	1.96	81.2
B $LiNiO_2$	+2.66	0.33	182	1.62	82

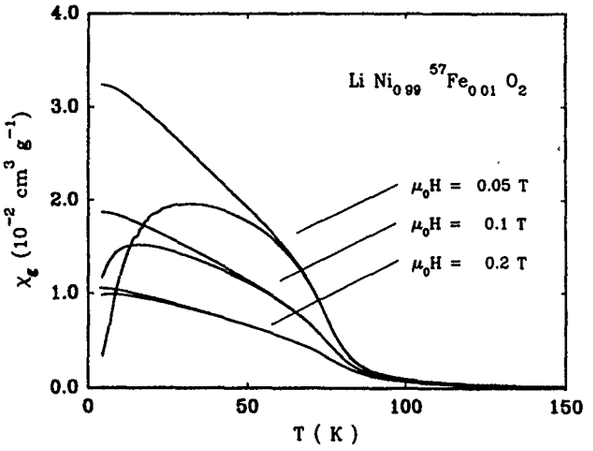

FIG. 3. Temperature dependence of the zero-field-cooled and field-cooled susceptibility of sample D.

cellent for the samples A and F. The slightly larger experimental values found for samples D and E can result from the presence of a small amount of the Ni atoms in form of Ni^{2+} ions with $S=1$. An interesting point is the behavior in low magnetic fields where different temperature dependencies for the zero-field-cooled (ZFC) and field-cooled (FC) regimes were observed as can be seen in Fig. 2 for sample A and Fig. 3 for the sample D. In weak fields at temperatures between 4.2 and 20 K the susceptibility has very low values. Above 20 K the susceptibility starts to rise in a way similar to that occurring in the case of reentrant spin glass behavior. The ZFC curves are below the FC ones and their maximum shifts to higher temperatures when decreasing the field. Above a given temperature which depends on the field strength there is no more any difference between ZFC and FC curves. Using the kink point method one can determine the magnetic ordering or freezing temperatures T_c given in the last column of Table I. One can see that as was the case with the magnetic susceptibility the T_c values increase with the Fe concentration.

At not too high values of the applied field the ZFC and FC values of the magnetization become identical. At any temperature below T_c the magnetization process in increasing fields has a hysteretic character as can be seen for the sample A in Fig. 4. The magnetization curve measured in fields up to 14 T is shown in the inset of the same figure. From this high-field measurement one obtains a value of the magnetization $M_S=56,9\ \mathrm{A\,m^2\,kg^{-1}}$ corresponding to an average moment per Ni atom of 1 μ_B. This value confirms again the assumption of the low spin state of Ni^{3+}. But in view of the presence of 15% Ni^{2+} ions in this sample according to the measured degree of oxidation we would expect a slightly higher value of the magnetization for a parallel alignment of all the Ni spins but the field of 14 T is not strong enough in order to reach the saturation.

When considering the magnetic properties of our samples the strong analogy with the behavior of spin glasses as we already mentioned in a previous paper[4] cannot be overlooked. The presence of strong ferromagnetic correlations

and spin glass behavior was also reported for $LiNiO_2$ by Kemp *et al.*[2] and spin glass behavior was mentioned very recently by Reimers *et al.*[5]

A deeper insight into the understanding of the magnetic properties of $LiNiO_2$ was gained from the Mössbauer spectroscopy study of the $LiNi_{1-x}{}^{57}Fe_xO_2$ samples. For all three compositions studied, the Mössbauer spectra were magnetically split below T_c. A distribution of hyperfine fields is always present, ranging for $x=0.01$ between 52.8 and 40.2 T for instance. Two main features characterize the Mössbauer spectra below T_c: (1) a strong Ising relaxation, and (2) the presence of a paramagnetic doublet above about 20 K with gradualy increasing intensity up to about 60 K followed by a drastic change up to 100% over a 10–15 K temperature interval.

The temperature dependence of the average hyperfine field HF and of the concentration of the paramagnetic component for $x=0.01$ and 0.05 are shown in Fig. 5. The relatively sharp increase of HF between 20 and 4.2 K evidences the possible occurrence of a peculiar change in the magnetic properties around 20 K reminding again a reentrant spin glass behavior as was the case with the temperature dependence of the susceptibility in low fields.

The presence of a temperature-dependent HF is clear evidence for spin freezing below T_c involving obviously both Fe and Ni spins. This result is in excellent agreement with the recent results of the neutron scattering studies of $LiNiO_2$, where strong inelastic diffuse scattering has been observed, instead of the antiferromagnetic Bragg scattering[6] together with an evidence for ferromagnetic short-range correlations increasing in intensity below 240 K and exhibiting a divergency at 35 K.[7]

A point which requires an explanation is the presence of the paramagnetic phase appearing around 20 K and increasing in intensity with temperature already mentioned above (Fig. 5). Matsubara and Inawashiro for instance analyzed the spin structure for a hexagonal close-packed (hcp) lattice with interlayer and intralayer next-neighbor interactions.[8] They could show that for the Ising-like case with strong frustration, their model exhibited at intermediate temperatures, a special paramagnetic phase with a short-range order of the z component of the spin characterized by an incomensurate period. At higher temperatures this phase transforms in the "pure" paramagnetic one, whereas at lower temperatures a so-called nonperiodic frozen spin phase will occur.

Is the above-mentioned paramagnetic component, which develops in the Mössbauer spectra of Fe-doped $LiNiO_2$ above 20 K, the phase predicted in Ref. 8? Or is the paramagnetic component the result of a distribution of spin freezing temperatures occurring owing to the frustration conditions arising in the triangular lattice and to the presence of such defects as for instance intersite exchanged Ni and Li ions? There is no definite answer to these questions at the present time.

In conclusion one can only say that the $LiNiO_2$ samples we studied as well as the other ones studied by other groups behave magnetically at low temperatures as concentrated spin glasses and in some respects they remind a reentrant spin glass behavior.

Disappearance of three-dimensional magnetic ordering in Gd_2CuO_4

T. Chattopadhyay and P. J. Brown
Institut Laue-Langevin, B.P. 156X, 38042 Grenoble Cedex, France

B. Roessli
Labor für Neutronenstreuung, ETHZ, CH-5232 Villigen PSI, Switzerland

The magnetic ordering of an isotope (^{158}Gd) enriched Gd_2CuO_4 single crystal has been investigated by neutron diffraction in the temperature range 1.5–50 K. The three-dimensional magnetic order of the Cu sublattice is found to disappear abruptly in a narrow temperature range close to 7 K which is just above the ordering temperature of the Gd sublattice [T_N(Gd)=6.4 K]. This result is thought to be intimately related to the structural distortion of the CuO planes which gives rise to weak ferromagnetism. The lack of three-dimensional order in the structural distortion imposes itself on the antiferromagnetic arrangement of the Cu sublattice through the Cu-Gd and Gd-Gd interactions and the different and incompatible wave vectors of the Cu and Gd magnetic sublattices.

The class of superconducting materials $R_{2-x}M_xCuO_4$(R=Pr, Nd, Sm, and Eu; M=Ce, Th), for which electrons, rather than holes, in the CuO_2 planes are the charge carriers have been investigated quite intensively.[1–4] The magnetic properties of these materials have also been studied in order to discover whether the magnetic interaction plays any role in Cooper pair formation. The Cu magnetic moments in the parent compounds R_2CuO_4 of the electron-doped superconductors order at temperatures in the range 245–285 K whereas the rare-earth moments, when they are nonzero, order only at much lower temperatures (1–6 K). Three types of magnetic interactions: Cu-Cu, Cu-R, and R-R, govern the magnetic properties of these materials of which the Cu-Cu interaction is by far the strongest. These magnetic interactions are presumably superexchange interactions via oxygen. The R-R magnetic interaction is weak being of the order of a few degrees K. The magnitude of the Cu-R interaction is not known definitely but cannot be much greater than that of R-R. For temperatures above about 50 K the magnetic properties of these compounds are essentially governed by the strong Cu-Cu interaction; but at lower temperatures Cu-R and R-R magnetic interactions become increasingly important. Interplay amongst these three types of interactions leads to interesting magnetic properties at lower temperatures. The inherent frustration of the structure with respect to antiferromagnetic ordering is also expected to play an important role in the magnetic properties of these classes of compounds.

Gd_2CuO_4 behaves rather differently from the rest of the R_2CuO_4 series. Although Gd_2CuO_4 is as easily doped with Ce or Th as the other members of the R_2CuO_4 (R=Pr, Nd, Sm, and Eu) family, it does not, as they do, become superconducting.[4] Gd_2CuO_4 along with other heavy rare-earth compounds (Eu through Yb) also shows weak ferromagnetism below the copper ordering temperature.[5] The antiferromagnetic ordering of both Gd and Cu sublattices has been investigated by neutron diffraction on isotope (^{158}Gd) enriched Gd_2CuO_4 single crystals.[6,7] Below T=6.4 K Gd moments order antiferromagnetically with the wave vector $\mathbf{k}$=(0,0,0). Ferromagnetic Gd layers parallel to the a-b plane are antiferromagnetically stacked along [001]. Cu^{2+} ions in Gd_2CuO_4 orders at T_N=285 K to the La_2NiO_4 type antiferromagnetic structure with the propagation vector $\mathbf{k}=(\frac{1}{2},\frac{1}{2},0)$. However, the previous neutron diffraction investigation[7] of the magnetic ordering of the Cu sublattice was restricted to temperatures above 40 K. In the present paper we report the investigation of the magnetic ordering of the Cu sublattice down to 1.5 K.

The neutron diffraction experiments were performed on the same isotope (^{158}Gd) enriched Gd_2CuO_4 plate shaped single crystal of Ref. 7 of size 20×10×2 mm^3 on the two-axis diffractometer P2AX of the Saphir reactor of the Labor für Neutronenstreuung, ETH Zürich. The crystal was mounted inside a helium cryostat on the diffractometer with the [1$\bar{1}$0] crystallographic direction parallel to the ω axis of the diffractometer. We have used both pyrolytic graphite (PG 002) and Cu(220) monochromators to get incident neutron wavelengths of 1.05 and 0.84 Å, respectively. To cut off higher order harmonics of the incident wavelengths we used Pu-Al alloy and Er filters for 1.05 and 0.84 Å, respectively.

Gd_2CuO_4 crystallizes in the tetragonal space group $I4/mmm$ (T'-phase). The lattice parameters at room temperatures are a=3.892 Å, c=11.878 Å. Figure 1 shows the magnetic structure of Gd_2CuO_4 below 6.4 K. This magnetic

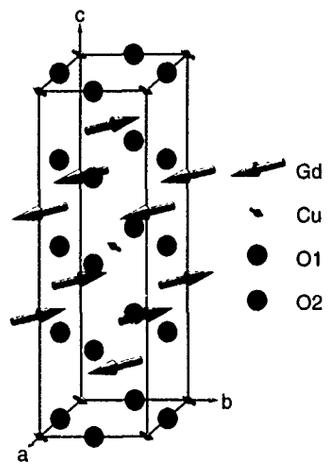

FIG. 1. Magnetic structure of Gd_2CuO_4 below T_N(Gd). Note that the spin directions of the Cu and Gd sublattices are at right angles. The structure model assumes a single-$\mathbf{k}$ ordering of the Cu sublattice.

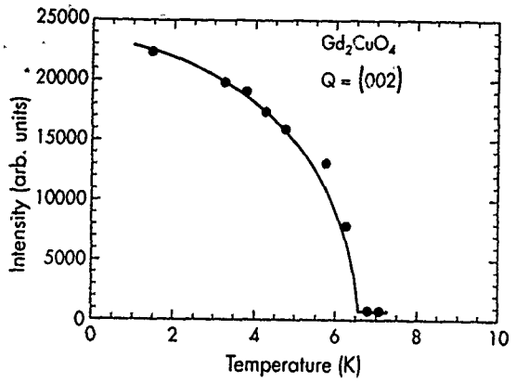

FIG. 2. Temperature variation of the integrated intensity of the 002 reflection. Below T_N(Gd) this reflection consists of nuclear and magnetic contributions of which the latter decreases continuously and disappears at T_N(Gd)=6.4 K. Above T_N(Gd) the 002 reflection is purely of nuclear origin. The presence of magnetic contribution to the 002 reflection excludes the possibility that the Gd magnetic moments are parallel to the c axis.

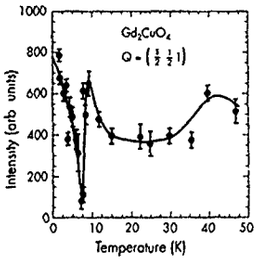

FIG. 3. Temperature variation of the integrated intensity of the $\frac{1}{2},\frac{1}{2},1$ reflection in the temperature range 1.5–45 K showing a broad minimum at about 20 K and a further sharp minimum at about 7 K. The first anomaly in associated with the weak ferromagnetism, whereas the second anomaly is interpreted to be due to the disappearance of the three-dimensional ordering of the Cu magnetic moments.

structure model of Gd_2CuO_4 below the ordering temperature of Gd sublattice has been derived from the neutron diffraction results of Refs. 6 and 7. Note that the order in the Cu sublattice is given by a single-**k** model and we have assumed that the Gd and Cu spin directions are perpendicular so that they are independent of one another. A noncollinear double-**k** magnetic structure of Cu sublattice can not be ruled out on the basis of the neutron diffraction measurements,[7] since it cannot be distinguished from the single-**k** model without applying either magnetic field or uniaxial stress. The magnetic structure of Gd_2CuO_4 in the temperature range 40 K$<T<$285 K is basically the structure of just the Cu sublattice in Fig. 1. The Gd sublattice is paramagnetic except for a small ordered magnetic moment aligned by interaction with the antiferromagnetic Cu sublattice.

In the present neutron diffraction investigations we have measured the temperature variation of the integrated intensities of 002, $\frac{1}{2},\frac{1}{2},1$ and $\frac{1}{2},\frac{1}{2},3$ reflections in the temperature range 1.5 to 50 K. The intensity of the 002 reflection was used to monitor the spontaneous ordering of the Gd sublattices. Figure 2 shows the temperature variation of this reflection. It showed no significant variation between 6.4 and 40 K indicating that in this temperature range it contains no appreciable magnetic contribution. The intensity of this reflection increases strongly with decreasing temperature below T_N(Gd)=6.4 K proving conclusively that the magnetic moment of Gd atoms cannot be oriented parallel to [001].[6] The integrated intensity of the $\frac{1}{2},\frac{1}{2},1$ magnetic reflection increases continuously with decreasing temperature below T_N(Cu)=285 K down to 45 K as was shown in Ref. 7. In Fig. 3 we show the temperature dependence of the integrated intensity of this reflection at lower temperatures. At about 45 K it starts to decrease and shows a minimum at about 20 K before it regains its previous maximum value at about 8 K. This broad minimum in intensity at about 20 K suggests some kind of phase transition also shown by magnetization and electron paramagnetic resonance (EPR) measurements.[8] The most unexpected feature of the data is the sudden and complete disappearance of the $\frac{1}{2},\frac{1}{2},1$ reflection at T=7 K. Below T_N(Gd) intensity of this reflection increases again in much the same way as the 002 reflection. The anomalies observed in the temperature dependence of the $\frac{1}{2},\frac{1}{2},1$ reflection probably have the same origin as those observed around the same temperatures in the magnetic susceptibility.[9] The $\frac{1}{2},\frac{1}{2},3$ reflection was found to be very weak and was difficult to measure because of $\lambda/2$ contamination from 116 which is a strong nuclear reflection. However, by using a neutron wavelength of 0.84 Å and a 0.5-mm Er filter it was possible to almost completely eliminate $\lambda/2$ and to show that the $\frac{1}{2},\frac{1}{2},3$ intensity remains close to zero in the whole temperature range. The scattering amplitude in this reflection due to the induced antiferromagnetic component of the moment on the Gd sublattice must therefore be of opposite sign and almost equal in magnitude to that contributed by the Cu sublattice. This implies that the susceptibility of the Gd sublattice is almost independent of temperature and that $\mu_{Gd}=\chi\mu_{Cu}$ with $\chi=0.9\pm0.3$. Search for magnetic reflections at $\mathbf{Q}=(\frac{1}{2},\frac{1}{2},0)$, $(\frac{1}{2},\frac{1}{2},2)$, and $(\frac{1}{2},\frac{1}{2},3)$ and other incommensurate positions in the Brillouin zone at the temperature (7 K) at which the $\frac{1}{2},\frac{1}{2},1$ disappeared did not reveal any magnetic intensity. The directions scanned are shown in Fig. 4. This result suggests that at this temperature the three-dimensional magnetic ordering of the copper sublattice temporarily disappears.

The disappearance of three-dimensional magnetic ordering of the Cu sublattice just above the ordering temperature of the Gd sublattice is intimately connected with the weak ferromagnetism of Gd_2CuO_4. Since weak ferromagnetism is forbidden both for nonzero propagation vectors and in the tetragonal space group $I4/mmm$ of Gd_2CuO_4 some structural distortion which changes the periodicity and lowers the symmetry must be present. It has been suggested[8] that it is oxygen displacements in the CuO_2 planes which allow weak ferromagnetism in Gd_2CuO_4. In a recent paper[8] we have proposed a model in which oxygen atoms are displaced perpendicular to the ideal Cu–O–Cu bond direction in accordance with the x-ray measurements. Of the two possible displacement patterns we chose the one for which there is a real antisymmetric exchange interaction of the Dzyaloshinski–Moriya type between the nearest neighbors within the CuO_2 planes. For macroscopic weak ferromagnetism to occur the

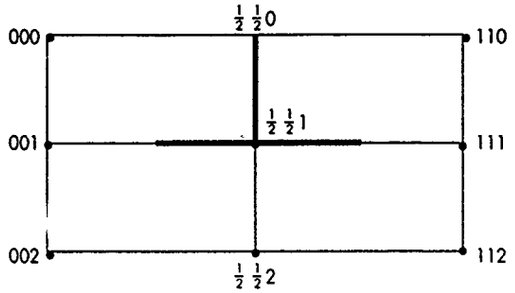

FIG. 4. The reciprocal lattice of Gd_2CuO_4 corresponding to the scattering plane. The directions scanned for detecting possible magnetic intensity are marked by thick lines. No magnetic Bragg intensity has been detected in the reciprocal scans indicated by the thick lines.

oxygen displacements within a plane must be coherent over relatively long distances. However, since there is no evidence for the superlattice reflections which would characterize three-dimensional order, there can be no appreciable correlation between the signs of the oxygen displacements in neighboring CuO_2 planes along the **c** direction. In the temperature range T_N(Cu) to about 20 K the overall magnetic structure of Gd_2CuO_4 is built up of weakly interacting sandwich layers stacked along **c**. Each such layer consists of a CuO_2 plane sandwiched between two Gd planes and possesses a spontaneous weak ferromagnetic moment. This model provides a possible explanation of the nature of the further transformations of the magnetic structure which occur at temperatures below 50 K. It seems probable that the driving mechanism for these structural changes is the antiferromagnetic interaction between neighboring Gd layers along **c**. Because of the large Gd moment this interaction becomes dominant at low temperature. At temperatures between T_N(Cu) and about 50 K the exchange between neighboring CuO_2 planes leads to three-dimensional antiferromagnetic ordering of the Cu sublattice in which the relative orientations of the antiferromagnetic vector **L** in neighboring CuO_2 planes are strongly correlated. Under these circumstances the random nature of the signs of structural distortions in different CuO_2 planes imposes a frustrated random arrangement of the weak ferromagnetic vector **M**. There are two distinct antiferromagnetic Gd-Gd interactions which are important: that between the Gd planes in adjacent sandwich layers and that between the two Gd planes in the same sandwich layer. Satisfying the former, forces the **M** vectors in adjacent layers to be antiparallel, and thus transfers the effects of randomness in the structural distortion to the antiferromagnetic vectors **L**. Satisfying the latter, on the other hand, destroys the weak ferromagnetic moment **M** of the layers themselves. The intensity variation of the $\frac{1}{2},\frac{1}{2},1$ reflection shown in Fig. 3 can be explained if the effects of interlayer Gd-Gd interactions start to be manifest at a higher temperature than those of intralayer interactions. Below 50 K the appearance of some correlation between the **M** vectors in adjacent sandwich layers leads to partial disorder of the **L** vectors and a consequent reduction of the intensity of the $\frac{1}{2},\frac{1}{2},1$ magnetic reflection. However, when the temperature falls to about 20 K, Gd-Gd antiferromagnetic correlation inside each sandwich layer starts to be important and to reduce the magnitude of the **M** vectors of the layers themselves. This effect not only lowers and finally eliminates the weak ferromagnetic moment, but also reduces the exchange field leading to the disorder of the **L** vectors. Hence, the recovery of the intensity of the $\frac{1}{2},\frac{1}{2},1$ reflection. The disappearance of the $\frac{1}{2},\frac{1}{2},1$ reflection just above T_N(Gd) indicates a temporary breakdown of the three-dimensional magnetic order of the Cu sublattice during the total reorganization of the magnetic structure required to satisfy the strong antiferromagnetic correlations in both the Cu and Gd sublattices.

Measurements of electron paramagnetic resonance (EPR) at 9 and 35 GHz between 2 and 300 K in single crystals and powder samples of $CuGeO_3$ are presented. Below 14 K a large decrease in the intensity of the Cu^{2+} EPR signal is observed. The data can be interpreted as due to a spin-Peierls transition. However, an alternative interpretation in terms of a simple structural transition cannot be ruled out. An opening of an energy gap of ~25 K is calculated from the analysis.

It is now well established that, as the temperature is reduced, a one-dimensional (1D) metallic lattice of uniformly spaced atoms with a half-filled conduction band can exhibit a Peierls transition.[1] Such a transition results from a distortion of the lattice in which alternate atoms are displaced in opposite directions. A splitting of the conduction band and a reduction in the energy of the electrons occupying the lower band is observed. There is a magnetic analog to the electronic Peierls instability, the so-called spin-Peierls (SP) transition.[2] A uniform antiferromagnetic (AF) quantum chain becomes unstable with respect to an underlying lattice distortion which dimerizes into AF chains.[2,3] It has been argued that for the SP transition to occur, the 3D lattice, where the 1D magnetic chains are embedded, needs first to undergo a strong softening. A softening of the phonons at high temperature in the undimerized state has been found in the few 1D organic materials where, at much lower temperature, a SP transition has been observed.[4]

The AF chains are characterized below the SP transition by an energy gap between a nondegenerate singlet ground state and a band of triple excited states. The energy gap is dependent on the degree of alternation and goes to zero in the uniform chain limit. In zero magnetic field the transition is second order and the degree of alternation increases as the temperature, T, is lowered, reaching its maximum at $T=0$ K.[2–4] The first experimental evidence confirming the existence of such compounds followed the discovery of the 1D organic materials TTF-CuBDT, TTF-AuBDT, and $MUM(TCNQ)_2$. Their properties can be satisfactorily explained within the framework of the theory of a SP transition.[5] In many instances the spin-Peierls nature has been disputed, questioning if the doubling of the period of the 1D unit cell is due to a SP instability. The observed alternation of the AF coupling between the spins can be just a consequence of a simple structural transition which results in the doubling of the lattice period. It is then important to find whether or not the AF interaction is essential to the phase transition.

Recently the presence of a SP transition has been reported in an inorganic compound, $CuGeO_3$.[6] That study showed that the susceptibility, χ, in all the directions of the crystal rapidly decreases to zero below 14 K. Besides, the magnetic field dependence of the transition temperature, T_{sp}, agrees well with the theoretical predictions and experimental results reported previously for the organic SP systems. Electron paramagnetic resonance (EPR) is an ideal technique to study $CuGeO_3$, as Cu^{2+} is one of the easiest ions to detect by EPR. This technique has been shown to be extremely sensitive for studying the dynamics of low-dimensional spin systems, which includes the already well characterized SP systems.[5,7,8] If an energy gap opens in this compound, with a nonmagnetic singlet ground state, a rapid decrease of the intensity of the Cu^{2+} ($S=1/2$) EPR signal is expected.

In this paper we present measurements of EPR at 9 and 35 GHz between 2 and 300 K on single crystals and powder samples of $CuGeO_3$. Single crystals of about $0.1\times0.5\times3$ mm^3 parallel to the $\vec{a}$, $\vec{b}$, and $\vec{c}$ axes, respectively, were obtained. Powder samples were prepared by the usual sintering method. X-ray studies shows no trace of impurity phases and the data are in good agreement with previous reports on this compound.[9] Previous EPR has been reported in $CuGeO_3$.[10] However, the authors did not observe a decrease in the intensity of the EPR signal or at least did not report it. Instead, they observed for $T\leq7$ K an increase of the magnetization and a broadening of the EPR linewidth which they attributed to long-range magnetic ordering.

Magnetization data on our samples are similar to the data reported by Hase *et al.*[6] That is, a rapid decrease of the susceptibility is observed below 14 K, with no significant increase below 7 K, contrary to the measurements reported by Petrakovskii *et al.*[10] A strong EPR signal of Cu^{2+} was measured for the single crystal as for the powder samples for $T\geq14$ K. The intensity, I, of the signal diminishes rapidly below this temperature. In Fig. 1 we show the linewidth, ΔH, as a function of T for a single crystal measured at 35 GHz. Similar data for ΔH are obtained at 9 GHz. The inten-

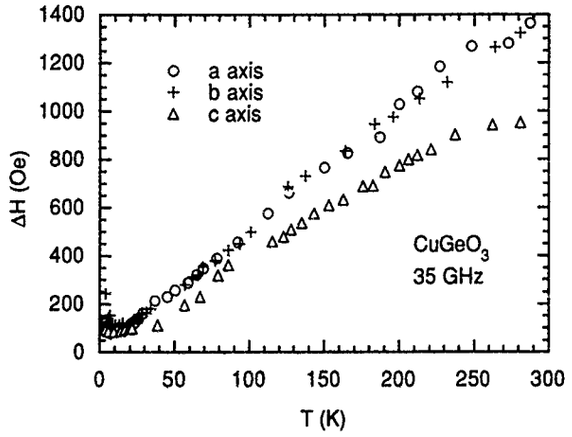

FIG. 1. EPR linewidth as a function of T for a $CuGeO_3$ single crystal measured at 35 GHz.

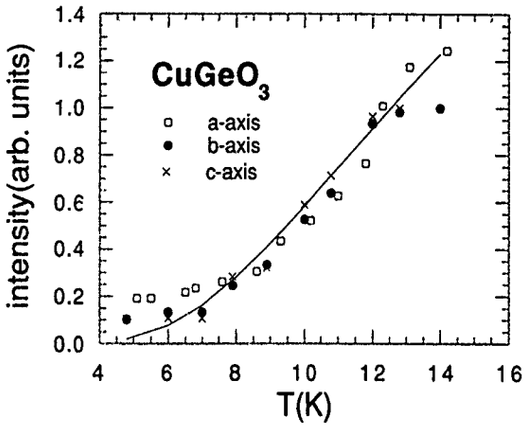

FIG. 3. Intensity vs T for a single crystal measured at 9 GHz. The solid curve corresponds to the best fitting to Eq. (2) with $m=40$ K.

sity was estimated by finding the area of the EPR signal. We present I vs T for a single crystal measured at 35 and 9 GHz, and susceptibility data in Figs. 2–4, respectively.

The angular dependence of the Cu^{2+} line can be described by the spin-Hamiltonian:

$$H=\mu_B \mathbf{S}\cdot\mathbf{g}\cdot\mathbf{H}, \tag{1}$$

where $S=1/2$, $\mathbf{g}$ is the gyromagnetic tensor, μ_B is the Bohr magneton, and $\mathbf{H}$ the external magnetic field. In Fig. 5 the angular variation of the gyromagnetic factor measured at 35 GHz for the three principal lattice planes is given. The g values for the principal axes, obtained from the best fit of the data, are listed in Table I for three temperatures.

The first question to ask is if $CuGeO_3$ is well described by 1D Heisenberg AF. If anisotropic components would be present in the coupling between the Cu spins, shifts in the g values as a function of T would be observed. As seen in Table I these shifts are small, so the principal exchange mechanism may be assumed to be isotropic.

In Fig. 1 we see that ΔH increases with T between ~40 and 300 K. It has been suggested that at high temperatures the long wavelength modes, $q\sim 0$, constitute the dominant contribution to ΔH for a 1D AF chain, with ΔH predicted to be proportional to χT.[11,12] In our case the agreement is good. The increase in ΔH observed in single crystals for $T\leq T_{sp}$ shown in Fig. 1 can be explained as follows: The number of nonmagnetic singlet pairs increases as we lower the temperature. Then, the exchange narrowing becomes less effective and ΔH broadens. However, no broadening below T_{sp} has been found in powder samples. We do not have an explanation for this behavior. Other mechanisms such as the interaction between chains, short-range ordering, etc., may also contribute to ΔH at lower temperatures. Finally, the broadening observed in our single crystals may be due to the presence of impurities or defects in them.

For $T\leq T_{sp}$ we have fitted the intensity of the electron spin resonance (ESR) line to

$$I(T)=\frac{A}{T}\exp\left(\frac{-m}{T}\right), \tag{2}$$

this expression was obtained by Bulaesvkii for an alternating chain of spins in the Hartree–Fock approximation.[13] This approximation is expected to be accurate for temperatures

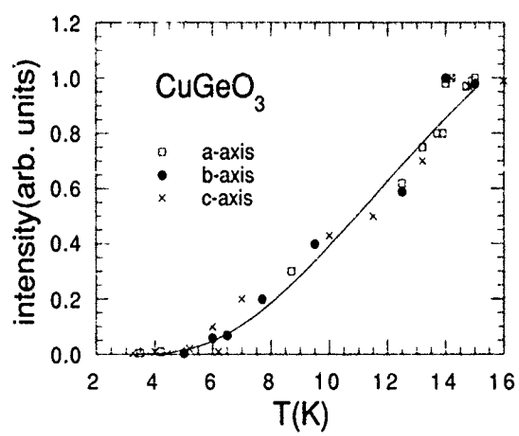

FIG. 2. Intensity of the Cu^{2+} EPR signal vs T, for a single crystal of $CuGeO_3$ measured at 35 GHz and $T\leq T_{sp}$. The solid curve corresponds to the fitting of Eq. (2) with $m=42$ K.

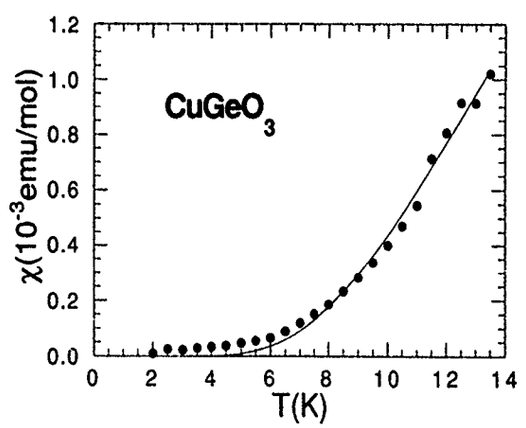

FIG. 4. Susceptibility data taken at 2 kOe in a powder sample. The solid curve is the best fitting to Eq. (2) with $m=45$ K.

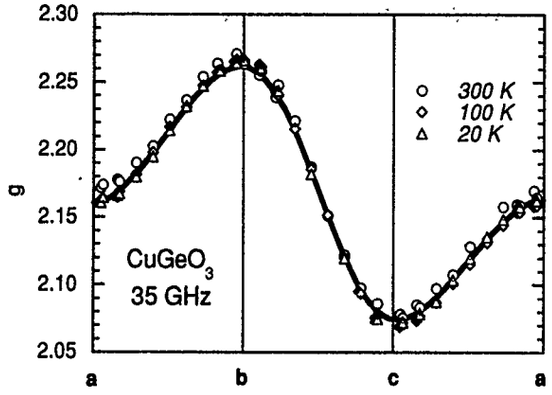

FIG. 5. Angular variation of the gyromagnetic factor at 300, 100, and 20 K. The solid curve corresponds to the best fitting to Eq. (1) for data taken at 20 K.

much smaller than the exchange interaction, $T \ll J$. As a value of $J \sim 90$ K is derived for $CuGeO_3$ from data,[6] Eq. (2) should be a good approximation for $T \leq T_{sp}$. The best fitting to the data taken in a single crystal measured at 9 and 35 GHz, on powder samples measured at 9 GHz, and susceptibility data give values of $m = 40$, 42, 46, and 45 K, respectively. In Figs. 2–4 the solid curve shows the fitting of the data to Eq. (2) for those values of m.

For $T \leq T_{sp}$ the Heisenberg Hamiltonian for a 1D chain may be written as[13]

$$H = \sum_{i=1}^{N/2} J_1 \mathbf{S}_{2i} \cdot \mathbf{S}_{2i-1} + J_2 \mathbf{S}_{2i} \cdot \mathbf{S}_{2i+1}, \tag{3}$$

where the relation between the two alternating J's of the chain are given by[5,14]

$$J_{1,2}(T) = J\{1 + \delta(T)\}, \tag{4}$$

according to mean-field theory the energy gap $\Delta(T)$ is given by

$$\Delta(T) = pJ\delta(T), \tag{5}$$

using values of $J = 90$ K,[6] $p = 1.637$,[3-5] and $m = 43$ K from our measurements, we obtained $J_2/J_1 \sim 0.7$, $\delta(0) \sim 0.17$, and $\Delta(0) \sim 25$ K in agreement with Hase *et al.*[6]

Preliminary specific heat measurements show a λ-shaped anomaly at ~14 K, similar to that observed in organic SP systems.[15] Measurements of the dc magnetization at high magnetic field, up to 26 T, show a rapid increase of M at ~12 T at low temperature.[16] In summary, our EPR results, preliminary specific heat and high-field dc magnetization could be interpreted as due to an SP transition in $CuGeO_3$. However, a careful analysis of the data is needed before we can rule out a structural transition with the doubling of the lattice period as the origin of the alternation of the exchange interaction in the spin chain.

The observation of a magnetization reversal and a superparamagnetic behavior are reported for films of copper ferrite sputtered in an oxygen atmosphere. X-ray diffraction studies indicate the presence of 14-nm nanoscale crystals of $CuFe_2O_4$ in the films. Data on the temperature dependence of the film magnetization M for zero-field-cooled (ZFC) and field-cooled (FC) show that ZFC and FC curves separate at a temperature T_f and that T_f decreases with increasing static field strength. For $T<T_f$, M vs T data for low fields indicate the presence of a compensation point in virgin samples. For $T>T_f$, a superparamagnetic character is evident form the high-field magnetization data. An average cluster size of 16 nm obtained from such data is in excellent agreement with the results of x-ray diffraction studies.

A series of magnetically ordered amorphous oxides have been synthesized by radio-frequency (rf) sputtering in the past few years.[1–7] In a recent article, we reported on the evidence for a long-range magnetic order in amorphous copper ferrite films prepared by rf sputtering in a mixed O_2-Ar atmosphere.[7] For such films, the magnetization, Curie temperature, and gyromagnetic ratio are in agreement with the values expected for the crystalline copper ferrite. Therefore, the spontaneous moment in the amorphous films is suggested to arise from ordered clusters with a magnetic structure similar to that of ferrimagnetic copper ferrite.

This paper deals with the magnetic properties of similar films sputtered in a pure O_2 atmosphere. The important results of this work are as follows: (i) Unlike the films sputtered in a mixed O_2-Ar atmosphere which are amorphous, x-ray diffraction (XRD) data for oxygen sputtered samples reveal the presence of nanoscale crystals of copper ferrite. (ii) Low-field magnetization (M) data for virgin samples show a sign reversal, i.e., a compensation point. However, the sign reversal does not occur in samples exposed to static fields (up to 50 kOe). (iii) Above the spin freezing temperature T_f (or blocking temperature), the films exhibit a superparamagnetic character. (iv) The cluster size estimated from the magnetization data agrees with the results of XRD data. Some details of these results are given below.

Samples of $CuFe_2O_4$ were sputtered from a target of polycrystalline copper ferrite prepared by the conventional ceramic technique. The target was mounted in a magnetron gun and the system was evacuated to a base pressure of 0.01 mTorr. The deposition was carried out in a sputter-down configuration in pure oxygen at a pressure of 1 mTorr and an rf power of 200 W at 13.6 MHz, 1-μm-thick films were obtained for a sputtering duration of 2 h on Corning 7059 glass and silicon substrates. The film composition was determined by energy dispersive x-ray spectroscopy. The films were rich in Fe and deficient in Cu, and the maximum deviation in the metal ion content was $\pm 10\%$. A Rigaku/DMax diffractometer was used for XRD studies. For magnetic measurements, a SQUID magnetometer (Quantum Design, model MPMS) was used over the temperature range of 5–300 K and static fields up to 50 kOe.

There is considerable evidence that the samples contain clusters (or nanoscale crystals) of $CuFe_2O_4$. Consider first the XRD data in Fig. 1 in which the diffraction patterns are shown for Corning 7059 substrates with and without the film. The sample spectra, obtained by subtracting the substrate background, show lines at angles corresponding to crystalline $CuFe_2O_4$. The lines are considerably broadened due to small particle size and nearby lines overlap. Using the most intense line near $2\theta=35°$ (combination of 220 and 311 lines) and using the Scherrer equation for the particle diameter $L=0.9\lambda/(\beta\cos\theta)$, where $\lambda=1.542$ Å is the x-ray wavelength and β is the corrected linewidth,[8] we obtain an average particle diameter of 14 nm. Additional evidence for clustering comes from magnetization data discussed in later sections.

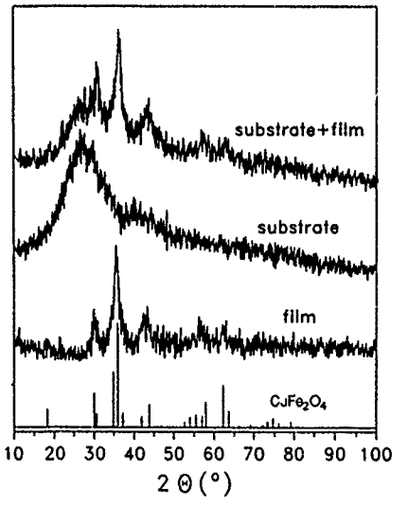

FIG. 1. X-ray powder diffractograms for an rf sputtered film of $CuFe_2O_4$ on a Corning 7059 glass substrate and for the substrate. The film was deposited in a pure oxygen atmosphere. The subtracted diffractogram for the film is also shown. The stick diagram is for single crystal $CuFe_2O_4$.

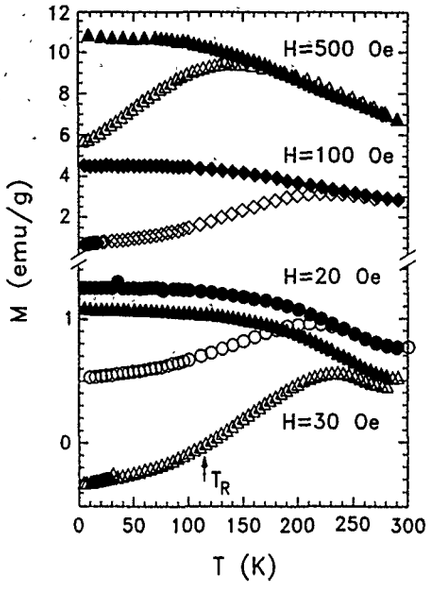

FIG. 2. Variation of magnetization M with temperature T for rf sputtered $CuFe_2O_4$ films. The data are for zero-field-cooled (open symbols) and field-cooled (while cooling) cases (filled symbols). Data for $H=30$, 100, and 500 Oe were taken on a virgin sample whereas data at $H=20$ Oe were obtained after subjecting the sample to high static magnetic fields. Notice that the ZFC and FC curves separate at the spin freezing temperature T_f.

Data on temperature and magnetic field dependence of M are shown in Fig. 2 for a "virgin" sample. Our measurements at $H=30$ Oe show that there is a sign reversal in M at $T_R \approx 115$ K in a ZFC (zero-field-cooled) sample in that M is negative at low temperatures, crossing zero near 115 K and then continues to increase smoothly reaching a maximum near 240 K. After reaching 300 K, we cooled the sample, at the same time taking the data (FC) as the sample cooled back to 5 K. The sign reversal in ZFC data is reminiscent of the compensation point observed in rare-earth substituted yttrium iron garnets and in rare-earth-transition metal alloys.[9,10]

Kaneyoshi and Jascur[11] have predicted a similar sign reversal in M for two-dimensional amorphous structures containing spin-1/2 and spin-1 ions. The theory also predicts a decrease in T_R with increasing H. However, it is not clear at present whether the present system could behave like an amorphous structure with spins frozen in a random direction even though M data, discussed later, show spin freezing at temperatures below 250 K. Further, we obtained M vs T data under ZFC conditions for $H=20$ Oe in order to examine the predicted field dependence of T_R. The data shown in Fig. 2 for a sample which was subjected previously to high static fields, on the order of 50 kOe, reveal that a sign reversal is no longer present. Thus it may be necessary to study the possible variation of T_R with H on virgin samples unexposed to large fields. The important inference here is that the observation of a compensation pointlike effect in the present system merits further investigation.

Similar measurements for the ZFC and FC cases were carried out for $H=100$ to 700 Oe. Representative data at 100 and 500 Oe are shown in Fig. 2. At these higher fields, there

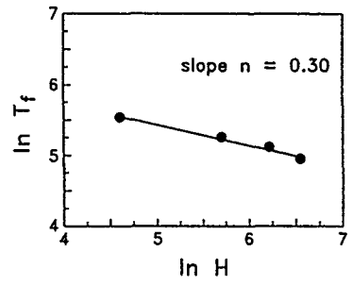

FIG. 3. Logarithmic (natural) plot of spin freezing temperature T_f vs static magnetic field H, yielding a slope of 0.30 with a correlation factor of 0.99. T_f values were obtained from data as in Fig. 2 for ZFC and FC samples.

is no sign reversal in M as it remains positive for all T values. The ZFC and FC curves separate at a temperature T_f, and T_f decreases with H according to the equation $T_f = AH^{-n}$, where A is a constant. The exponent n can be determined from a plot of ln T_f vs ln H, as in Fig. 3, and we obtain $n=0.30$ with a correlation factor $R=0.99$. Such a decrease in T_f with H, with $n=0.25$, has been reported for Bi-Fe-Cu oxide samples.[12]

A superparamagnetic behavior for the sputtered films was inferred from M vs H data at a series of temperatures. The two criteria for such a behavior are (i) the magnetization above the spin freezing (or blocking) temperature must scale as H/T; and (ii) M vs H data should show no hysteresis above the blocking temperature.[13] Figure 4 shows the variation of M/M_∞ with H/T at three temperatures, viz., 200, 250, and 300 K. Here, M_∞ represents the M value at an applied static field of 30 kOe. It is obvious from the figure that the magnetization curves at different temperatures collapse on to the same curve.

Figure 5 shows M vs H data at 5 and 300 K, i.e., for T values above and below the spin freezing temperatures of 150 to 250 K. The data were obtained by varying H in steps from zero to 25 kOe and back to zero. The data at 5 K show hysteresis and a remanence of 11.5 emu/g whereas the data at 300 K do not show any hysteresis. Thus data in Figs. 4 and 5 lead to the conclusion that copper ferrite nanocrystals in the films are superparamagnetic.

Data on H dependence of M at 300 K can then be used to estimate the distribution $f(D)$ in the size of clusters,

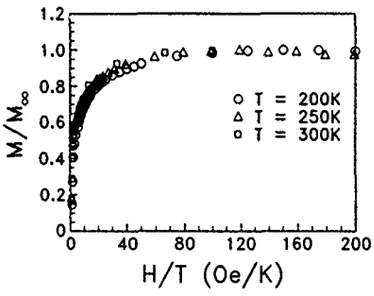

FIG. 4. Variation of the relative magnetization M/M_∞ with H/T for $T=200$, 250, and 300 K. M_∞ corresponds to the magnetization at a static field of 30 kOe. The data indicate a superparamagnetic character for $CuFe_2O_4$ films.

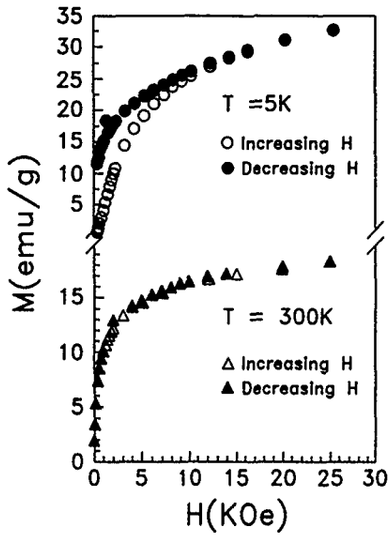

FIG. 5. Static magnetic field dependence of the magnetization for $CuFe_2O_4$ films at 5 and 300 K. The data indicate hysteresis at 5 K and no hysteresis at 300 K.

where D is the size (diameter) of the clusters, assuming a log normal distribution.[14] We determined a cluster size distribution centered around 16 nm with the particle size ranging from 9 to 24 nm.

In conclusion, structural and magnetic characterization of copper ferrite films sputtered in oxygen atmospheres show that the films contain nanoscale crystals of $CuFe_2O_4$.

The structure and spin dynamics of lanthanide-bearing silicate glasses

A. J. G. Ellison, C.-K. Loong, and J. Wagner
Argonne National Laboratory, Argonne, Illinois 60439

The structure of $3Na_2O \cdot R_2O_3 \cdot 6SiO_2$ (R=Nd, Yb and Lu) glasses has been studied by time-of-flight neutron diffraction. The average Si-O and O-O nearest-neighbor coordination is found to be similar to those of the SiO_4 tetrahedral units in vitreous SiO_2 and other silicate glasses. The rare-earth (RE) ions coordinate with no more than seven nearest-neighbor oxygen atoms. The dynamic and static response of these glasses and their isochemical crystalline analogs has been investigated by inelastic neutron scattering and magnetic susceptibility measurements. The magnetic excitation spectra were analyzed by a ligand-field model using a method of descending symmetry. The correlation between short-range atomic order in a network glass and magnetic interactions of the RE ions with the local environment is discussed.

Oxide glasses containing rare-earth (RE) elements serve a wide range of technological functions, ranging from glass lasers to optical components with exceptionally high indices of refraction. Addition of RE elements to glasses influences the behavior of other components, such as the principal glass-forming components, and mobile charge-carrying species in ionically conducting glasses. RE elements are also important components in high-level radioactive waste, which in the United States is expected to be permanently stored in borosilicate glass. Thus there has been considerable interest in probing the environments of the RE elements in oxide glasses and the impact they have upon the chemistry of other components.

In the $(M_2O)_x \cdot (R_2O_3)_y \cdot (SiO_2)_{1-x-y}$ glasses (M=Na, K; R=RE element) glasses, Raman spectroscopy implies that the chemistry of oxygen is significantly affected by changes in the concentration of M^+ and R^{3+}.[1] However, little is known about the effect that changes in the concentration of M^+ or R^{3+} might have upon the chemistry of each other. Inelastic neutron scattering from glasses containing lanthanides with no magnetic moment, such as La^{3+} or Lu^{3+}, can be used to obtain an average neutron-weighted vibrational density of states, which can be used to develop a more comprehensive model of contributions to various vibrational modes in the glasses. The interaction between the neutron magnetic moment and the partially filled f orbitals of a RE element produces an additional magnetic scattering component which reflects the average coordination environment in the glass. When combined with data from neutron total diffraction data for the coordination number of the RE, it is possible to model the average coordination environment of RE elements in the glass.

$3Na_2O \cdot Nd_2O_3 \cdot 6SiO_2$, $3Na_2O \cdot Yb_2O_3 \cdot 6SiO_2$, and $3Na_2O \cdot Lu_2O_3 \cdot 6SiO_2$ glasses were prepared in 100-g batches by combining appropriate amounts of reagent-grade Na_2CO_3, Nd_2O_3, (Yb_2O_3 or Lu_2O_3) and SiO_2 in a ball mill. The mixture was placed in a Pt crucible and fired at 1000 °C for 1 h to drive off CO_2 from the carbonate, then at 1400 °C for 8–12 h. The mixture was stirred several times to ensure homogeneity. The furnace temperature was then increased to 1500 °C, and after equilibration the sample was removed and quenched by pouring it onto a massive copper block. Polycrystalline $Na_3YbSi_3O_9$ was prepared by direct crystallization of the $3Na_2O \cdot Yb_2O_3 \cdot 6SiO_2$ glass at 1250 °C.

Neutron time-of-flight diffraction experiments for the glasses and a $Na_3YbSi_3O_9$ crystal were performed using the glass, liquid, and amorphous diffractometer (GLAD) and the general purpose powder diffractometer (GPPD), respectively, at the Argonne Intense Pulsed Neutron Source, IPNS. Diffraction data indicated that while all glasses were homogeneous, the $Na_3YbSi_3O_9$ crystal contained a minor amorphous component. Inelastic neutron-scattering measurements were performed using the high-resolution medium-energy chopper spectrometer (HRMECS). The magnetic contribution to the total scattering in the Yb- and Nd-bearing compounds was identified by an examination of the momentum-transfer dependence of the observed intensities and by a comparison with the spectra of the nonmagnetic $3Na_2O \cdot Lu_2O_3 \cdot 6SiO_2$ glass. The data were corrected for background scattering and the effect of sample self-shielding by subtracting the combined empty-container and neutron-absorber (i.e., cadmium) runs. Measurements of the elastic incoherent scattering from a vanadium standard provided detector calibration and intensity normalization.

Since glasses lack long-range order, their structures in real space are generally expressed in terms of distribution functions obtained from the Fourier transform of their structure factors $S(Q)$. The best known of these are the pair correlation function $G(r)$, the total distribution function $T(r)$, and the radial distribution function $N(r)$:

$$G(r)=\frac{1}{2\pi^2\rho_0}\int_0^\infty [S(Q)-1]Q^2\frac{\sin Qr}{Qr}\,dQ, \tag{1}$$

$$T(r)=4\pi r\rho_0 G(r), \tag{2}$$

and

$$N(r)=4\pi r^2\rho_0 G(r). \tag{3}$$

$N(r)\,dr$ has a direct physical interpretation as the number of atoms lying within a range $(r,r+dr)$ from any given atom. Figure 1 shows $T(r)$ obtained from the diffraction measurement of $3Na_2O \cdot Yb_2O_3 \cdot 6SiO_2$ glass. Peaks in $T(r)$ represent the most probable (average) bond distances for element pairs. The peaks at 1.63, 2.23, 2.33, and 2.65 Å correspond to the Si-O, Yb-O, Na-O, and O-O nearest-neighbor distances, respectively. The Si-O and O-O distances are typical

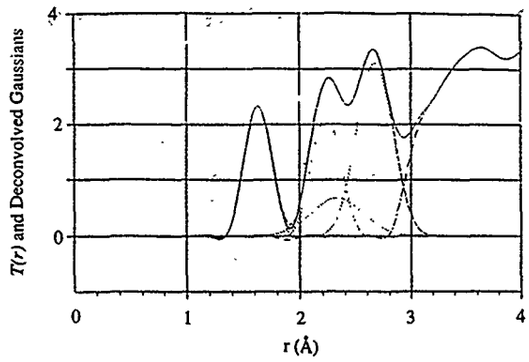

FIG. 1. The total distribution function $T(r)$, solid line, and the deconvolved Gaussian components, dotted and dot–dashed lines, of $3Na_2O \cdot Yb_2O_3 \cdot 6SiO_2$ glass.

of those found in other silicate glasses.[2] The area under a peak in a plot of $N(r)=rT(r)$ vs r is directly proportional to the coordination number of the atoms. Such an area under the Si-O peak gives a coordination number of 3.85, which is less than the expected value of 4 due to instrument resolution. The $N(r)$ vs r area under the Yb-O peak implies a coordination number for Yb of 5.5 ± 0.5.

For inelastic neutron magnetic scattering the magnetic intensity of a transition between two states (e.g., $\langle i|$ and $\langle j|$) for a single ion is proportional to the square of the matrix element $\langle i|J_\perp|j\rangle$ (where $J_\perp$ is the component of the total angular momentum operator perpendicular to the neutron wave vector) and the observed peak position is equal to the energy separation of the two states. Since the local symmetry of the RE ions in a glass varies from one site to another, the spectrum is expected to be broad. Therefore, it is instructive to compare the excitation spectra of a glass with those of an isochemical crystalline compound where better defined crystal-field spectra peaks can be identified.

We used the spectra of the $3Na_2O \cdot Lu_2O_3 \cdot 6SiO_2$ glass as the base to estimate the nuclear-scattering component for all the Yb and Nd materials. Lu has a complete $4f$ orbital thereby giving no magnetic scattering, and the small difference in the mass only affects the very low-energy phonon modes. Consequently, the magnetic intensities of the Yb and Nd materials were obtained by subtracting off from the total (nuclear and magnetic) excitation spectra the $3Na_2O \cdot Lu_2O_3 \cdot 6SiO_2$ spectrum weighted by the average nuclear-scattering cross section of its components. The resulting magnetic spectra of crystalline $Na_3YbSi_3O_9$ are shown in Fig. 2(a). According to the Kramers theorem the lowest symmetry of a state affected by a ligand electrostatic field for an odd-number electron system is a twofold degeneracy. Thus the Yb^{3+} Russell–Saunder ground multiplet is at most spit into $2\Gamma_6$ and $2\Gamma_7$ doublets. If all the Yb sites in a crystal are equivalent and have a local point-symmetry less than a cubic symmetry, one expects a low-temperature magnetic excitation spectrum containing a peak at zero energy corresponding to elastic scattering within the ground-state doublet and three sharp inelastic lines corresponding to excitations from the ground state to the excited states. The excitation spectrum of crystalline $Na_3YbSi_3O_9$ can be analyzed in terms of three broad components centered at 13.8, 41.9, and 57.7 meV, as shown in Fig. 2(a). The large widths of these excitations are probably caused by multiple Yb sites in the crystal and by the effect of chemical disorder from the minor glassy component in the material. The magnetic spectrum of the $3Na_2O \cdot Yb_2O_3 \cdot 6SiO_2$ glass [see Fig. 2(b)] shows a strong and sharp elastic peak as in the crystalline analog but the inelastic intensity is flat up to about 70 meV with a long tail extended to over 100 meV.

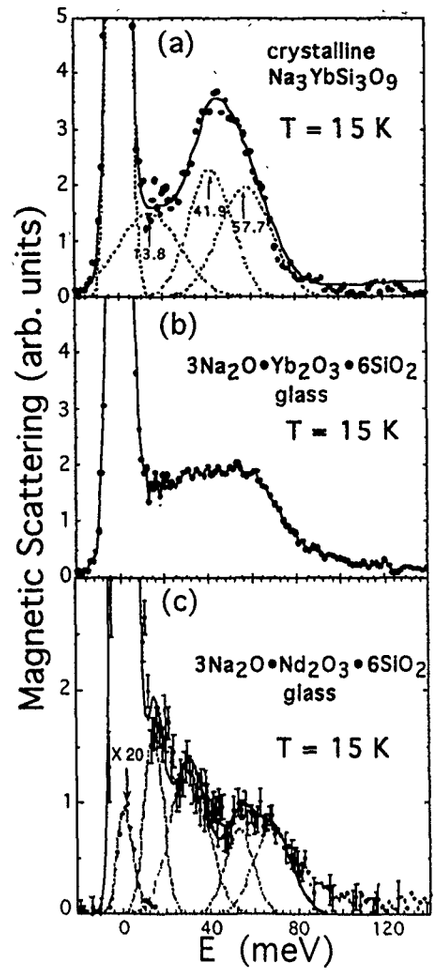

FIG. 2. (a) The magnetic excitation spectrum of crystalline $Na_3YbSi_3O_9$ (circles) and a fit to the data (solid line) by a sum of four Gaussian functions (dotted lines). (b) The magnetic excitation spectrum of the $3Na_2O \cdot Yb_2O_3 \cdot 6SiO_2$ glass (circles). The line is a guide to the eye. (c) The magnetic excitation spectrum of $3Na_2O \cdot Nd_2O_3 \cdot 6SiO_2$ glass (circles) and a fit to the data (solid line) by a sum of five Gaussian functions (dotted lines).

To assess the extent to which the local environments of the RE ions may affect the energy scale of the magnetic excitations in the crystalline and vitreous states, we analyzed the spectra using a single-ion crystal-field model. The Hamiltonian includes the atomic free-ion and crystal-field interactions for an f^N configuration ($N=3$ and 13 for Nd^{3+} and Yb^{3+} ions, respectively), formulated under the scheme of intermediate coupling using spherical tensor techniques.[3] We compared the $Na_3YbSi_3O_9$ spectrum with the model first assuming octahedral coordination corresponding to six equidis-

tant O ligands for the Yb ions. After reasonable agreement with the data was achieved, the cubic environment was relaxed to allow for lower symmetries. This approach is supported by the diffraction results which indicate an average 5.6 coordination of the Yb-O atoms and the satisfactory description of a distorted octahedral environment for Yb^{3+} in oxide glasses given previously by optical spectroscopy.[4,5] In this cubic approximation, the Yb ground multiplet splits into two doublets, Γ_6 and Γ_7, and a quartet Γ_8, and transitions between Γ_6 and Γ_7 are forbidden. Therefore, we fitted the $Na_3YbSi_3O_9$ spectrum by assigning the 45-meV band to excitation from the ground state to Γ_8 and obtained the ratio between the fourth- and sixth-order crystal-field parameters. Next, a B_0^2 term was added to fit the 0-, 13.8-, 41.9-, and 57.7-meV peaks as Γ_7, Γ_6, Γ_7, and Γ_6, respectively. The final parameters are B_0^2=54, B_0^4=−57.8, B_0^6=86.5 meV, $B_4^4 = -\sqrt{5/14}B_0^4$, and $B_4^6 = \sqrt{7/2}B_0^6$. The calculated energies and intensities for the three transitions agree well the observed spectrum of $Na_3YbSi_3O_9$.

Next we examine whether small changes in the crystal-field parameters calculated for the crystal, such as relaxing the constraints of cubic symmetry for the parameters B_4^4 and B_4^6, can produce a magnetic spectrum similar to what are obtained for the glass. We find that varying B_4^4 between −5 to 200 meV produced shifts of the calculated magnetic spectrum to lower and higher energies, respectively, to simulate the filling of observed intensities in the 10–30 and 80–120 meV regions. Furthermore, the calculated paramagnetic susceptibility obtained using crystal-field parameters discussed above agree well with the measured susceptibility of $3Na_2O{\cdot}Yb_2O_3{\cdot}6SiO_2$ glass.[6] Therefore, the observed scattering is probably best explained as a superposition of the ligand-field strengths given by small variations in the crystal-field parameters away from the nominal values obtained for the crystal.

A similar approach can be taken to interpret the observed magnetic excitation spectrum for the $3Na_2O{\cdot}Nd_2O_3{\cdot}6SiO_2$ glass as shown in Fig. 2(c). The five-peak structure between 0 and 80 meV resembles the splitting of the Nd^{3+} $^4I_{9/2}$ ground multiplet into five Kramers doublets. Under a sixfold octahedral environment of cubic symmetry, the $^4I_{9/2}$ multiplet is split into two Γ_8 quartets and one Γ_6 doublets. Therefore, if the two peaks at 0 and 15 meV and at 53 and 68 meV are assigned as splittings of the Γ_8 quartets into doublets, the observed magnetic spectrum of the $3Na_2O{\cdot}Nd_2O_3{\cdot}6SiO_2$ glass is consistent with a nominal sixfold coordinated Nd-O environment with a distorted octahedral symmetry.

RE environments in alkali silicate glasses have been investigated using numerous techniques. Robinson and Fournier[4,7] analyzed the optical data of Nd- and Yb-bearing alkali barium silicate glasses using a crystal-field scheme and found evidence of sixfold coordination of the RE ions. An extended x-ray absorption fine structure measurement of an Er-bearing sodium silicate glass by Marcus and Polman showed that the Er ions have about six O first neighbors at a mean distance of 2.26 Å,[8] and Ponader and Brown[9] and Barber and Obermyer[5] obtained similar results for Yb^{3+}. The present neutron diffraction and magnetic-scattering studies show that Yb and Lu ions in $3Na_2O{\cdot}R_2O_3{\cdot}6SiO_2$ glasses have average coordination numbers about 6.0 and mean R-O bond lengths of 2.23 Å, which are consistent with the above findings.

Larson and co-workers[10] and Ponader and Brown[9] studied the coordination environments of La^{3+} in alkali silicate glasses using x-ray absorption spectroscopy and report coordination numbers of seven or less and a mean La-O bond length of 2.42±0.03 Å. Mockovciak and co-workers[11] and Mann and DeShazer[12] studied the optical absorption and fluorescence spectra of different Nd doped silicate glasses and concluded an average sevenfold coordination of Nd-O atoms similar to the crystalline environment in Nd_2O_3. In the case of the $3Na_2O{\cdot}Nd_2O_3{\cdot}6SiO_2$ glass, although our crystal-field analysis supports a nominal distorted octahedral coordination, a larger than six coordination number cannot be ruled out because such local environments also split the Nd^{3+} ground multiplet into five doublet states. Since the RE ionic radii decrease with increasing atomic number, Nd^{3+} and La^{3+} are expected to have coordination numbers at least as large as Yb^{3+}, a result consistent with the magnetic scattering data.

We thank S. Skanthakumar and J. W. Richardson, Jr. for their assistance in the GPPD diffraction experiment. Work performed at Argonne National Laboratories is supported by the U.S. DOE, Basic Energy Sciences under Contract No. W-31-109-ENG-38.

Magnetization and ferromagnetic resonance studies on amorphous films of Fe_2O_3-Bi_2O_3-Li_2O

J. Chen, S. Cheney, and G. Srinivasan
Physics Department, Oakland University, Rochester, Michigan 48309

This report is on magnetic properties of samples of 0.5 Fe_2O_3-$(0.5-x)Bi_2O_3$-xLi_2O (x=0.1–0.4) prepared in oxygen atmospheres by rf sputtering techniques. The films develop a spontaneous moment M only when annealed in air at temperatures $T_a \geq 675$ K. The room-temperature M vs T_a data show a maximum in M for T_a=775–875 K even though x-ray diffraction data do not show the precipitation of any crystalline ferromagnetic or ferrimagnetic phases. The spontaneous moment could be attributed to the presence of ordered clusters in the amorphous film. The magnetization is found to be dependent on the concentration of nonmagnetic Li_2O: M increases with increase in x. An in-plane anisotropy in the films is evident from ferromagnetic resonance studies (FMR) at x-band frequencies. The anisotropy field increases with increasing x. The room-temperature in-plane FMR linewidth decreases with increasing x.

Nakamura and others investigated the structural and magnetic properties of ternary oxides in the system Fe_2O_3-Bi_2O_3-Li_2O.[1,2] The samples prepared by rapid quenching turned out to be x-ray amorphous and high-resolution electron microscopy studies revealed the formation of dense microcrystalline domains.[2] Magnetic characterization of the ribbons indicated a spontaneous moment. An irreversible thermomagnetization process, indicative of magnetic frustration, was observed below 200 K. Mössbauer studies provided evidence for two types of magnetic phases in the samples; a short-range antiferromagnetic phase and a ferrimagnetic phase associated with the microcrystalline phase.[1] Studies on rapidly quenched Fe_2O_3-Bi_2O_3 containing ZnO, CuO, or CaO showed a similar ferrimagnetic character.[2–5]

Here, we report on the magnetic characterization of films of Fe_2O_3-Bi_2O_3-Li_2O prepared in an oxygen atmosphere by rf sputtering techniques. Data on magnetization and ferromagnetic resonance (FMR) parameters such as the effective magnetization, linewidth, and gyromagnetic ratio have been obtained as functions of Li_2O concentration and annealing temperature. A long-range magnetic order in the films is evident from such studies.

Films of 0.5 Fe_2O_3-$(0.5-x)Bi_2O_3$-xLi_2O (x=0.1–0.4) were prepared. A 2-in.-diam polycrystalline sintered target prepared by standard ceramic techniques was mounted in a magnetron gun. The system was evacuated to a pressure of 0.01 mTorr. The sputtering was carried out in pure oxygen atmospheres at 1 mTorr and an rf power of 200 W at 13.6 MHz. Films were deposited on Corning 7059 glass substrates mounted on a rotating unheated platform placed below the target. Samples with a thickness on the order of 1 μm are obtained for a sputtering duration of 120 min.

Techniques used for structural characterization of the films were x-ray diffraction and scanning electron microscopy. As-sputtered samples were found to be x-ray amorphous. Energy dispersive x-ray spectroscopy studies were done for chemical analysis of the samples. For magnetic characterization, a Faraday susceptibility balance and an x-band FMR spectrometer were used.

As-deposited samples of Fe-Bi-Li oxides with x=0.1–0.4 show a paramagnetic susceptibility χ of about 2×10^{-5} emu/g at room temperature. We did not observe any systematic variation in χ with the concentration x of Li_2O. The films were then annealed for 60 min in air at temperatures T_a ranging from 500 to 1075 K, in steps of 50 K. Figure 1 shows the variation of the room-temperature magnetization M with T_a. Data for films with x=0.1 to 0.4 are given in the figure. For T_a<625 K, M remains small and constant. A substantial increase in M is seen for $T_a \geq 675$ K. The data show a broad maximum in M extending from 725 to 1025 K for all x values. A constant M for high T_a values implies that any crystalline phases precipitated at high temperatures during the annealing process does not involve Fe from the amorphous structure. The magnetization could not be obtained for higher T_a values since the glass substrates melted and reacted with the films. Since the Fe_2O_3 content in the films is independent of x, the data in Fig. 1 indicate a dependence of M on the concentration of nonmagnetic Li_2O. One observes a general increase in M with x. The highest magnetization, about 27 emu/g, is achieved for x=0.4.

Effects of annealing on the crystal structure of the films were investigated with x-ray diffraction (XRD). Such data

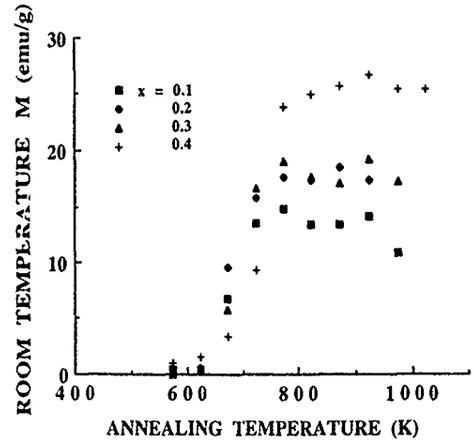

FIG. 1. Magnetization M at room temperature as a function of annealing temperature T_a for samples of 0.5 Fe_2O_3-$(0.5-x)Bi_2O_3$-xLi_2O. The films prepared by rf sputtering in pure oxygen were annealed at T_a for 60 min. M was measured with a static field H=5 kOe applied parallel to the film plane.

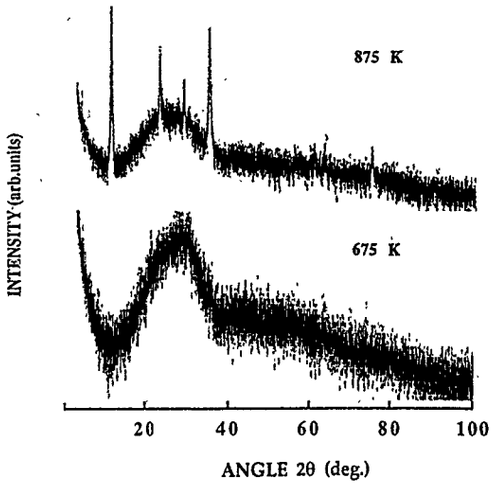

FIG. 2. X-ray diffraction pattern for films of 0.5 Fe_2O_3-0.3 Bi_2O_3-0.2 Li_2O annealed at 675 and 875 K. Peaks in intensity for the film annealed at 875 K are due to crystalline nonmagnetic Bi_2SiO_5.

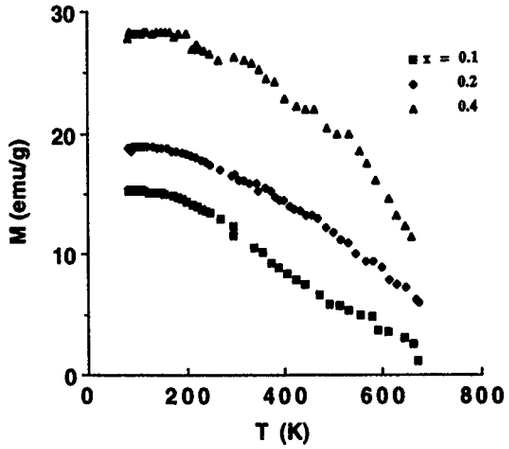

FIG. 3. Magnetization as a function of temperature for an annealed sample of 0.5 Fe_2O_3-$(0.5-x)Bi_2O_3$-x Li_2O. The films were cooled to 77 K in zero field and M was measured at 5 kOe as T was increased.

for a film with $x=0.2$ annealed at 675 and 875 K are shown in Fig. 2. A broad peak centered at $2\theta=30°$ appears due to the glass substrate. The film annealed at 675 K which shows a room-temperature M of 15 emu/g (refer to Fig. 1) is amorphous. The XRD pattern for the film annealed at 875 K shows peaks corresponding to crystalline nonmagnetic Bi_2SiO_5. Such an impurity phase is formed most likely due to reaction with Si in the glass substrate. The most important result from XRD studies is that the sample is free of any crystalline ferrimagnetic compounds such as γ-Fe_2O_3, Fe_3O_4, $Li_{0.5}Fe_{2.5}O_4$, or $Bi_3Fe_5O_{12}$. The observed M of 15 emu/g corresponds to a substantial volume fraction of any of the above phases, well above the limit of at least 5%–10% required for detection by XRD. Since the data in Fig. 2 do not show any peaks at positions corresponding to crystalline phases, the presence of microcrystals of any of the ferrimagnetic oxides can be ruled out.

The spontaneous moment is possibly due to ordered clusters in the film. A similar appearance of a spontaneous magnetic moment due to annealing at high temperatures has been reported in Fe_2O_3-Bi_2O_3 containing ABO_3-type compounds (AB=BaTi, PbTi, PbZr), CuO, ZnO, or CaO.[6–12] The moment has been suggested to arise from the formation of ferrimagnetically ordered clusters during the annealing process.

Figure 3 shows data on the temperature dependence of magnetization for a series of x values. These results are for films annealed at 600–650 °C. Data could not be obtained for temperatures above 700 K due to limitations on our system. The data show an increase in M value with x for all temperatures. The Curie temperature T_c determined from linear extrapolation of high-temperature magnetization ranges from 700 to 750 K. The T_c values do not agree with T_c for any of the crystalline ferrimagnetic phases mentioned earlier.[13] The magnetic anisotropy field H_u for the films were determined from data on the effective magnetization $4\pi M_{\text{eff}}=4\pi M-H_u$ obtained from FMR studies at 9.2 GHz.

Figure 4 shows H_u vs T data for annealed films. The anisotropy fields are negative, indicating a planar anisotropy character for the films. The magnitude of H_u increases with the concentration of nonmagnetic Li_2O in the films. As T increases, the magnitude of H_u decreases for all x values.

We also studied the composition and temperature dependence of the gyromagnetic ratio γ and the linewidth ΔH. The linewidth is found to decrease with increasing x. Figure 5 shows data on γ and ΔH vs T measured at 9.2 GHz for an annealed film with $x=0.3$. Data on ΔH are for static magnetic fields parallel and perpendicular to the film plane. Both γ and ΔH decrease with increasing T.

As mentioned earlier, Fe-Bi-Li oxides prepared by rapid quenching also show evidence for magnetic order. The largest room-temperature M of 4.5 emu/g was obtained for the sample with $x=0.25$.[1,2] A Curie temperature of 800 K was measured for the samples. High-resolution transmission microscopy studies provided evidence for the presence of microcrystals with an average size of about 10 nm.[2] Films prepared by rf sputtering in the present study show a much

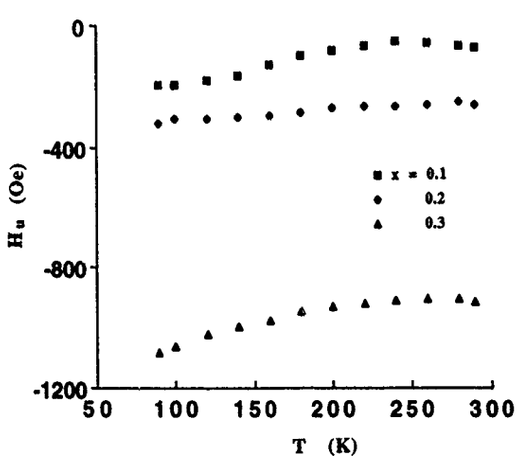

FIG. 4. The in-plane anisotropy field H_u vs temperature data for annealed films of 0.5 Fe_2O_3-$(0.5-x)Bi_2O_3$-x Li_2O.

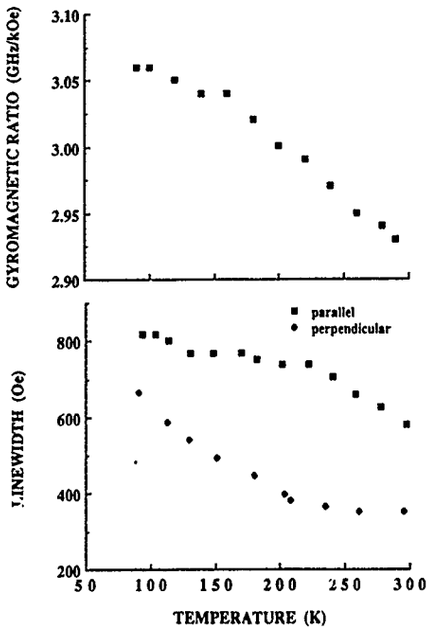

FIG. 5. Temperature dependence of the gyromagnetic ratio γ and FMR line width ΔH (for parallel and perpendicular orientation of H) for an annealed sample of 0.5 Fe_2O_3-0.2 Bi_2O_3-0.3 Li_2O.

higher magnetization, about a factor of 6 larger than for rapidly quenched samples, and a slightly smaller T_c value. The magnetization for the sputtered sample is comparable to room-temperature M for several crystalline spinel ferrites and is larger than M values for yttrium and rare-earth iron garnets. Further studies such as Mössbauer spectroscopy: and neutron diffraction on sputtered samples are important for an understanding of the origin of magnetism in the oxides.

Hysteresis and magnetic aftereffect in amorphous CoZrDy films: Trends and variations versus Dy content

G. Suran and K. Roky
Laboratoire de Magnétisme et Matériaux Magnétiques, CNRS, 92195 Meudon Cedex, France

The magnetization process was studied in amorphous $(Co_{95}Zr_5)_{100-x}Dy_x$ thin films, where $4 \leqslant x \leqslant 26$, between 6 and 300 K. The films exhibit a well-defined in-plane uniaxial anisotropy K_u. The temperature dependence of the coercive field H_c could be related to the variations of the local anisotropy K_{loc}, K_u and local defects. The thermally activated magnetic relaxation was detected for $T \leqslant 40$ K, and it follows with time the law $\ln(M/M_s) = at$. The constant a changes rapidly with the applied field H. The results are explained by the sharp distribution of the energy barriers. The as deduced activation volume is about the order of the ferromagnetically correlated volume.

The study of the magnetic aftereffect in magnetically disordered media is actually an active field, because theoretical computations,[1] predict that a magnetic quantum tunneling (MQT) could be observed if these systems possess some specific magnetic parameters. Very recently several experimental studies were reported,[2–4] performed on various magnetically disordered compounds, where the magnetization process occurred by rotation of magnetization or tunneling of domain walls. Several of these systems exhibited a more or less well identified MQT, in the temperature range 1 K$<T<$5 K.

The aim of the present paper is to report a first systematic investigation of the magnetization process and of the magnetic aftereffect on a somewhat magnetically new system: $(Co_{95}Zr_5)_{100-x}Dy_x$ amorphous thin films. The as-prepared layers exhibit a very well-defined in-plane uniaxial anisotropy K_u, which should assign a particularly simple mechanism for the magnetization process: It ought to occur essentially by pure wall displacement. The films possess also a random local anisotropy K_{loc} related to the single-ion anisotropy mechanism. Consequently, the magnetization process is believed to be determined by the respective magnitude of these two terms, assumption verified by the investigations performed on films with various Dy concentrations.

The amorphous $(Co_{95}Zr_5)_{100-x}Dy_x$ thin films of thickness 0.3 ± 0.05 μm were prepared by rf cosputtering. The concentration range investigated is $4 \leqslant x \leqslant 26$. The in-plane uniaxial anisotropy was formed by applying a dc magnetic field of 700 Oe along the film plane during deposition. The substrate temperature was held at 20 °C. The Ar sputtering pressure P_{Ar} was 2 mTorr. Other details on the sample preparation are reported in Refs. 5 and 6.

The magnetization measurements were performed by a vibrating sample magnetometer (VSM). Some limitations of the present investigations were imposed by the characteristics of our VSM. The lowest temperature at which measurements could be made is about 6–7 K. Another problem was the overall sensitivity and long-term stability. Consequently, no sufficiently precise measurements could be performed when the magnetization change with time is really small. So the aftereffect could not be studied in the Rayleigh region and at very low temperatures, conditions for which the probability to detect a MQT is the highest. K_u and its temperature dependence was measured by an automatic torque magnetometer.

The magnetization process was studied by applying the external magnetic field in the film plane along the easy axis. At room temperature and for x up to $x=22$ a rectangular hysteresis loop is detected.[6] On films with compositions close to room-temperature compensation ($x \simeq 20$) the rectangularity was verified at temperatures somewhat lower then 300 K.

The measurements revealed a strong temperature dependence of the coercive field H_c accompanied by an evolution of the loop's shape. The trends are the same whatever the composition of the deposits: H_c increases slowly as a function of decreasing temperature down to 50–40 K and exponentially for $T<40$ K (Fig. 1). These outcomes can be discussed by considering the expression for H_c valid for pure wall deplacement[7]

$$H_c = \frac{1}{4\pi} \frac{K_{loc}^2}{K_u M_s} \frac{a^3}{d^3}, \tag{1}$$

where a is the structural correlation length ($\simeq 10$ Å) and d is the wall width $d = 5\sqrt{A/K_u}$.

Equation (1) shows that the as observed variations are essentially related to that of K_{loc} and to the domain wall

width via K_u. The concentration and temperature dependence of K_u, measured, respectively, at 295 and 4 K are reported on Fig. 2. At both temperatures K_u varies linearly as a function of x and its value at 4 K is roughly an order of magnitude higher than that obtained at room temperature. A detailed numerical analysis,[5] shows that its origin is related to a single-ion anisotropy mechanism.

We propose the following model for the variations of H_c: K_u results from a more or less close alignment of the local easy axis, corresponding to sites containing Dy^{3+} ions, along the field applied during deposition. At room temperature K_u is relatively small, and the width of the domain wall is broad, so even for small applied field the sample is in an aligned state. Now the value of H_c is characteristic of soft or quasisoft ferromagnets.[1]

With decreasing temperature both K_{loc} and K_u increases largely, the variations of K_u being particularly marked down to 40 K. K_{loc} affect the absolute value of H_c [see Eq. (1)] and the local magnetic structure, a ferromagnet with a wandering axis forms progressively, characterized by a fluctuation of the direction of local magnetization. This process is governed by H_r^4/H_{ex}^3, where[9] H_r and H_{ex} are the local anisotropy and the exchange field, respectively. Here, H_r increases strongly, while the variations of H_{ex} is of the second order with decreasing T, which explains the as formed magnetic structure. The large increases of K_u affect essentially the width of the wall which becomes fairly narrow at low T. The magnitude and the local directional fluctuation of the anisotropy is much stronger at low than at room temperature and the domain walls are much narrower so more easily pinned. This wandering structure modifies probably the magnetization process (MP), which does not occur anymore by pure wall deplacement but also partly by rotation of magnetization, because the local direction of M_s fluctuates even within the domains.

The evolution of the shape of the loops with temperature is also in favor of this mechanism. The high rectangularity is conserved down to 40–50 K. For lower T the loops are slightly distorted. The remanent magnetization M_R remains equal to M_s within experimental uncertainties, but the loops are rounded up near $H=H_c$. It is well known that for $H\simeq H_c$ the shape of the loop is very sensitive to the local magnetic structure so indicates a broader distribution of the energy barriers. Now the influence of preparation related local defects, the effect of which could be much more marked at low T, cannot be discarded.

H_c and the shape of the loops are practically independent from the field variation rate down to 100 K. The magnetic aftereffect could be observed whatever the composition of the layers for temperatures lower than 50–40 K. The time dependence of the magnetization process was measured as follows: The films were saturated along the in-plane easy axis in a positive field. Then H was reversed, decreased and stopped at a negative value $|H|<|H_c|$ and $M_s(t)$ recorded at this constant field.

Here, dM/dt at a given T varies as a function of the applied field, behavior in favor of a thermally activated magnetization renversal. Its rate is determined by $\epsilon=|H-H_c|/H_c$ and increases for smaller ϵ. The variation of $M(t)$ with time (Fig. 3) is determined by the distribution δE_a of the energy barrier E_a. It should follow an exponential $M(t)/M_s=\exp(-t/\tau)$ or logarithmic $M(t)/M_s=\ln(t/\tau)$ law, where $\tau=\tau_0\exp(E_a/k_BT)$, following that the distribution δE_a is sharp ($\delta E_a \ll k_BT$) or broad ($\delta E_a \gg k_BT$).

In most of the magnetic systems investigated previously[2-4] $M(t)/M_s$ follows a logarithmic law. Our experimental data differ markedly from the previously reported ones. We found effectively that presently an exponential law i.e., $\ln[M(t)/M_s]=at$ (a=constant) is generally well obeyed whatever the composition, and for the applied field range (with $\epsilon<25\%$) used. This result shows that the apparent distribution of E_a is fairly sharp. It is believed to be related to the intrinsic magnetic properties of the films and the experimental conditions used. As a result of the quasialignment of the local easy axis along the direction of K_u the distribution of the anisotropy energy barriers are obviously much smaller than in previously studied systems. The amplitude of the as used applied field could also favor the observed results. A model of hysteresis based upon wall dis-

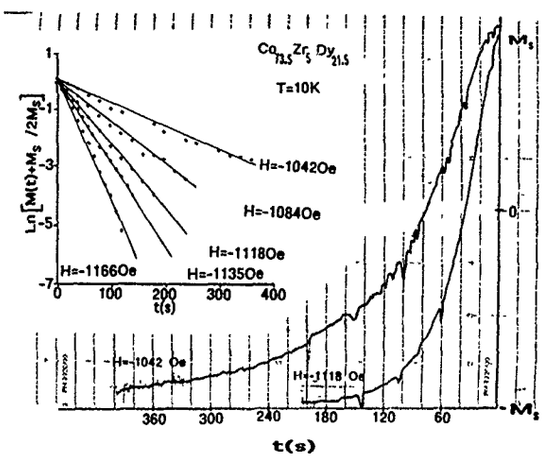

FIG. 4. Typical viscosity rate at $T=20$ K and for $\epsilon=19\%$ in film with various Dy concentration.

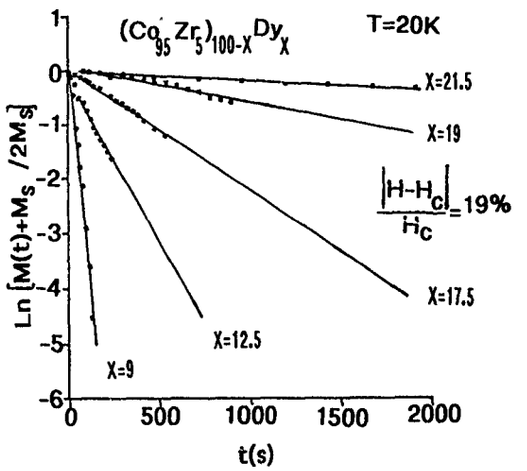

FIG. 5. Thermal variation of the average activation volume in films with various Dy concentration.

placement process states that getting over an obstacle requires the application of a field H at least equal to a critical one H_{crit} characterizing the obstacle. Obviously when H so $H-H_{crit}$ is large, the domain wall displacement process will be, only scarcely perturbed. Consequently, if the anisotropy barriers are distributed around a mean value K_u, the contribution of obstacles with $H_{crit} \ll H$ should be small or negligible.

We established the correlation between the magnetic viscosity and the Dy concentration in the films, by comparing dM/dt measured on the various samples at different T and for the same value of ϵ. When T is sufficiently high (see Fig. 4) the viscosity increases continuously with increasing Dy content. This result confirms that the relaxation rate is governed by K_{loc}. However, for lower temperatures ($T \leqslant 10$ K) this experimental rule is no more followed so regularly. These last results are related probably to the much smaller variations of K_{loc} from sample-to-sample as shown by the temperature and concentration dependence of activation volume V.

One can determine V when the distribution of the activation energy is sharp. Now at a given T a single relaxation time τ should exist and E_a is related to V by

$$E_a = VM_s(\iota I_c - H). \tag{2}$$

It can shown easily that $\ln \tau$ should vary linearly as a function of the applied field, in agreement with the experimental data, and VM_s/k_BT correspond to the slope of this line. The values of V varies (Fig. 5) from 5×10^3 Å^3 to 9×10^4 Å^3 at 6 K and 10^5 Å^3 to 13×10^5 Å^3 at 40 K. A numerical computation, the details being reported elsewhere, shows that if one estimates K_{loc} from H_c and evaluate the ferromagnetic correlation length r_f using formula proposed by Chudnovsky[9] we find effectively $r_f \simeq V^{1/0.3}$.

In conclusion the magnetization process and magnetic aftereffect were studied in CoZrDy amorphous thin films. The magnetization relaxation mechanism $\ln[M(t)/M_s]$ follow a linear time dependence result related to the well-defined K_u. The other characteristics of the relaxation process appears to be controlled by K_{loc}, similarly to other highly anisotropic materials.[2-4] Further experiments performed at sufficiently small T and/or low applied field is necessary to find out if these films exhibit a MQT.

First-principles calculation of orbital moment distribution in amorphous Fe

Xue-Fu Zhong and W. Y. Ching
Department of Physics, University of Missouri-Kansas City, Kansas City, Missouri 64110

A model calculation on a large periodic unit cell of amorphous Fe containing 200 atoms is carried out to determine the distribution of its local orbital moments. A spin-polarized orthogonalized linear combination of atomic orbitals method including spin-orbit coupling is used for the calculation of the electronic structure. It is shown that spin-orbit coupling brings about a small change in the density of states for amorphous Fe. The average orbital moment in amorphous Fe is found to be 0.01 μ_B, which is much smaller than the value of 0.09 μ_B for crystalline fcc Fe. The distribution of orbital moments over various sites is rather broad, indicating a strong quenching effect as a result of variation in the local structure in the amorphous case. It is speculated that such ground-state properties are favorable to the formation of the spin glass phase.

It has been speculated that structural disorder in magnetic materials may or may not lead to different types of magnetic ordering. There were many past investigations on this subject yet controversies remain.[1–3] In general, a spin glass (SG) phase is characterized by the random distribution of the local moments (LM) of the magnetic ions, both in magnitude and in direction. From the study of Fe-rich alloys (90% or more), it is found that the SG phase is most likely caused by the structural disorder rather than chemical disorder.[4] Theoretical investigations on this subject[1,2,5] indicate that the local environment effect is responsible for the magnetic properties of many amorphous transition metals. For example, it is found that in amorphous Fe, Fe atoms with large LM usually couple ferromagnetically with the neighbors, while those with small LM couple antiferromagnetically.[1] It is obvious that LM on magnetic ions are strongly influenced by their local structural environments.

In the classical theory of magnetic anisotropy for a crystalline solid, it is assumed that the local moment orientation is controlled by spin-orbit interaction, because spin itself is not related to any spatial direction. This is true in the single-ion anisotropy theory, which attributes this orientation to the orbital moments of some dominating ions (usually rare-earth ions), and also in the "pair model," in which the orbital moment may eventually lead to anisotropic exchange.[6] In fact, the local orbital moment that remains after quenching by the neighboring atoms is of crucial importance. If a small amount of orbital moment remains unquenched, a part of the d electron orbit may rotate, carrying with it the spin magnetic moment through spin-orbit coupling. The rotation of the orbit will, in turn, change the overlap of the wave functions between the neighboring atoms, thus affect the electrostatic and exchange interactions. A process of orientation of the spin moment in the real space is thus realized. Recent work by Jansen[7] on magnetic anisotropy theory which takes the relativistic effect into account also emphasized the influence from local orbital moment. It is shown that not only the spin-orbit coupling in the same atom is important, the coupling between the orbitals moments of the neighboring atoms is equally essential in determining the local anisotropy. It is, therefore, important to study the distribution of local orbital moments in disordered system by means of realistic first-principles calculation.

In order to separate the influence of chemical disorder that is present in a multicomponent system from the topological disorder, we choose the pure amorphous Fe (a-Fe) system represented by a periodic model containing 200 atoms for our calculation. The electronic structure and the distribution of local spin moment for this model have been reported in an earlier paper by Xu, He, and Ching.[8] The site-specific distribution of the Fe spin moment in an amorphous environment is analyzed as a function of local short-range order, such as the number of nearest-neighbor atoms and the average nearest-neighbor distances. The present calculation is an extension of that study to explore the distribution of the orbital moments and includes the spin-orbital coupling in the electronic structure calculation.

We use the spin-polarized version of the orthogonalized linear combination of atomic orbitals (OLCAO) method[9] to calculate the electronic structure of the 200-atom a-Fe model. The model was constructed by a Monte Carlo relaxation method using a pairwise Lennard–Jones type of interatomic potential. The calculated radial distribution function of the model is in close agreement with experiment.[8] We thus consider the model to be a fairly realistic representation of the a-Fe structure. In order to extract the information about the orbital moment, the spin-orbit coupling term

$$H_{sl}=\xi \mathbf{l}\cdot\mathbf{s}=\xi/2(J^2-l^2-s^2) \tag{1}$$

is added to the Hamiltonian so that the spin-up and spin-down energy bands are mixed.[10] The eigenvalue for the operator in Eq. (1) is simply $\xi\,[j(j+1)-l(l+1)-3/4)]/2$. The secular equation to be solved is, therefore, twice as large as in the spin moment calculation in which the spin-up and spin-down Hamiltonians were diagonalized separately.[8] The spin-orbit coupling constant ξ=0.0137 a.u. is taken from the corresponding atomic value for Fe.[11] This may lead to about 10% deviation from the corresponding value of ξ in crystalline Fe.[10] Since we are mainly interested in the distribution of orbital moments, not the fine structures in the energy spectrum, this approximation will not cause any significant error in our result.

The site decomposed local orbital momentum is calculated according to

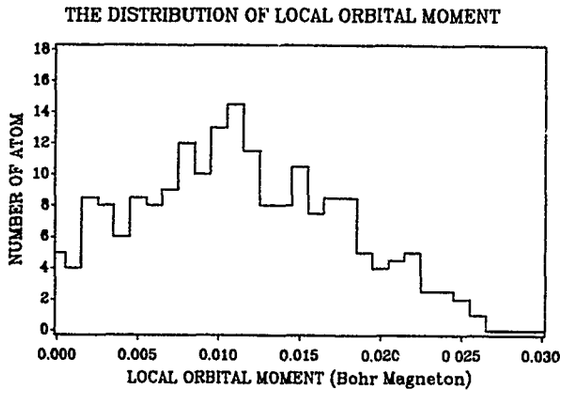

FIG. 1. The distribution of local orbital moments in the 200-atom a-Fe model.

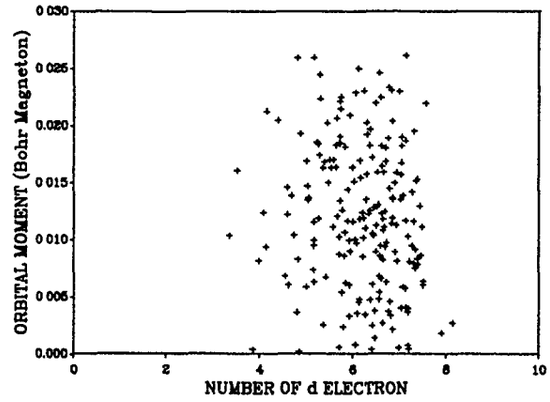

FIG. 2. Correlation plot of local orbital moment vs the number of d electrons on the Fe atom in the 200-atom a-Fe model. No obvious correlation can be established.

$$M_1 = g \sum_{n,k}^{E_F} \langle \Psi_{n,k} | L_Z | \Psi_{n,k} \rangle$$

$$= g \sum_{n,k}^{E_F} \sum_{\alpha i} \sum_{\beta j} C^*_{nk,\alpha i} C_{nk,\beta j} \int b^*_{\alpha i}(\mathbf{k}) L_Z b_{\beta j}(\mathbf{k}) d\tau, \tag{2}$$

where $|\Psi_{n,k}\rangle$ are the band wave functions, $C^*_{nk,\alpha i}$, the eigenvector coefficients, $b_{\alpha i}(\mathbf{k})$, the Bloch bases, and the summation runs over all the occupied states. Because the unit cell is sufficiently large, the $\mathbf{k}=0$ solution is sufficient. Test calculations on the density of states DOS at $\mathbf{k}=0$ and at $\mathbf{k}=2\pi/a$ (1,1,1) show no discernable difference. Due to spin-orbit coupling, the eigenstates $|\Psi_{n,k}\rangle$ are characteristic of the total angular momentum j rather than the spin or the orbital momentum separately.

The integral in Eq. (2) can be evaluated rather straightforwardly,

$$\int b^*_{\alpha i}(\mathbf{k}) L_Z b_{\beta j}(\mathbf{k}) d\tau$$

$$= \frac{1}{N} \sum_{m,n} \exp\left[i\mathbf{k}\cdot(\mathbf{R}_n - \mathbf{R}_m) \right] \int u_i^*(\mathbf{r} - \mathbf{R}_m - \tau_\alpha) L_Z u_j \times (\mathbf{r} - \mathbf{R}_n - \tau_\beta) d\tau$$

$$= \sum_{\mu} \exp(i\mathbf{k}\cdot\mathbf{R}_\mu) \int u_i^*(\mathbf{r} - \tau_\alpha) \times L_Z u_j(\mathbf{r} - \mathbf{R}_\mu - \tau_\beta) d\tau, \tag{3}$$

where $\mathbf{R}_\mu$ labels the lattice translational vector, α, β atoms in the model, and i,j the orbital states of the atom. Since atomic wave function u_i in the OLCAO method is classified by the angular momentum quantum number, the calculation of integrals in Eq. (3) amounts to a rearrangement of the matrix elements of the overlap integrals, which have already been calculated in forming the secular equation.

Our calculated distribution of the local orbital moments in the 200-atom a-Fe model is shown in Fig. 1. The outstanding feature of this distribution is the large spread of its magnitude, from near 0 to a maximum of 0.026 μ_B. The central position of the distribution is around 0.01 μ_B, which can be taken as the average local orbital moment for the system. This low value of the orbital moment in a-Fe indicates a strong quenching effect in the amorphous case. The local orbital moment for the crystalline fcc Fe is about 0.09 μ_B.[12] At first sight, it appears that a small value for the orbital moment implies almost no obvious preferential direction for the LM in a-Fe, since the orbital planes of the conduction electrons rotate almost equally around all directions. However, the nonvanishing values for the remaining orbital moments in ground state may be important for the formation of the SG structure. In fact, a large local orbital moment implies a preferential direction for the local moment through spin-orbit coupling (in the same atom), resulting in either ferromagnetic or antiferromagnetic ordering. In a SG phase, local moments are easy to reorient under the influence of a small field. Only a weak driving force for the orientation of local moment is favorable for the formation of this structure. Moreover, the randomness in the orientation of the local moments in a SG structure requires a rather wide distribution of local orbital moments. The deviation of the orbital moment from the average value in our calculation is actually larger than the average value itself (both the deviation and the average are around 0.01 μ_B). Therefore, our result is consistent with the notion that a SG structure is possible for an amorphous transition metal system.

We hope our first-principles approach to the study of orbital moments in a-Fe will lead to a more refined theory such that a quantitative use of the distribution of local orbital moments is possible. Kakehashi has pointed out[1] that the main-peak position in the noninteracting densities of states (without the interaction between local moments in the calculation of electronic structure) is important in determining the ferromagnetic properties of amorphous alloys. This is because the nature of magnetic coupling (exchange interaction) depends on the charge density, or the d-electron number. However, this by itself is not sufficient to explain some salient features of amorphous magnetism in transition metal systems. For example, there is no obvious correlation be-

tween the local orbital moment and the number of d electron on each Fe atom. This is illustrated in Fig. 2 in which we plot the orbital moment on each Fe atom versus the effective d-electron number as determined by the Mullikan population analysis of the wave function. This is because the orbital moment is more sensitive to the geometry of the local environment than the charge density. The orientation of local moments in a SG structure is a different problem from the simple magnetic coupling. The randomness in the local moments is intimately related to the local orbital moment which also determines the spatial orientation. Its average value determines the strength of the driving force in the orientation of the local moments, while the deviation from the mean is related to the randomness of the orientation. Both are necessary in the study of the magnetic properties of amorphous transition metal systems.

In summary, our calculation of the distribution of orbital moments in the amorphous Fe system provides a direct evidence for a strong quenching effect in such a disorder system. It may shed some light on the microscopic origin of the formation for the SG structure.

A magnetocalorimetric study of spin fluctuations in amorphous Fe_xZr_{100-x}

A. LeR. Dawson and D. H. Ryan
Centre for the Physics of Materials Department of Physics, McGill University, 3600 University St., Montreal, Quebec, H3A 2T8, Canada

Low temperature calorimetry data on amorphous Fe_xZr_{100-x} samples near the ferromagnetic/paramagnetic phase boundary at $x=37.5$ are reported, as well as some magnetocalorimetry data in magnetic fields of up to 5 T. The data are analyzed in terms of two models, one describing the effect of spin fluctuations (SF) and the other the effect of superparamagnetic clusters. The data are shown to favor the SF model and taken with earlier resistivity work, provides convincing evidence for the existence of SF in a-Fe_xZr_{100-x}.

Spin fluctuations (SF) are nonmonodispersive long wavelength magnetic excitations of characteristic energy T_{SF}, not accounted for by mean-field theories, which were predicted to apply to nearly ferromagnetic Fermi liquids and explained the specific heat capacity (C_P) of liquid ^{3}He.[1] Ikeda *et al.*[2] have given an extensive review of the quenching by high (~10 T) magnetic fields of the SF contribution to the low-temperature C_P. Their study surveyed several highly exchange-enhanced d- and f-band magnets for which the Stoner enhancement factor, S, is greater than 10. $Ni_{3+x}Al_{1-x}$, for example, exhibits a transition from an exchange-enhanced paramagnet to a weak ferromagnet for small values of x. SF models have been shown to be necessary to explain the values of both the Curie temperature and the ordered moment in Ni_3Al.[3] A recent magnetocalorimetry study of $Ni_{3+x}Al_{1-x}$[4,5] used elastic constant measurements to separate the phonon contribution to C_P and detected a small SF enhancement, which was greatest at the critical composition. Field quenching of this enhancement was found to be in agreement with predictions from T_{SF} measured in zero field. The effect of a magnetic field also ruled out the presence of superparamagnetic clusters due to possible compositional inhomogeneities in their samples, which could also have accounted for the zero-field data.

Amorphous d-band metals offer many advantages for the study of SF. The rapid quenching from the liquid state leads to a high degree of compositional homogeneity and inhibits magnetic cluster formation. Furthermore, slightly varying the sample composition should not significantly change the phonon C_P, a complication which can occur in crystalline systems. a-Fe_xZr_{100-x} is an ideal candidate system for the study of SF. It is a good glass former[6] in the range $20<x<43$, where it exhibits three distinct phases, superconductivity for $x<30$, ferromagnetism for $x>37.5$ and paramagnetism for intermediate compositions. The susceptibility of the paramagnetic alloys suggests that they are strongly exchange-enhanced paramagnets with Stoner factors approaching 10, and the superconducting alloys exhibit a mass enhancement factor possibly arising from SF.[7] A low-temperature resistivity study of alloys near $x=37.5$ showed a strong temperature dependence which could be analyzed using a model including scattering by SF.[8] This analysis yielded rough estimates for T_{SF} which were as low as 20 K.

Previous C_P studies of a-Fe_xZr_{100-x} at broadly spaced compositions have been discussed in terms of a cluster model.[9,10] In this preliminary work, we report on the low-temperature C_P of several closely spaced a-Fe_xZr_{100-x} alloys near the ferromagnetic phase boundary at $x=37.5$. We have analyzed our data in terms of both a magnetic cluster model and a SF-model.

Appropriate amounts of Fe (99.98%) and Zr (99.9%) were induction melted on a water-cooled copper boat in a Ti-gettered argon atmosphere. The boules were twice remelted to ensure homogeneity. The alloys were then rapidly quenched by melt spinning in a He atmosphere with a tangential wheel speed of around 50 m/s, yielding meter length ribbons 1 mm wide and ~20 μm thick. Cu K_α x-ray diffraction using an automated Nicolet–Stoe powder diffractometer showed the samples to be amorphous. Some samples near $x=30\%$ showed small crystal peaks which did not appear on the wheel side of the ribbon and could be easily removed from the free side by a very light sanding. Sample compositions were determined by electron microprobe analysis.

Absolute C_P data were measured between 2 and 25 K using a time relaxation technique[11] modified by the use of an ac chopped[12] Au-0.07% Fe thermocouple and a thick film ruthenium oxide resistance thermometer.[13] The microcalorimeter was checked for accuracy by measuring gold and copper standards[14] and the overall accuracy and precision were each found to be 2%. Approximately 40 mg of ribbon were wound into a ~7-mm-diam coil and silver pasted to the addenda. This mounting technique allows large sample loading with a fast internal relaxation time. The calorimeter could be placed in the bore of a 5 T superconducting solenoid with the field axis parallel to that of the sample coil to minimize demagnetization effects. The small magnetoresistance of the carbon glass thermometer was corrected for using a field-independent capacitance thermometer.

Figure 1 shows the specific heat of several of our a-Fe_xZr_{100-x} samples. Normally, for $T<\Theta_D/40$, C_P can be written as

$$C_P=\gamma T+\beta T^3, \tag{1}$$

where

$$\gamma=\tfrac{1}{3}\pi^2 k_B^2(1+\lambda_{e-p})N_0(E_F)\equiv(1+\lambda_{e-p})\gamma_0$$

and

$$\beta=\frac{(1.944\times10^6\ \text{mJ/mol K})}{\Theta_D^3}.$$

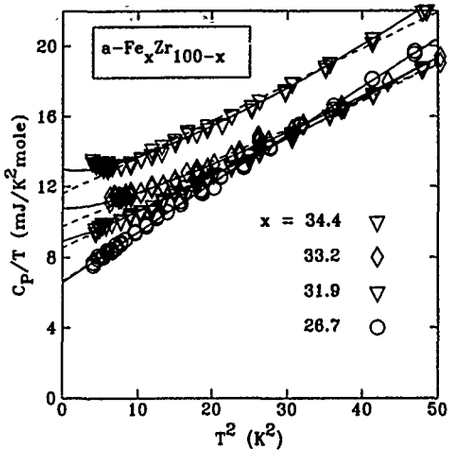

FIG. 1. C_P/T vs T^2 for a-Fe_xZr_{100-x}. The dashed and solid lines are fits to Eqs. (1) and (3), respectively.

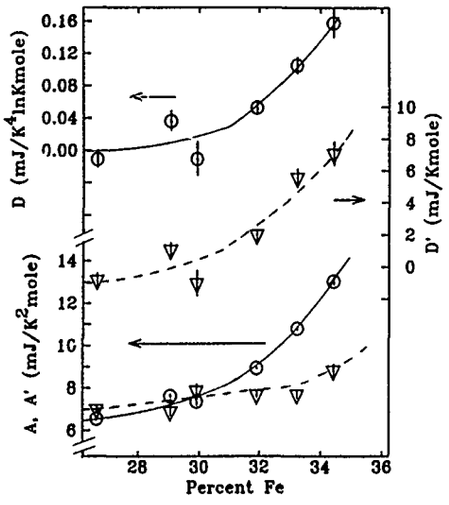

FIG. 2. Some of the parameters resulting from fits of the C_P data below 7 K: (○) A and D from Eq. (3) and (▽) A' and D' from Eq. (4). The solid and dashed lines are guides for the fits to Eqs. (3) and (4), respectively. Error bars are also calculated by the fitting program.

Since $\Theta_D \sim 200$ K,[9] we expect plots of C_P/T vs T^2 to yield straight lines. This is clearly not the case, as Fig. 1 shows definite upturns for some alloys below $T^2=10$ K^2.

In the presence of SF, Eq. (1) becomes[4]

$$C_P=\gamma_0 T\left(\frac{m^*}{m}\right)+\beta T^3+DT^3\ \ln\left(\frac{T}{T_{SF}}\right). \tag{2}$$

This may be more conveniently rewritten as

$$C_P=AT+BT^3+DT^3\ \ln T, \tag{3}$$

where

$$B=\beta-D\ \ln T_{SF}$$

and

$$A=\gamma_0 m^*/m=\gamma_0(1+\lambda_{e-p}+\lambda_{spin}),$$

λ_{spin} is the the SF electron mass enhancement.

The theory also predicts that both A and D increase with the Stoner factor S. This is not surprising since a large electronic specific heat γ and the existence of magnetic order in itinerant systems are both associated with a high density of states at the Fermi level. Plotted as C_P/T vs T^2, Eq. (2) shows a characteristic upturn at temperatures below T_{SF}. Since Eq. (2) is only valid for $T \ll T_{SF}$, in fitting to it, the range of data must be restricted to temperatures not too far above the upturn.

The parameters derived from fits of Eq. (3) to the data in Fig. 1 are shown as a function of iron content in Fig. 2. The composition dependences of the coefficients of the linear term, A, and the $T^3 \ln T$ term, D, are very similar as expected from their dependence on S. We take this similarity as support for the SF model. Assuming $\lambda_{spin}=0$ for a-$Fe_{26.7}Zr_{73.3}$, and using $\lambda_{e-p}=0.4$[9] we can calculate γ_0 for $x=26.7$. Assuming γ_0 and λ_{e-p} remain unchanged for $x=34.4$, we obtain $\lambda_{spin}=1.4$ for a-$Fe_{34.4}Zr_{65.6}$.

We have also fitted Eq. (1) to the data between 7 and 10 K, where the SF term is expected to be small. The β resulting from these fits is shown in Fig. 3. Analysis of the a-$Fe_{26.7}Zr_{73.3}$ data, which exhibits normal metallic behavior at low temperatures, shows that the specific heat drops below that predicted by a Debye function even below 7 K. Therefore, we cannot exactly determine the phonon contribution to B in Eq. (3) by extrapolation from the high-temperature fits. The departure from T^3 behavior appears as a slight downturn in a C_P/T vs T^2 plot and leads us to underestimate D, and results in slightly negative values in some cases.

Nonetheless, using the high-temperature β value and the definition of B in Eq. (3) we estimate T_{SF} for our samples which show a clear deviation from normal behavior [Eq. (1)]. These are shown in Fig. 3 together with the approximate curve obtained from the resistivity of a-Fe_xZr_{100-x}.[8] Altounian *et al.*[15] have done a more detailed determination of T_{SF} through a study of the isostructural system

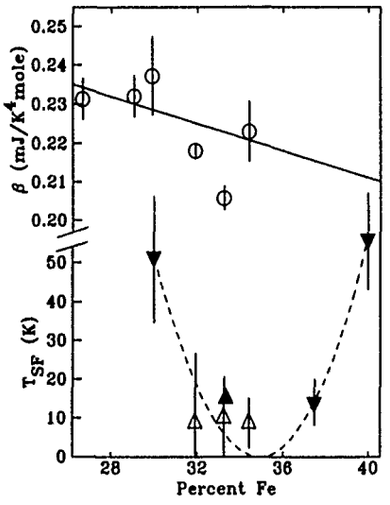

FIG. 3. (○) Phonon C_P coefficient, β, resulting from fits of the data between 7 and 10 K to Eq. (1). The straight solid line is a guide to the eye. Displayed in the lower section are approximate values of T_{SF} whose derivation is discussed in the text (△). Data taken from resistivity studies of Ref. 8 (▼ and dashed line) and Ref. 15 (▲) are also shown for comparison.

a-$(Fe_yNi_{100-y})_{33.3}Zr_{66.7}$. Substitution of Fe by Ni allowed separation of the resistivity due to SF from that due to electron–phonon scattering since for $y<0.4$, the latter process dominates. They find $T_{SF}=15$ K for $y=100$ which is also shown in Fig. 3. We take the good agreement between the T_{SF} derived from two very different measurements as further support for the SF model. The values of T_{SF} and that of λ_{spin} discussed earlier are similar to those for $Ni_{3+x}Al_{1-x}$ and so a-Fe_xZr_{100-x} can probably be classed as the same type of spin fluctuator.[2]

We now turn our attention to the only other plausible explanation for the data. Upturns similar to those of Fig. 1 have been seen the C_P of $Cu_{60}Ni_{40}Fe_{0.02}$[16] and result from superparamagnetic moment clusters which form about the Fe atoms and extend for several lattice spacings. The clusters contribute an extra component to C_P as they are small enough that their energy in the local crystal field is comparable with k_BT. This contribution to C_P can be described as a Schottky-like function which we have approximated by a constant to yield the expression:

$$C_P=A'T+\beta'T^3+D'. \tag{4}$$

The fits are as good as those to Eq. (3) and the results are also shown in Fig. 2. The size and composition dependence of the D' term resembles that of and earlier study[10] however we do not observe a divergence in Θ_D. Identifying D' with k_B times the number of magnetic clusters per mole, we can derive a lower bound of order 10^{-3} clusters per mole. Such a small number of clusters seems unlikely in the presence of so much iron. While SF and magnetic clusters both yield an enhanced susceptibility, a more complete study of the high-field magnetization could rule out the magnetic cluster picture.

Finally, we discuss the magnetocalorimetry results. In a sample with magnetic clusters, the applied field adds to the local field felt by the clusters so that when the two are of the same order, the magnetic C_P component, D', should increase significantly since we are on the high-temperature side of the Schottky anomoly.[16] These local fields must be less than 1 T, since we know that the Schottky peak is at $T\leqslant 1$ K$\sim\mu_B\times$(1 T), so that we would expect a significant change in the magnetic C_P at 5 T. For SF, the effect of a magnetic field appears as a change in the linear C_P:[2]

$$\frac{\gamma(B=0)-\gamma(B)}{\gamma(B=0)}=0.1\,\frac{S}{\ln S}\left(\frac{\mu_BB}{k_BT_{SF}}\right)^2. \tag{5}$$

With $T_{SF}=10$ K and $S=10$, we would expect a decrease in γ of order 3% in a field of 5 T. The C_P of $x=31.6$ and $x=30.3$ samples were measured in fields of 0, 3.5, and 5 T. No change was found to within 3%. Our results, therefore, support the SF picture.

In conclusion, we have presented observations of a spin fluctuation contribution to C_P in a nearly ferromagnetic amorphous alloy. While fits to the data cannot unequivocally distinguish between a SF model and a magnetic cluster model, interpretation of the fit parameters favors the SF model, as does the preliminary field work. Taken together with earlier results on the low-temperature resistivity[8,15] and susceptibility,[7] this is strong evidence of spin fluctuations in this system.

Magnetic properties of colloidal silica: Potassium silicate gel/iron nanocomposites

R. D. Shull, H. M. Kerch, and J. J. Ritter
Materials Science and Engineering Laboratory, National Institute of Standards and Technology, Gaithersburg, Maryland 20899

Homogeneous composites of Fe and silica containing 5–40 wt % Fe have been prepared by infiltration of ferric nitrate solution into a colloidal silica: potassium silicate gel at room temperature. Previous electron microscopy, small angle neutron scattering, and nitrogen sorption (BET) measurements on such gels have shown they are comprised of an interconnected silica matrix, having pores ranging from 2–800 nm in size. Mössbauer effect and magnetization data show the Fe is in a paramagnetic environment with weak antiferromagnetic interactions. Curie–Weiss analysis indicated negative intercepts of the temperature axis for all the samples and that the magnetic moment per Fe atom (μ_{Fe}) *decreased* as the Fe content *increased* at a rate of ~0.0058 μ_B/% Fe. For most of the samples $\mu_{Fe} \approx 2.1\ \mu_B$. By contrast, in silica gel/Fe nanocomposites formed by the polymerization of an aqueous solution of tetraethoxysilane and iron nitrate, the Fe possessed magnetic moments varying from 3.9 to 2.9 μ_B. It is suggested that the difference is a result of the different pore structures of the gels, and not due to the different methods (e.g., postmatrix infiltration as compared to premixing prior to matrix polymerization) used to introduce the Fe.

Fine dispersions of magnetic particles in nonmagnetic matrices have been found to possess different magnetic characteristics that the same particles compacted together into a bulk material without the nonmagnetic constituent.[1] In fact, the properties may be tailored by proper adjustment of the relative composition of the two species (an easy variable to control) and the thermal-magnetic treatment given the material. Applications of such materials to recording heads,[2] high-density recording media,[3] color reproduction,[4] and magnetic refrigeration[5] have been suggested. For the creation of bulk solids containing such fine particle dispersions, sol-gel methods have been found to be particularly effective.[6,7] After preparation, their magnetic character can even be changed on demand by treatment in various gases at about 350 °C. Many magnetic phenomena have been found in materials prepared via the sol-gel route, including paramagnetism, ferromagnetism, superparamagnetism, and spin-glass behavior. Initially, it was thought that the matrix gel provided only a support for the fine Fe particles.[6] However, subsequent studies of silica gel/Fe (SG/Fe)[8] and alumina gel/Fe (AG/Fe)[7] systems showed that the matrix played an active role in determining the magnitude and concentration dependence of the magnetic moment of the Fe. Recently, another type of gel, colloidal silica: potassium silicate gel (CSPS),[9] came to our attention. This material possessed a much larger pore volume but with a combination of pore sizes varying down to a few nanometers. Fe loading in the new gel is accomplished by infiltration after formation of the gel. This process is in contrast to that followed in the previous studies of the SG/Fe and AG/Fe nanocomposites wherein the matrix gel and Fe clusters were formed simultaneously. As a test of the effect of infiltration on the magnetic character of the composite and as an attempt to increase the Fe loading without a concomitant increase in Fe cluster size, the present study was initiated.

A colloidal gel (CSPS) was made by a process developed by Shoup[9] wherein an electrostatically stabilized sol of colloidal silica [Ludox HS-40][10,11] in a 90 wt % potassium silicate solution [Kasil No. 1][12] is gelled using an aqueous formamide gelling agent at a *p*H of 10.8. After curing for 2–3 h at 80 °C, the alkali species were removed by ionic exchange in a 1*N* solution of NH_4NO_3 (90 °C) followed by immersion in a 1*N* solution of nitric acid (90 °C) and a wash in distilled water.[13] Previous electron microscopy, small angle neutron scattering, and nitrogen sorption (BET) measurements on such gels have shown they are comprised of an interconnected silica matrix with extremely high surface area, having intracluster pores ranging from 2–10 nm in size and a bimodal distribution of intercluster voids with diameters centered around 200 and 800 nm.[13] The infiltration of magnetic species into these gels was accomplished by placing carefully weighed drops of aqueous solutions of $Fe(NO_3)_3$ on top of 3-mm-thick (25-mm-diam) slices of the dried gel. Within an hour the liquid was absorbed into the solid, and the gel changed from a white to a light brownish color homogeneously throughout the sample. Magnetic measurements were performed on this material after drying in air at 300 K for two weeks. In this study nanocomposites of CSPS/Fe containing 5.7%, 10.6%, 20.3%, 30.0%, and 40.3% iron were prepared. All Fe contents herein are quoted in weight percent of the final composite, consistent with the labeling convention used for the SG/Fe and AG/Fe gels of the earlier studies. Mössbauer effect measurements were performed using the sample as the absorber and a 20 mCi ^{57}Co in Rh source. Velocity calibration of the Mössbauer equipment was performed using Fe_2O_3, and zero velocity is the center of a pure Fe spectrum. The magnetization measurements were performed between 300 and 5 K in a SQUID magnetometer. Magnetic hysteresis measurements were performed by measuring the sample's magnetization as the magnetic field was cycled in steps from positive to negative and back to positive values after first cooling the material to the

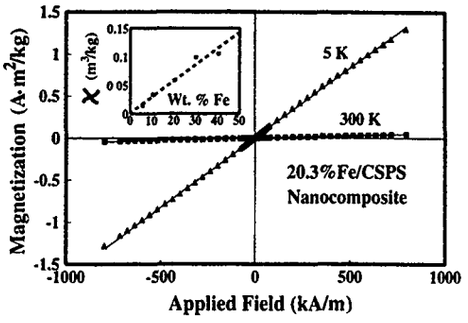

FIG. 2. Magnetization vs temperature data measured at the indicated temperatures for a 20.3% Fe/CSPS nanocomposite, and the room-temperature magnetic susceptibility (χ) vs wt % Fe (W_{Fe}) for a series of CSPS/Fe nanocomposites (inset). The dashed line (χ=0.002 85W_{Fe}) is a linear least-squares fit of the data.

measurement temperature in an 800-kA/m field.

Figure 1(a) shows an example of the Mössbauer effect spectra obtained for the CSPS/Fe nanocomposites at 300 K. The data are characterized by an absorption doublet (0.67-mm/s electric quadrupole splitting) having a small isomer shift of 0.4 mm/s. This is very similar to that which was observed at room temperature for the SG/Fe and AG/Fe nanocomposites formed by the polymerization of either tetraethoxysilane (TEOS) or aluminum triisopropoxide, respectively, in the presence of aqueous Fe nitrate.[7,8] Those materials possessed an interconnected network of pores inside which the iron complexes formed, but those pores exhibited only a single size distribution centered about 30 nm.[7] On cooling the 10.6% Fe CSPS/Fe sample to 4.2 K, however, the room-temperature Mössbauer effect doublet does not broaden or decompose into a six-line spectra indicative of fine Fe-containing particles slowing down their magnetic spin-flipping rate, as was observed in the previously studied SG/Fe and AG/Fe nanocomposites. Instead, for the CSPS/Fe composite of the present investigation, there is a sharpening of the room-temperature doublet (isomer shift remains at 0.4 mm/s, but the quadrupole splitting decreases to 0.52 mm/s), see Fig. 1(b). In addition, at 4.2 K there is the appearance of a second absorption doublet having a larger 0.62-mm/s isomer shift and a larger 1.56-mm/s quadrupole splitting. One possible explanation for this result is that the iron atoms in the infiltrated CSPS/Fe sample are located in two different local environments in either one or two *paramagnetic* lattices in the pores, each type of Fe atom having a different electric quadrupole temperature dependence. By contrast, the iron atoms in the SG/Fe and AG/Fe nanocomposites are located in nanometer-sized clusters of a *ferromagnetic* lattice.[6,7] This difference is surprising, even if one realizes the matrix plays a role other than support for the iron. In the previous SG/Fe and AG/Fe studies, a difference in the nature of the iron had been discovered when the matrix was chemically different, as in a silica-gel compared to an alumina-gel matrix. However, in the present case both the CSPS/Fe and SG/Fe nanocomposites possess a silica matrix, and would therefore still have been expected to be magnetically similar. Since the major differences between these two silica gel/Fe nanocomposites are their vastly different morphologies and the different methods used to introduce the iron, it is attractive to conclude that either of these factors led to the different magnetic character of the nanocomposites.

Magnetic hysteresis measurements on the CSPS/Fe nanocomposites also showed that all the materials containing less than 30% Fe are paramagnetic at both room temperature and 5 K, consistent with the Mössbauer experiments. A typical example of these data is shown in Fig. 2. Note the linear relationship between field and magnetization indicative of this type of magnetic state. At room temperature the magnetic susceptibility for these materials increased linearly with Fe content from 1.36×10^{-2} m^3/kg for the 5.7% Fe sample at a rate of 2.85×10^{-3} m^3/kg per percent Fe (see inset of Fig. 2), thereby providing confidence in the quoted concentrations. Typically, a 40-fold increase in susceptibility was found for all these samples on cooling from 300 to 5 K (e.g., see Fig. 2), typical of that expected for a paramagnet. For the 40% Fe sample, there is a slight curvature toward the field axis (with essentially zero remanence) in the initial part of the hysteresis loop at both 300 and 5 K. Since the higher field data ($|H|>15$ kA/m) possess a linear M-H behavior, these data suggest a small admixture of either a superparamagnetic or ferromagnetic component with the majority paramagnetic phase. The magnetic susceptibility values are about one-tenth that measured for the SG/Fe nanocomposites studied earlier,[8] indicating a lower magnetic moment per Fe atom in the present samples. In order to determine this more quantitatively, the temperature dependence of the susceptibility was measured for the CSPS/Fe material. Figure 3 is representative of this data. Note, there are no discontinuities in the susceptibility data indicating the lack of magnetic transitions between 300 and 5 K. The dashed line in this figure is a least-squares fit of the high-temperature inverse susceptibility data to a straight line. All the samples in this study exhibited this Curie–Weiss behavior with significant deviations at low temperatures. The slopes of the high-temperature $1/\chi$ vs T fits were analyzed as in Ref. 8 to obtain the magnetic moment per Fe atom, and these results are shown in

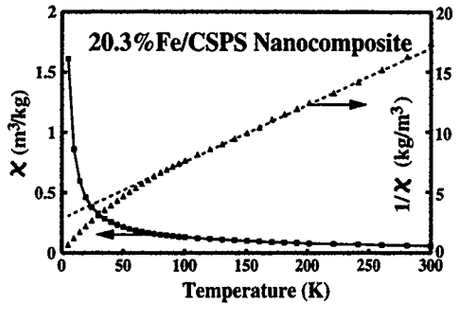

FIG. 3. Magnetic susceptibility, χ, (filled squares) and inverse susceptibility (triangles) vs temperature for a 20.3% Fe/CSPS nanocomposite showing Curie–Weiss behavior. The arrows indicate the appropriate axes. The dashed line is a least-squares fit of the high-temperature $1/\chi$ data.

Fig. 4. In the SG/Fe cluster materials of the earlier studies, the magnetic moments were above 3 μ_B/Fe atom and they decreased with increasing Fe content at a rate of 0.038 μ_B/% Fe. The situation is much different for the present infiltrated CSPS/Fe nanocomposites. The present materials possess much smaller values near 2.1 μ_B/Fe atom. Similar to the SG/Fe nanocomposites,[8] the magnetic moment per Fe atom in the CSPS/Fe materials also *decreases* with *increasing* Fe content, although at the much lower rate of 0.0058 μ_B/% Fe. This decrease can be explained by the presence of weak antiferromagnetic interactions between the Fe atoms similar to that reported for ferrites via intermediary oxygen atoms.[14] This interpretation is also consistent with the "negative" temperature-axis intercept found for the extrapolated high-temperature behavior for all the CSPS/Fe samples (see Fig. 3). Iron is present during the formation of the gel in the SG/Fe material and may, therefore, participate in the gellation chemistry. However, in the CSPS/Fe material the Fe is added after the formation of the CSPS matrix. Thus the interaction of the Fe with the matrices may be quite different in the two systems. In order to check this possibility, a pure

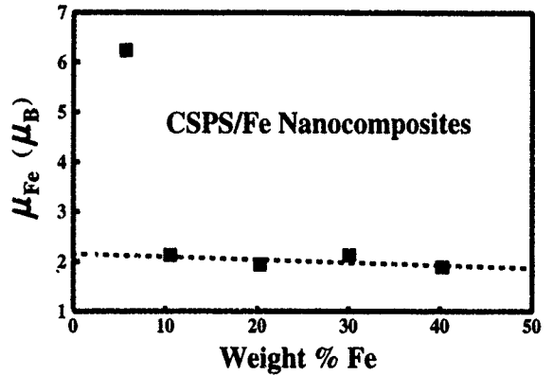

FIG. 4. Magnetic moment per Fe atom (μ_{Fe}), in Bohr magnetrons (μ_B), vs wt % Fe (W_{Fe}) for a series of CSPS/Fe nanocomposites. The dashed line (μ_{Fe}=2.15–0.005 75W_{Fe}) is a linear least-squares fit of the data for the four most concentrated materials.

silica gel sample was prepared using the preparation technique of the SG/Fe nanocomposites. Iron was subsequently introduced into the gel to a concentration of 16% using the infiltration technique of the CSPS/Fe nanocomposites. At room temperature, the Mössbauer spectra was similar to that shown in Fig. 1(a) (isomer shift of 0.5 mm/s and an electric quadrupole splitting of 0.68 mm/s), but at 4.2 K the spectra consisted of an admixture of the room temperature central doublet and a prominent six-line hyperfine field pattern (isomer shift of 0.37 mm/s and hyperfine field of 40.3 kA/m). This result indicates the iron is in nanometer-sized ferromagnetic clusters. This result is also identical to that observed earlier for the SG/Fe nanocomposites wherein the iron was introduced *before* the solution polymerization.[6] Consequently, we suggest the different magnetic behavior of the CSPS/Fe nanocomposites is due to different Fe-matrix interactions caused by the material's much different morphology, including the very fine 2–10 nm intracluster pores and the 200–800 nm intercluster voids,[13] and pore chemistry. A similar phenomena was observed earlier in ion-exchange resins.[4] In that case, the pore structures were found to be responsible for the *in situ* formation of metastable γ-Fe_2O_3 (maghemite) at room temperature.

In conclusion, the form of the Fe in the CSPS/Fe nanocomposites was found to be different from that in the SG/Fe nanocomposites, even though the source of the Fe was the same in both cases and the matrix in both cases was silica. It is suggested that the difference is a result of the different morphology and pore chemistry of the materials rather than the methods (e.g., postmatrix infiltration as compared to premixing prior to matrix polymerization) used to introduce the Fe.

The authors express their appreciation to L. Swartzendruber and W. Haller for helpful discussions of the data. Special appreciation is expressed to H. Brown for performing the magnetization measurements of this study.

Origin of high coercive force in rare-earth–transmission-metal thin film

D. Roy Callaby, Robert D. Lorentz, and Shigeki Yatsuya
3M Company, St. Paul, Minnesota 55144

A sequence of rare-earth/transmission-metal (RE-TM) films have been sputter coated and an increase in the coercive force of over six times has been measured for a change in argon pressure from 2 to 10 mTorr. By using small-angle x-ray scattering measurements, a strong correlation has been found between the number or volume of voids and the coercive force in sputtered coatings of RE-TM materials, especially Tb-Fe-Co. A transmission electron microscopy technique has shown that the majority of these voids accumulate in the observed gaps between columns.

I. INTRODUCTION

The majority of rare-earth/transition-metal (RE-TM) magneto-optic (MO) materials used for information storage are made by sputtering, usually under argon, with a pressure above 1 mTorr. Calculations indicate that the coercive force H_c depends very much not only on the composition but also upon the sizes of voids.[1] In addition, it has been reported that the coercive force is very dependant on the argon pressure used for sputtering.[2] In this article we report on the effects of argon pressure on the value of H_c and on the number and sizes of voids in the MO coatings. We have also determined the position of these voids. The effects of different dielectrics and of different coating thicknesses are also discussed.

II. EXPERIMENT

The MO and SiC dielectric layers were prepared by dc sputtering, while for the SiN dielectric, rf sputtering was used. The samples were made either as an alloy or as a nanolayered structure of iron cobalt and terbium using a separate terbium target. The magnetic properties were measured with a vibrating sample magnetometer and the microstructural imaging of the films was performed with an electron microscope. The sizes and volume fractions of the voids were determined using small-angle x-ray scattering (SAXS).

III. RESULTS

A. Magnetic measurements

Measurements of the composition of the deposited films showed small variations around the average terbium content (21 at. %), resulting from the different argon deposition pressures used in this study. These compositional variations correspondingly cause slight changes in the compensation temperature T_c and this changes both H_c and M_r, but not M_rH_c. Figure 1 shows a comparison between coatings made at 5000 (for the SAXS measurements), 700, and 200 Å. It can be seen that there is a significant rise in H_c (or M_rH_c) as the thickness is reduced but the slope of M_rH_c versus pressure increases as the thickness is reduced. Also shown in Fig. 1 is the effect of different dielectrics (SiC and SiN). Examination of the separate contributions of M_r and H_c show that the value of M_r changed very little, probably because of the low value of the compensation temperature used; most of the measured change with pressure was caused by changes in H_c. For these measurements, we used a nanolayered structure consisting of one layer of terbium for each layer of iron cobalt, as this gave the highest values of H_c.[3] Measurements made using alloy coatings showed smaller values of H_c but the same percent increase of H_c with coating pressure.

B. Small-angle x-ray scattering measurements

Small-angle x-ray scattering (SAXS) was used to investigate the void densities contained in sputtered amorphous Tb-Fe-Co films. SAXS is sensitive to long-range (>10 Å) electron density fluctuations. These fluctuations might arise from voids or from other composition fluctuations. In this experiment, modeling was used to determine that the only reasonable explanation of the observed SAXS is that it originates from voids, rather than from phase-separated materials.

The small-angle x-ray scattering experiments were performed using Cu$K\alpha$ radiation over a k range of $0.006<k<0.304$ Å^{-1}, where $k=(4\pi \sin\theta)/\lambda$. A transmission geometry was used, thereby sampling correlations in the plane of

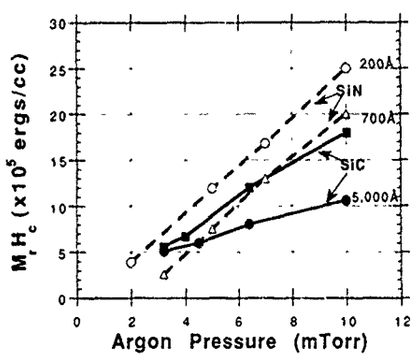

FIG. 1. M_rH_c of MO layers of thicknesses 200, 700, and 5000 Å coated onto SiC and SiN dielectric layers plotted against argon coating pressure. The M_rH_c values were measured at 30 °C or (for high H_c values) were obtained by extrapolation from values measured at higher temperatures.

the films. Some anisotropy in the void structures in the plane of the film and normal to it must be expected. The sizes of the voids in the plane are of interest to determine since they are relevant to the movement of domain walls.[1] The contribution to the total sample SAXS signal from the substrate was measured and removed and the resulting scattering was put on an absolute scale by referencing a standard to determine the scattering efficiency per unit thickness. The scattered efficiency is then on an absolute scale with units of inverse length and can then be compared directly to the results of calculations for various models.

SAXS can arise from many sources, including phase separation, voids, etc. To determine which of these are, and are not, consistent with the experimentally observed patterns, the scattering from several simple models was calculated. All modeling was done assuming spherically symmetric particles of a given radius in a homogeneous matrix. The scattered efficiency per unit sample thickness for closely packed spherical particles[4] as an approximate solution for a fluid of noninteracting hard spheres was calculated. This calculation then also has units of inverse length. This method for generating the calculated data cannot be expected to reflect the actual arrangements in the alloys to a high degree. It can be, at best, only a reasonable approximation due, in part, to the assumption of spherical particles of a uniform size. It has proven sufficient, however, to eliminate potential models and to determine the approximate size of inhomogeneities in the materials.

Modeling of the SAXS from these samples was attempted with two distinct types of physical structures. In one case, we calculated the SAXS for phase separation models, in which the samples consisted of two compositionally distinct amorphous phases. No compositionally consistent models were able to simultaneously reproduce the amplitudes and shapes of the experimentally observed SAXS patterns.

Calculations were also made of the scattering expected for a Tb-Fe-Co matrix and spherical voids in that matrix. Models with large voids were chosen to represent the low-angle scattering and smaller voids were used for the higher angles. With the appropriate selection of void sizes and densities, the main features of the observed SAXS patterns were easy to fit.

The observed SAXS varies with changes in deposition pressure and period. Figure 2 shows the SAXS patterns for four films deposited at different sputtering pressures. As the pressure is increased from 3.2 to 4.5, and then to 6.4 mTorr, the amplitude of the low-angle scattering, which represents large voids, increases. Modeling indicates that the large void size drops from approximately 165 to 120 to 100 Å in these films, while the large void density increases from 1.4×10^{13} to 2×10^{14} to 3×10^{15} voids/cm^3, respectively. These void densities can also be expressed as void volumes. Then, the corresponding void volumes would be 0.026%, 0.15%, and 1.3%. At 10 mTorr, a shoulder has appeared in this low-angle region. This hump is due to a higher density (6.5×10^{17} voids/cm^3, 7.4% void volume) of smaller voids, about 30 Å in radius. The large voids increase in size to 165 Å, and the corresponding void density, as described above, is 4.5×10^{13} voids/cm^3 (0.095% void volume). Hence, in the 10 mTorr

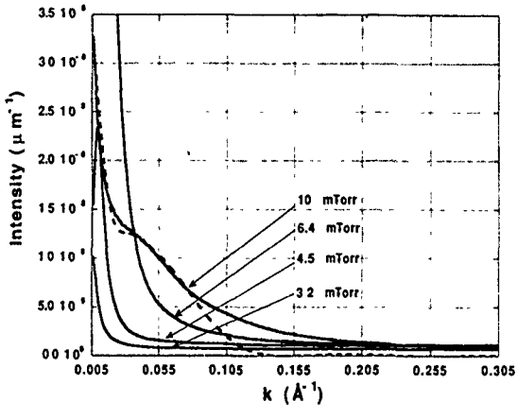

FIG. 2. Small-angle x-ray scattering from Tb-Fe-Co films deposited at 3.2, 4.5, 6.4, and 10 mTorr. The dotted line is the sum of separate calculations using models with an amorphous Tb-Fe-Co matrix plus voids of 165 Å radius and with 30 Å voids and shows a good fit to the scattering from the 10 mTorr sample.

film, the total void volume has increased substantially. Figure 2 shows the sum of the calculated scattering from the large and small void models as a dotted line. This sum fits the experimental data remarkably well, considering that there is expected to be a distribution in void size and number in the films.

C. Electron microscopy measurements

The microstructural imaging of the films was carried out using a JEOL 200CX operated at 200 kV. Two kinds of transmission electron microscopy (TEM) samples were prepared. One is a plane-view sample and the other is a cross-sectional view sample. For the plane-view samples, film stacks of SiC(150 Å)/RE-TM(~300 Å)/SiC(150 Å) were deposited on NaCl (100) crystal substrates and on SiO substrates. Films grown on NaCl substrates were floated off the NaCl substrates in water and placed on TEM grids. For the cross-sectional view samples, the same film stack was deposited on Si (100) wafers. The cross-section samples were prepared by first mechanically polishing, followed by dimpling, and finally ion milling.

Figure 3 shows a cross-sectional view of the Gd-Co thin film. The film stack of SiC/Gd-Co/SiC/Si(100) is shown in the direction of Si ⟨110⟩. The Si substrate shows the structure image and there is a Si oxide layer 10–20 Å thick on the Si substrate. The SiC grown on the Si substrate is amorphous and its surface is as smooth as the Si substrate. The Gd-Co layer is also amorphous and has a columnar structure, with the top of the columns being hemispherical in shape. The diameter of the columns is around 10 nm, which is consistent with the data obtained from a plane-view image.

The second SiC layer on the Gd-Co layer is amorphous, while its surface has ripples as if it followed the Gd-Co film surface. The thickness of the SiC layer t_2 on the Gd-Co film is smaller than that of the SiC layer t_1 on the Si crystal, although the same amount of SiC was deposited for both SiC layers. Assuming the sticking coefficient of SiC on the

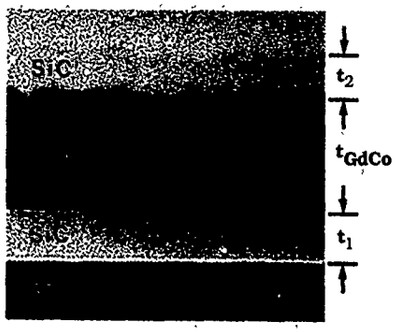

FIG. 3. Cross-sectional view of the SiC/Gd-Co/SiC film stack on a Si wafer (100). t_1 is the thickness of the SiC layer on the Si substrate, t_2 is the thickness of the SiC layer on the Gd-Co layer, and $t_{Gd\text{-}Co}$ is the thickness of the Gd-Co layer.

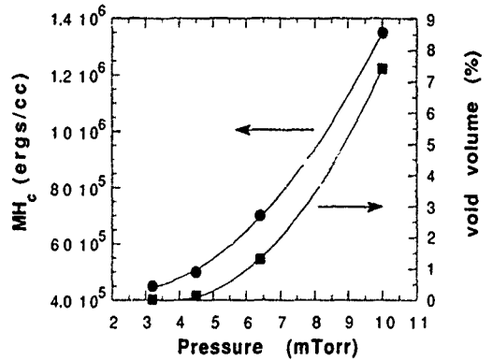

FIG. 5. M_rH_c and void volume determined by SAXS vs sputtering pressure for 5000-Å-thick Tb-Fe-Co films with 10 Å period.

Gd-Co layer is similar to that on the Si substrate, SiC material corresponding to the amount of $t_1 - t_2$ per unit area entered into the gaps between columns. The value of $(t_1 - t_2)/(t_{Gd\text{-}Co})$ is equal to the gap density between columns, where $t_{Gd\text{-}Co}$ is the thickness of the Gd-Co layer. This gap density was measured to be approximately 8.5%.[5]

The columnar structures of Tb-Fe-Co films become more distinctive as the pressure increases.[2] The gap densities of the films sputtered at 3.2 and 6.4 mTorr were also measured from the cross-sectional views in the same manner described above. The gap densities are plotted against pressure in Fig. 4. The gap density at 10 mTorr was obtained from the Gd-Co film and the other two points were measured from the Tb-Fe-Co films. In this study, we assume that the data obtained from Tb-Fe-Co at 10 mTorr is similar to that from Gd-Co at 10 mTorr, because the plane view of the Tb-Fe-Co film resembles that of the Gd-Co film. Tb-Fe-Co has been seen to have similar physical properties to Gd-Co. It can be concluded that the gap density increases with pressure. This relationship resembles that between M_rH_c (mainly H_c) and pressure as shown in Fig. 1.

IV. DISCUSSION

The void volumes in the 5000-Å-thick films, with 10 Å period, were determined by this modeling. The numbers of voids increased substantially as the deposition pressure was increased, as discussed above. When void volumes and M_rH_c values are plotted versus deposition pressure, remarkably similar dependencies are seen (Fig. 5). This strongly suggests that the volume of sizeable voids, like those expected between columns, is a determinant of the H_c values in MO films. The measured relationship between void volume and H_c is in good agreement with the modeling results obtained by Mansuripur.[1]

The gap volume measured by the TEM technique described in this article also shows that this increases as the argon pressure is increased. While the measured volumes obtained from both techniques seem to agree at 10 mTorr pressure (see Figs. 4 and 5), it should be noted that the SAXS results were obtained using 5000-Å-thick samples and the TEM results were measured from 200–300-Å-thick samples, so exact agreement should not be expected. Of more importance is the fact that both void volume, gap density, and H_c increase with increase of argon sputtering pressure. The anisotropy K_u can influence H_c but measurements by Merchant and Kryder[6] have shown that increasing the argon pressure over the range used here results in a small reduction of K_u rather than any increase.

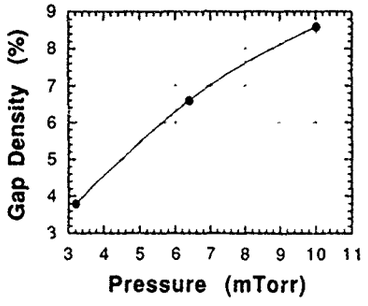

FIG. 4. Measured gap densities plotted against argon coating pressure.

V. CONCLUSIONS

The SAXS and VSM results show that both the void volumes and the values of H_c increase with coating pressure. The electron microscope results have shown the presence of gaps between the columns of the RE/TM coatings. It follows that there is a significant contribution to the increase of H_c with coating pressure by the increasing volume fraction of these voids located in the gaps between the columns of the MO films.

Study of the effect of defect sizes and their distribution on the coercivity of magnetic media

James A. Jatau and Edward Della Torre
Institute for Magnetics Research, George Washington University, Washington, DC 20052

The nature of domain-wall motion coercivity in magnetic media is studied using a two-dimensional numerical micromagnetic model. It is necessarily assumed that the source of the coercivity is cylindrical anomalies in the material that have anisotropy or exchange parameters which are either larger or smaller than that of the surrounding media. Varying these parameters from those required to obtain the observed coercivity shows that a larger decrease in either parameter is required to obtain the same change in coercivity as a given increase. Thus, the dependence of coercivity on these parameters is nonlinear. It was also found that the computed coercivity decreases with an increase in the separation of the defects, and increases with an increase in defect size. It is shown that a correction for the calculated coercivity is required to account for the statistical distribution in defect sizes and locations. Finally, a suitable variation in the defect parameters can accurately characterize the temperature behavior of the coercivity.

I. INTRODUCTION

This article extends the work described in Ref. 1 by carrying out detailed calculations in the study of the nature of coercivity in media in which the magnetization reversal mechanism is domain-wall motion. In these media coercivity is introduced by defects imbedded in the lattice. Soft magnetic materials and magneto-optic media have this property. Due to the stiffness of the equations which describe the micromagnetic problem, we developed an efficient mode-pushing technique to accelerate the convergence of the numerical calculations.[2] Cylindrical defects in a regular periodic array are introduced in an otherwise perfect material. The problem then reduces to solving for the shape of a domain wall pinned at its ends by the defects. On the application of a magnetic field the wall bends, and at the critical field is pulled away from the defects.

Computer simulations were performed on a rectangular region measuring 15 nm in the y direction and 60 nm in the x direction. The choice of the size of this region ensured that the region included approximately two domain wall widths in the x direction, while the average distance between defects was used in the y direction. Due to the symmetry, calculations only had to be carried out over half of that region. This region was then discretized into a 60×240 square mesh. Thus, the lattice constant was 0.25 nm.

II. TYPES OF DEFECTS

In Ref. 3 the coercivity of magneto-optic media was studied using a one-dimensional energy well model. In that model it was assumed that magnetic parameters such as anisotropy and exchange are locally decreased within the defects. On the other hand, in Ref. 4 we implemented a one-dimensional case where the material parameters are assumed to be larger within the defects compared to that of the surrounding media. The implementation in Ref. 4 was based on the observation that for epitaxial garnet crystals with negative magnetostriction, localized compressive stresses resulted in an increase in the uniaxial anisotropy. The result of these observations is reported in Ref. 5. While the present study is not carried out for garnet materials, it is noted that at present the actual sources of coercivity in the media studied is not completely understood, although our models are able to predict the coercivity observed in practice. In using this model, it is noted that in the case of the energy well the domain wall is centered on the depression, since this corresponds to the lowest-energy position. The application of a magnetic field pulls the wall away from this position until a Barkhausen jump occurs when the wall is freed from the well. In the case of the energy barrier, on the other hand, the domain wall is pinned at a location in front of the barrier, and this repulsive action is gradually overcome as the wall climbs toward the barrier with increasing magnetic field. At the critical field the wall is able to push past the defects. Coercivity was determined by tracking both the 90° and 30° loci on the domain wall. Calculations were continued until the 30° locus of the domain wall went past the pinning points.

In the following calculations, the magnetic parameters used were: an anisotropy constant of 3.2×10^{-4} J/m^3, an exchange constant of 3.6×10^{-12} J/m, and a saturation magnetization of 4.2×10^{4} A/m. Experimental evidence suggests, that for the material studied, the average defect size is 3 nm and the average distance between defects is 15 nm. Using this data we computed the coercivity as a function of the magnetic parameters within the defect. The magnetic properties of the defects will henceforth be expressed as a percentage relative to the nominal values above. Figure 1 shows this variation for the energy well model, while Fig. 2 shows this variation for the energy barrier model. It should be noted that only one material parameter is varied at a time in the above simulations. Thus, the exchange constant is kept at its nominal value when the anisotropy is varied, and vice versa. A comparison between Figs. 1 and 2 shows that for the same percentage change in the parameters, higher values of coercivity are obtained for the energy barrier model than for the well model. For example, a 20% change in anisotropy and exchange gives a coercivity of about 75 kA/m for the barrier model while for the well model the coercivity is about 22 and 30 kA/m for the same 20% change in anisotropy and exchange, respectively. It is seen in both cases, however, that

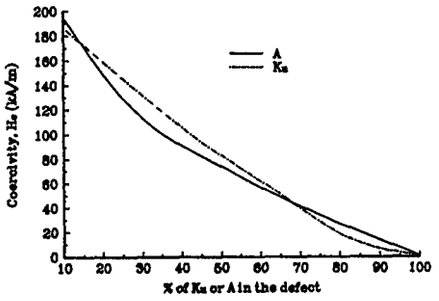

FIG. 1. Variation of coercivity as a function of the percentage of exchange or anisotropy in the defect for energy well model.

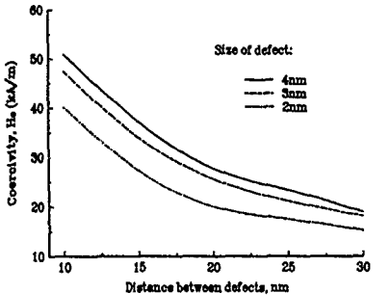

FIG. 3. Coercivity as a function of the distance between defects for anisotropy energy well model.

the relationship between the coercivity and the change in the magnetic parameters is nonlinear.

III. EFFECT OF DEFECT SIZE AND SEPARATION

We just discussed the fact that both the energy well and energy barrier models can be used to model the coercivity. In these calculations the average defect size and the average distance between defects was used. In order to determine the effect of a distribution in defect size and separation, the coercivity was calculated for defect sizes from 2 to 4 nm, and for distances between defects from 10 to 30 nm. It was observed, as shown in Fig. 3, that as the distance between the defects increased, the coercivity decreased nonlinearly. Figure 4 gives a plot of coercivity as function of defect sizes, for values of defect sizes less than the domain-wall thickness. A nonlinear relationship is observed, where the coercivity increases with increasing defect size. This observation agrees with the one-dimensional model calculations where the coercivity was found to increase with increase in the size of the defect and peaked when the size was of the same order of magnitude as the domain-wall thickness. This observation also agrees with the results of Ref. 6, where in their two-dimensional simulation of nucleation coercivity they observed a similar trend. The results of Figs. 3 and 4 were obtained using the anisotropy energy well model, however, the value of the anisotropy was kept at abitrary values of 50% and 75%, respectively. A similar trend was observed when the energy well model was replaced by the barrier model. We noticed, however, that unlike our models which are able to calculate the observed coercivity, the barrier-type model of Ref. 6 calculated a much lower coercivity than that which was observed. Since this model is able to account for the bowing of the domain wall, a consequence of this is to make the wall more rigid when the defects are closer together than when they are further apart, thus resulting in a stronger field being needed to initiate the bowing of the domain wall. It is also expected that the two-dimensional model would exhibit the same trend as the one-dimensional model[4] where the coercivity attains a maximum when the defect size is on the same order of magnitude as the domain-wall thickness.

The foregoing discussion assumed that the defects are all identical and distributed in a regular array. However, in practice, the defects are randomly distributed throughout the medium, thus a domain wall in any position will be pinned by a distribution of defects. Equally important is the fact that the sizes and therefore the pinning strength of these defects is not the same. Since the expected value of a function of a random variable is equal to the function of the expected value of the random variable only if the function is linear, and since our results show that the relationship between the coercivity and both the defect sizes and defect separation is nonlinear, it is necessary to correct the coercivity computed using the average values for the distribution in defect size and separation.

For a distribution of identical defects the calculated coercivity is found to exhibit approximately the following relationship:

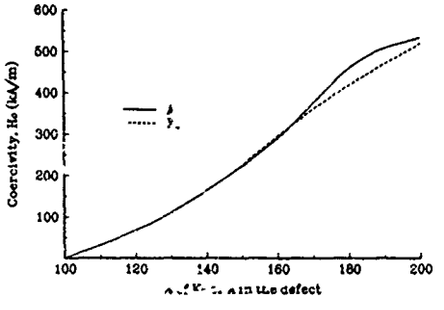

FIG. 2. Variation of coercivity as a function of the percentage of exchange or anisotropy in the defect for energy barrier model.

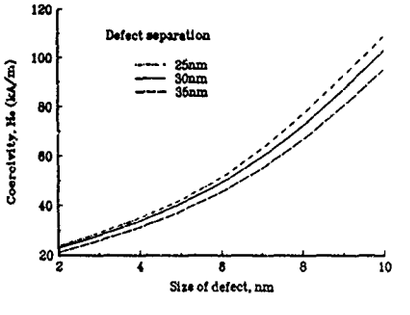

FIG. 4. Coercivity as a function of defect size for anisotropy energy well model.

$$\langle H_c \rangle \propto d^2, \tag{1}$$

where d is the average defect size. In order to assess the effect of a distribution in the defect size, a knowledge of the form of this distribution must be available or assumed. Thus, if we assume it is a normal distribution, the probability density function is given by

$$f(d)=\frac{1}{\sqrt{2\pi}\sigma_d}\ \exp\left(-\frac{(d-\langle d\rangle)^2}{2\sigma_d^2}\right), \tag{2}$$

where $\langle d \rangle$ is the average defect size and σ_d is the standard deviation in the size of the defect. Thus for this distribution function, we have

$$\langle d^2 \rangle = \langle d \rangle^2 \left(1+\frac{\sigma_d^2}{\langle d \rangle^2}\right), \tag{3}$$

and the expected value of the coercivity is given by

$$\langle H_c \rangle = H_c(\langle d \rangle)\ \frac{\langle d^2 \rangle}{\langle d \rangle^2}\,. \tag{4}$$

If we assume five different defect sizes of 2, 4, 6, 8, and 10 nm, and uniformly distributed, then we will expect an increase in the coercivity of almost 30%.

In a similar way, it is seen that the coercivity varies approximately as the square of the reciprocal of the distance between defects. Thus the coercivity calculated using the average distance between defects must be corrected in the same way that the defect size was corrected. Thus, following Eq. (3) and (4), we have

$$\langle \lambda^2 \rangle = \langle \lambda \rangle^2 \left(1+\frac{\sigma_\lambda^{\,2}}{\langle \lambda \rangle^2}\right) \tag{5}$$

and

$$\langle H_c \rangle = H_c(\langle \lambda \rangle)\ \frac{\langle \lambda^2 \rangle}{\langle \lambda \rangle^2}\,, \tag{6}$$

where $\langle \lambda \rangle$ is the average distance between defects. If we assume five different defect separations of 10, 15, 20, 25, and 30 nm of uniform defect sizes, then the coercivity calculated using the average distance between the defects must be corrected by multiplying by a factor of approximately 1.156.

IV. TEMPERATURE DEPENDENCE OF COERCIVITY

We have used our models to simulate the temperature dependence of coercivity of TbFeCo material (see Fig. 5) Using the data given in Ref. 7, where the magnetic parameters were measured at the temperatures specified, we computed the coercivity of the medium using both the well and barrier models. In this simulation, the average defect size and the average distance between defect were used. However, the percentage of anisotropy or exchange for the well model was set at 10%, while for the energy barrier model these were set to 150%. While both models are able to predict the general trend in the variation of coercivity with temperature, it is seen that a much larger decrease in the magnetic parameters is required in the well to achieve the same coercivity for a given increase of these parameters.

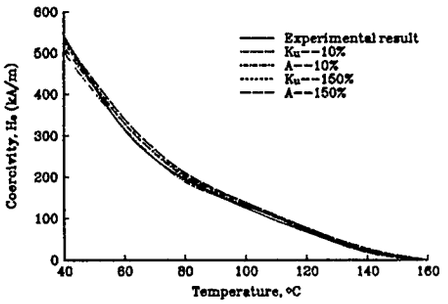

FIG. 5. Coercivity as a function of temperature for experimental and computed values.

V. CONCLUSIONS

Two models of wall motion coercivity have been implemented by assuming a change from the surrounding medium of either the anisotropy or exchange, using a two-dimensional numerical micromagnetic model. It has been shown that both the barrier and well models for either the anisotropy or exchange can predict the values of the coercive field obtained in practice, as demonstrated using experimental results given at various temperatures. It has also been shown that due to the nonlinear variation of coercivity with defect sizes and their separation a correction is required in the calculated value of the coercivity to account for the different defect sizes and their random distribution.

Reversal processes in Tb/Fe multilayer films are reported. The form of the hysteresis is explained as a function of the number of bilayers in terms of a two-coercivity model. Remanence measurements have been made which provide an insight into the distribution of the energy barriers for the two coercive processes associated with nucleation or domain-wall motion. The time dependence of magnetization has also been measured and this has been used to evaluate fluctuation fields and activation volumes for the series of films. The variation of the fluctuation field with applied field indicates that the two-coercivity model proposed is consistent with the time dependence. An increase is seen in the average activation volume with the number of bilayers.

I. INTRODUCTION

Tb/Fe multilayers are potential magneto-optic recording media. These films possess large perpendicular anisotropy, the main requirement for such media. Also of importance is the signal-to-noise ratio (SNR) which may be affected by the uniformity of written domains and their stability over time. A material is required in which domain-wall creep is a minimum to get the maximum lifetime from a medium.

Reversal processes in magneto-optic thin films may be descibed by a two-coercivity model in which there are two fields H_N and H_{DW}, representing the nucleation and domain-wall critical fields, respectively.[1] If we have a film in which H_N is greater than H_{DW} then the corresponding hysteresis loop will be square since as soon as reverse domains are nucleated they will immediately overcome the domain-wall critical fields. If, however $H_{DW}>H_N$ then reverse domains will be formed and be subject to pinning of their walls causing a rounding of the hysteresis loop. In a separate study on Pt/Co multilayers[2] we have found that this leads to the formation of smaller domains, which would be a potential advantage for magneto-optic recording.

We have examined magnetization reversal via a study of the two primary remanence curves. The isothermal remanence magnetisation (IRM) curve is a measurement of the remanence aquired as a function of the magnetizing field applied to an originally demagnetized sample and thus determines the distribution of H_{DW} since it begins from a state in which domains are present in both directions. The demagnetizing remanence (DCD) curve is a measurement of the remanence after the application of a demagnetizing field to a previously saturated sample and thus determines the distribution of either process depending on the mean activation energy.

II. EXPERIMENT

The multilayers were fabricated by sputtering. The layer thicknesses were 14.3 Å Tb/~8.5 Å Fe. Multilayers were produced with varying numbers of bilayers from 6 to 32 and were capped with a 100 Å aluminum protection layer. Magnetic measurements were made at room temperature using an automated AGFM. Hysteresis loops, IRM, and DCD curves were measured perpendicular to the film plane. The hysteresis loops were measured with a sweep time of about 2 min and switching of the magnetization from saturation to zero took much less than 1 s. During the DCD measurements the applied field was removed from the sample in a fraction of a second keeping time-dependent effects to a minimum.

The time dependence was measured by first saturating the film in one direction then applying a reverse field and monitoring the magnetization over a 12 min period. This process was continued using increasingly larger reverse fields until the nucleation field, measured from the hysteresis loop, was approached at which point reversal of the magnetization took place in less than 1 s.

Analysis of the time-dependence data was made using the method proposed by Street, McCormick, and Folks,[3] in which the Arrhenius relation is differentiated to give

$$\frac{dH}{d\ \ln[\dot{M}(H)/\dot{M}(0)]} = -\frac{kT}{vM_s} = -H_f, \tag{1}$$

where v is the activation volume, $\dot{M}(H)$ the change of magnetization with time, and H_f the fluctuation field. If we consider two time-dependence measurements of M, separated by an interval of applied field ΔH, then Eq. (1) may be rewritten as

$$H_f = \left.\frac{\Delta H}{\ln \dot{M}_1 - \ln \dot{M}_2}\right|_M, \tag{2}$$

where $\dot{M}_1$ and $\dot{M}_2$ are the slopes of the time-dependent magnetization at some constant value of magnetization M. It can be seen from Eq. (2) that if there is a large change in the time-dependent behavior induced by the change in applied field ΔH, then the fluctuation field will decrease, conversely small changes in the time dependence with increasing H will be reflected in an increase in the fluctuation field. Measurements were made with ΔH in the range 10–15 Oe and the slopes of the curves were evaluated at $M=0$, i.e., the coercive point, so as to negate the effects of demagnetizing fields.

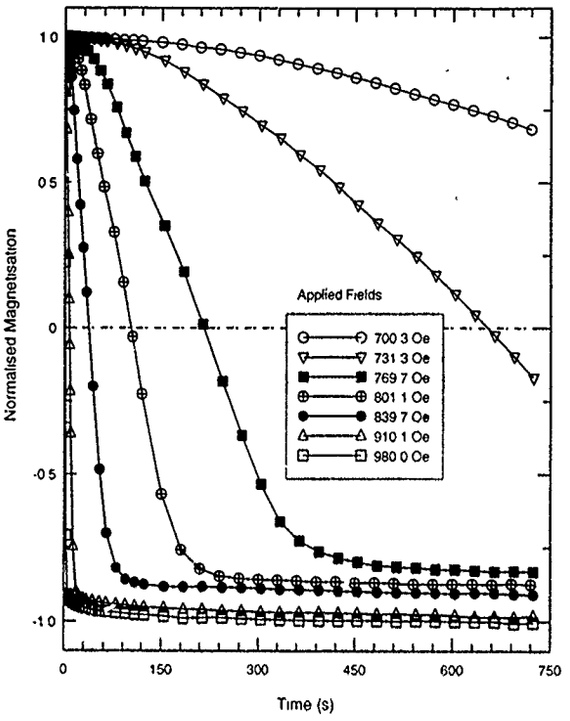

FIG. 1. Time-dependence data from the 32 bi .n obtained at various applied fields.

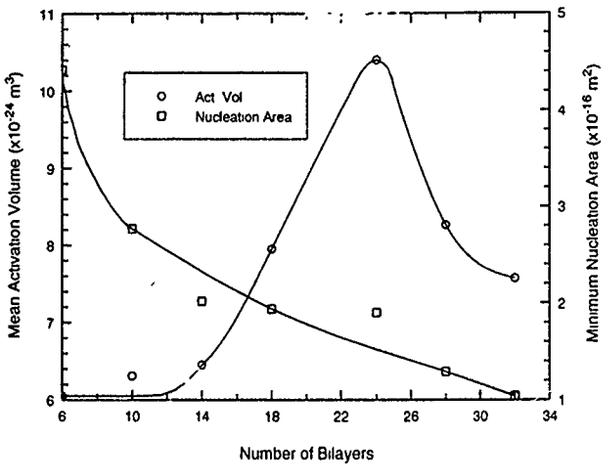

FIG. 2. Activation volumes and nucleation areas for the series of films.

III. RESULTS

The coercivity is found to decrease as the number of bilayers increases. Conversely, the magnetization increases with the number of bilayers although it is fairly constant for 14 or more bilayers. The hysteresis loops for these films are square for the samples with less than 20 bilayers. As the number of bilayers increases above 20 the hysteresis loop becomes rounded and the switching field distribution increases. This behavior is attributed to the existance of the two critical fields discussed above.

Time-dependence measurements were made at fields below the coercivity values obtained from the hysteresis loops. As the hysteresis loop coercivity was approached the time dependence became too rapid to measure accurately. Over the measuring period a wide range of applied fields below the hysteresis loop coercivity was found to produce reversal of the magnetisation. Figure 1 shows some of the data collected from the 32 bilayer film; there is an applied field range of 250 Oe in which the magnetization reaches zero. The time dependence is approximately linear with time around $M=0$, which is where the slopes used to calculate the fluctuation fields were evaluated. Also, at this point the overall demagnetizing field is zero, the thin nature of these films means that at any other value of M the demagnetizing field is large and changing as M changes with time.

Upon evaluation of the fluctuation fields two trends become apparant. For films with less than 20 bilayers the fluctuation field decreases with increasing applied field. This implies that as the field is increased and reverse domains are nucleated, they quickly expand, causing an increase in the slope of the time-dependence curve. This arises because the nucleation field is greater than the domain-wall critical field. Where we have films with more than 20 bilayers the fluctuation field increases with applied field. This kind of behavior may be associated with pinning of the movement of the nucleated domain walls, slowing down the time-dependent change of M which is due to thermal activation of the domain walls allowing them to pass the pinning sites.

From Eq. (1) the activation volume is inversely proportional to the fluctuation field so the activation volume increases with applied field for films with less than 20 bilayers and decreases with applied field for thicker films. The average values of the activation volumes show an increase as the films become thicker. This data is shown in Fig. 2 along with the calculated values of the minimum domain nucleation area for each multilayer. We see that the minimum area decreases with increasing number of bilayers. If we assume that these volumes and areas may be related to the physical sizes of domains in these films then we can say that the average diameter of a circular domain in a film with 6 bilayers will be 24 nm and in a film with 32 bilayers it will be 12 nm.

The differentials of the IRM curves show the irreversible susceptibility $\chi^{i}_{\mathrm{irr}}(H)$ which is the energy barrier distribution of the pinning sites while the DCD differentials $\chi^{d}_{\mathrm{irr}}(H)$ show where nucleation from the saturated state occurs. These curves represent the energy barrier distribution and show that for films with less than 20 bilayers the IRM differential curve falls almost entirely to the left-hand side of the DCD differential, i.e., the domain-wall energy barrier distribution falls at field values less than the nucleation field distibution. Hence, once domains nucleate they can sweep unimpeded through the sample resulting in a very square hysteresis loop. Figure 3 shows the two differentials for a sample with 14 bilayers. Shown in Fig. 4 are the same two curves but for a sample with 28 bilayers from which it is clear that not all of the barriers to domain-wall motion have been passed by the time reverse domains begin to appear; this results in pinning of the domain walls and a reduction in hysteresis loop squareness. This also leads to the production of smaller domains as we reported previously.[1]

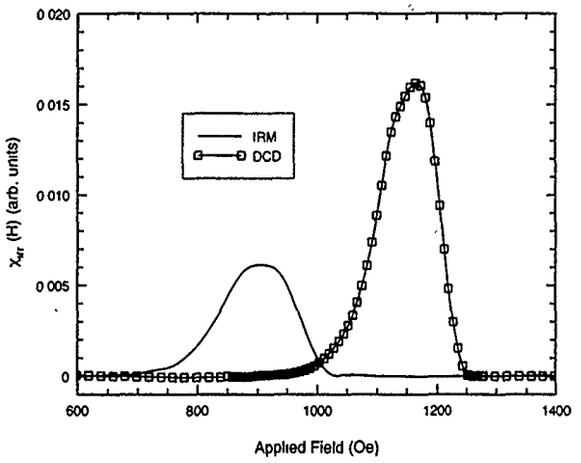

FIG. 3. IRM and DCD differentials for the 14 bilayer sample.

The behavior we have observed here is similar to that seen in MnBi films by Dekker and Huijer.[4] As the film thickness decreases the nucleation field increases. This may be explained by assuming that domain walls are always present in the film, even in the saturated state. These are known as vestigial domains. As the film thickness increases the magnetostatic pressure on the domain walls increases. The nucleation field may now be defined as the field at which the domain walls become unstable and run out to form observable domains. Calculations by Cape and Lehman[5] suggest that the abrupt reversal of magnetization seen here could be attributed to cylindrical vestigial domains as opposed to vestigial stripe domains. The calculations of Dekker and Huijer predict that below a certain film thickness the nucleation field will exceed the coercive field.

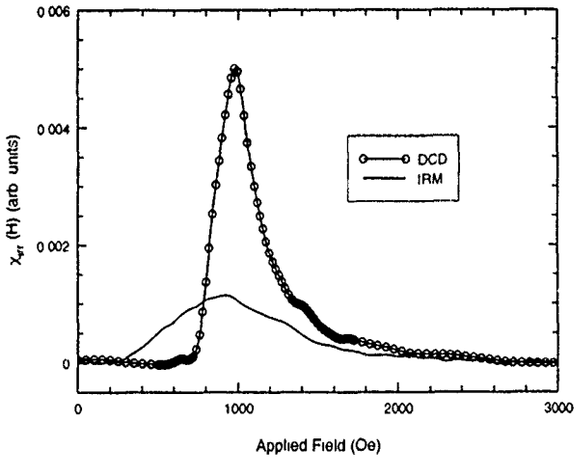

FIG. 4. IRM and DCD differentials for the 28 bilayer sample.

IV. DISCUSSION AND CONCLUSIONS

In this article we have shown that the reversal process in Tb/Fe multilayers is controlled by the relative values of the domain-wall and nucleation critical fields. We have also shown that remanence curves may be used to examine the distribution of these fields. The decrease of the nucleation critical field with increasing number of bilayers could be a consequence of the minimum area which nucleates a reverse domain also decreasing with increased film thickness thus increasing the number of possible nucleation sites. We have seen that the minimum area which may nucleate a reverse domain is about 1/3 the size, at 32 bilayers, of the area at 10 bilayers. However, those domains which do nucleate at lower reverse fields do not have sufficient energy, during the time scale of the measurements, to pass the pinning sites.

For magneto-optic recording applications it should be advantageous to have stable domains (i.e., with pinned walls) which increase the SNR performance of the films. Domains nucleated in a film with a highly square hysteresis loop may run out over a large area due to the lack of impediments to wall motion. Also, the potential storage density should be increased in films with more than 20 bilayers since we have shown that reverse domains may be smaller than in thinner films. Thus, despite the reduced coercivity of the thicker films they are the more suitable for long-term data storage.

Domain size changes due to thermal relaxation after high laser power irradiation on amorphous TbFeCo films were studied. In order to achieve mark edge recording for high-density magneto-optical memory, accurate domain size recording is required even after a million erase/write cycles. Highly accelerated erase/write test was performed on typical recording media, rare-earth (RE) -rich and transition-metal (TM) -rich disks. The elongation of the domain size written on the TM-rich film after erase/write cycles was clearly evident; however, the change in the domain size of RE-rich films was small. The small domain size change of the RE-rich disk can be explained in terms of the rapid increase in the coercive force with decreasing temperature and the smaller domain-wall driving force at recording temperature than those for the TM-rich disk, even though both have the same level of structural relaxation.

I. INTRODUCTION

Mark edge recording can achieve significantly higher magneto-optical (MO) recording densities than the conventional mark position recording.[1] In this method, precise control of the recording mark shape on a magneto-optical disk must be achieved even after a million cycles of data writing and erasing. However, it is expected that the domain size expands with increasing erase/write cycles, because erase/write cycles cause reduction of the perpendicular anisotropy energy of the amorphous TbFeCo due to structural relaxation.[2] In order to successfully achieve mark edge recording, a material with minimal change in mark edge and width must be explored.

In this article two typical MO media, such as rare-earth (RE) -rich and transition-metal (TM) -rich TbFeCo disks, were studied in terms of erase/write cyclability for mark edge recording.

II. EXPERIMENTAL PROCEDURE AND RESULTS

RE- and TM-rich disk having the same thermal structure (identical layer thickness and structure) were prepared by magnetron sputtering. The construction of the disks is included in Fig. 1(a). Details of the erase/write cycle test are summarized in Table I. To carry out the erase/write cycles in a shorter amount of time, a higher laser power (11.0 mW) and reduced number of cycles (max 10^4) than normal (6.5 mW, 10^6 cycles) were used.

The temperature dependence of saturation magnetization M_s and coercive force H_c of RE-rich and TM-rich films is shown in Figs. 1(a) and 1(b). These data show typical magnetic properties of the RE- and TM-rich film. The Curie temperature T_c of the TM-rich disk is higher than that of the RE-rich disk. It is known that if RE- and TM-rich disks have the same T_c and thermal structure, the domain size of the RE-rich disk is smaller than that of the TM-rich disk under the same writing condition.[3] From this result, it is expected that domains of the same size can be written on both TM- and RE-rich disks provided that T_c is higher for the TM-rich film. RE- and TM-rich disks shown in Fig. 1 were found to provide the same domain size under the same writing condition.

The most dense recording pattern before and after erase/write cycles must be investigated because these patterns are most severe for mark edge recording. Here, the writing domain length and the gap length are both 0.75 μm. After 2000 erase/write cycles by using a highly accelerated erase power of 11.0 mW, the carrier-to-noise ratio (C/N) of the RE-rich disk did not decrease; however, that of the TM-rich disk decreased rapidly, i.e., the C/N value reduces to 43 dB from an initial value of 53 dB.

In order to investigate this difference in the change of C/N, the recorded domain size of both disks before and after

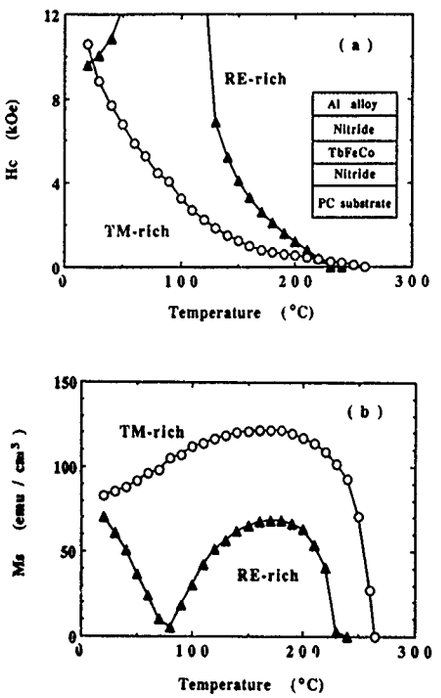

FIG. 1. Temperature dependence of (a) H_c and (b) M_s of RE- and TM-rich films. Details of the construction of the disks is included in (a).

TABLE I. Detail of the erase/write cycle test.

Accelerated erase power	11.0 mW
(nominal erase power)	(6.5 mW)
Applied field	600 Oe
Linear velocity of the disk	9.4 m/s
Laser wavelength	780 nm
Lens numerical aperture	0.55
Reading power	1.5 mW

2000 erase/write cycles was observed by polarized microscopy. To facilitate the observation of the change in domain size after erase/write cycles, larger domain length (2.8 μm) and gap (2.1 μm) were prepared. The results are shown in Fig. 2. The domain position of both disks does not change before and after erase/write cycles. The domain size of the TM-rich film is elongated compared with that of the RE-rich film after 2000 erase/write cycles. It is found that the degradation of C/N in the TM-rich disk can be explained by waveform interference due to the elongated domain.

The domain length after erase/write cycles was evaluated by the half-width of the wave form of the readout signal (Fig. 3). Here, the interval between the most dense recording marks was long enough to prevent from wave-form interference. The domain length of the TM-rich film increases with increasing erase/write cycles. On the other hand, the domain length of the RE-rich film does not so change.

When a domain size (length and width) changes along with erase/write cycles, the center of the domain does not move so that influence of the domain size change is small in the case of mark position recording. However, in case of mark edge recording, domain size change directly causes edge shift in the readout wave form. Therefore, mark edge recording is more severe than mark position recording in terms of erase/write cycles.

As shown in Fig. 2(a) with the TM-rich disk, the domain edge at the central part of the track is particularly elongated, because the temperature of the film at the central part of the laser spot tends to be high. The ratio of the power change to write a stripe domain of 0.4 μm width is shown in Fig. 4. This figure shows writing sensitivity change at the central part of the track. It was found that the ratio $\Delta P_w/P_w$ of the writing power change ΔP_w of the RE-rich disk is smaller than that of the TM-rich disk. For example, after 2000 erase/write cycles, $\Delta P_w/P_w$ of RE- and TM-rich disks decreased by 12% and 37%, respectively.

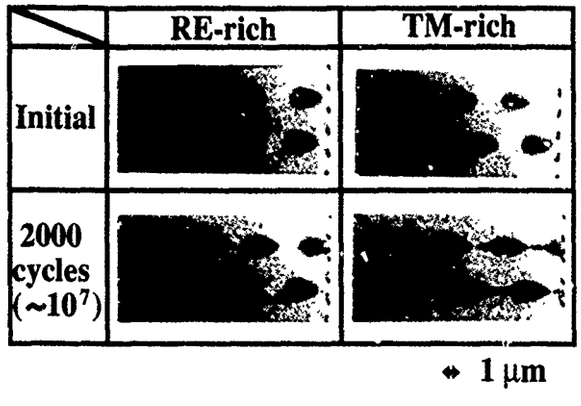

FIG. 2. Recorded domain shape for (a) RE- and (b) TM-rich disks before and after 2000 erase/write cycles.

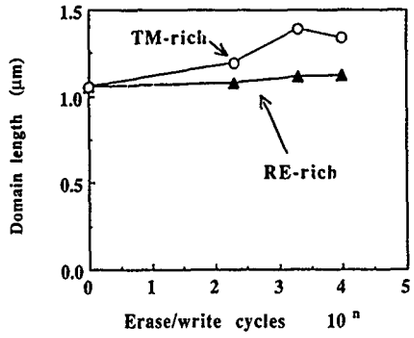

FIG. 3. Dependence of the domain length of RE- and TM-rich disks as a function of the number of erase/write cycles.

Compared with TM-rich disks, the domain length and width of the RE-rich disk is very stable even after erase/write cycles. Therefore, in terms of write/erase cyclability, the RE-rich TbFeCo recording material is suitable for mark edge recording. These results are consistent with the earlier measurements confirming the ability of RE-rich media to withstand 10^6 erase/write cycles.[4] 2 Gbit capacity in a 5.25-in.-diam disk was achieved with mark edge recording MO by using the RE-rich film.[4]

III. DISCUSSION

The stability of domain size was expressed by Huth,[5]

$$H_c = H_a + H_d - \frac{\sigma_w}{2rM_s} - \frac{1}{2M_s}\frac{\partial \sigma_w}{\partial r}, \tag{1}$$

where H_c, H_a, and H_d are the coercive force, applied field, and demagnetization field, respectively. M_s is the saturation magnetization, σ_w is the domain-wall energy, r is the domain radius. The entire right-hand side of Eq. (1) corresponds to the wall driving force and is called H_{total}. Domain size is determined at the point where H_c balances H_{total}.

Degradation of H_c and σ_w with erase cycles has been thought to originate from structural relaxation in amorphous

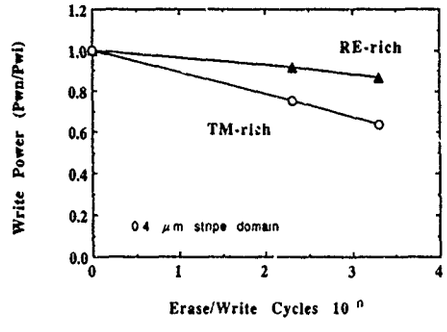

FIG. 4. Dependence of the normalized writing power vs erase/write cycles.

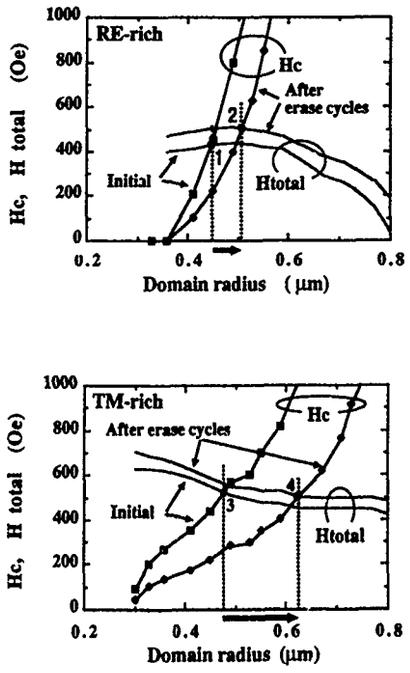

FIG. 5. Functional dependence of H_c and H_{total} on the domain radius calculated on the basis of Eq. (1). Initial and final (after erase/write cycles) curves are shown. Here, film temperature increases with decreasing radius.

TbFeCo.[2,6] On the other hand, M_s is independent of the structural relaxation.[6] Based on the initial dependence of H_c and H_{total} of the film on the domain radius,[3] a semiquantative discussion of the force balance of H_c and H_{total} after erase/write cycles can be constructed (Fig. 5). Here H_c and σ_w were assumed to degrade by 50% and 30%, respectively, because σ_w is proportional to square root of H_c. Moreover, it was assumed that RE- and TM-rich films have the same level of structural relaxation. The intersection points, 1 (RE-rich film) and 3 (TM-rich film), correspond to the initial domain size. After erase/write cycles, H_c decreases and H_{total} increases and then the intersection points, 1 in RE-rich and 3 in TM-rich films, move to 2 and 4, respectively. The elongated domain length is shown by the hatched area. The area of RE-rich film is much smaller than that of the TM-rich one. This is due to the rapid increase in H_c with decreasing temperature and the smaller domain-wall driving force at the recording temperature for the TM-rich film. Thus, better cyclability of the RE-rich disk can be explained.

IV. CONCLUSIONS

Domain size change of typical two different TbFeCo media, RE and TM rich, before and after erase/write cycles was studied for mark edge recording. The domain length and width of the TM-rich disk were found to be elongated with increasing erase/write cycles, while that of the RE-rich film does not change that much. The small domain size change of the RE-rich disk can be explained in terms of the rapid increase in the coercive force with decreasing temperature and smaller domain-wall driving force at recording temperature than those for the TM-rich film, even though both have the same level of structural relaxation. 2 Gbit capacity on a 5.25-in.-diam disk was achieved with mark edge MO recording by using the RE-rich film. A RE-rich film is the key to achieving much higher-density MO than with a 2 Gbit/5.25 in. disk with mark edge recording in the future as well.

Recording characteristics of Kr-sputtered Tb/FeCo multilayer magneto-optical disks

Hiro Karube, Kunihiko Matsumura, Masafumi Nakada, and Osamu Okada
Functional Devices Research Laboratories, NEC Corp., Kawasaki 216 Japan

Recording magnetic-field sensitivity and readout stability for Tb/FeCo multilayer magneto-optical (MO) disks, made by sputtering with Kr and Ar gas, were studied. The 100 Oe recording magnetic-field sensitivity for Kr disks was obtained. The readout stability for Kr disk is superior to that for Ar disk. It seems that high readout stability for Kr disks is caused by the large wall coercivity and the large ratio of wall coercivity to nucleation coercivity.

High recording magnetic-field sensitivity is necessary for a magnetic-field modulation method. There are many ways improving the recording magnetic-field sensitivity, such as adding a capping layer (a capping layer disk),[1] adding a GdFeCo layer (a five-layer disk),[2] and varying a disk preparation condition.[3–5] However, a disk structure for the capping layer disk or the five-layer disk is more complex than conventional disks. Readout stability is important for a disk reliability. The readout stability is concerned with the high recording magnetic-field sensitivity. The readout stability is inferior when the SiN underlayer etching is carried out in order to improve the magnetic-field sensitivity.[3] It is important to find an appropriate method with both high magnetic-field sensitivity and high readout stability.

It is considered that wall coercivity and nucleation coercivity affect the recording magnetic-field sensitivity and readout stability. These characteristics are influenced by the microstructure of a magnetic film.[6] The authors reported that perpendicular magnetic anisotropy of Tb/FeCo multilayers (Kr film), prepared by cosputtering with Kr gas, was larger than that of Tb/FeCo multilayers, prepared by cosputtering with Ar gas (Ar film)[7] and that the magnetic anisotropy improvement for Kr film originates from a low-anisotropy dispersion.[8] It is shown that the microstructure for Kr film is different from that for Ar film. In this article recording characteristics of Kr disks are studied from the recording magnetic-field sensitivity and readout stability viewpoint.

Magneto-optical (MO) disks utilized a four-layer structure that comprised a first SiN layer (1000 Å thick), a Tb/FeCo magnetic multilayer (200 Å thick), a second SiN layer (400 Å thick), and an Al layer (400 Å thick). A polycarbonate (PC) substrate (1.6 μm track pitch) was used. SiN layers were prepared by reactive rf sputtering with $Ar+N_2$ gas. The Al layer was prepared by vapor deposition. Tb/FeCo multilayers were prepared by dc magnetron cosputtering alternately from Tb and $Fe_{90}Co_{10}$ alloy targets. Two series of disks with different sputtering gases were prepared. One had a Tb/FeCo multilayer prepared by dc cosputtering with Kr gas (Kr disks). The others had a Tb/FeCo multilayer prepared by dc cosputtering with Ar gas (Ar disks). Ar disks were prepared in order to compare with Kr disks. The layer thickness of Tb was 6.4 Å and that of FeCo was varied from 8.3 to 10 Å. The substrate table was rotated at 20 rpm and the sputtering rate was selected to keep the same value at Ar and Kr sputtering. During deposition, the sputtering gas pressure was kept constant at 8×10^{-2} Pa. Recording characteristics were measured with the read/write tester (λ=830 nm, numerical aperture=0.50) at 3.7 MHz (duty 50%) recording frequency and 11.1 m/s linear velocity. Wall coercivity and nucleation coercivity (coercive force) were determined from the Kerr hysteresis loop for the as-deposited film onto PC substrates at room temperature.[3]

Figure 1 shows the recording magnetic-field dependence of carrier and noise level on the Kr disks. Both "land" and "groove" were erased to the same direction, before the recording had been carried out. The recording power, minimizing the ratio of second-harmonics level to carrier level, was ranged from 8.5 to 9.0 mW. The erasing magnetic field was −400 Oe and the readout power was 1.0 mW. Over 400 and over 100 Oe recording magnetic field were required for noise saturation in the Kr disk with 8.3-Å-layer FeCo thick and in Kr disk with 9.6-Å-thick FeCo layer, respectively. That is, the FeCo layer thickness affected the recording magnetic-field saturated noise level.

Figure 2 shows the recording magnetic-field dependence of carrier and noise level on the Ar disks. The recording power, minimizing the ratio of the second-harmonics level to carrier level, was ranged from 7.5 to 8.0 mW. The other

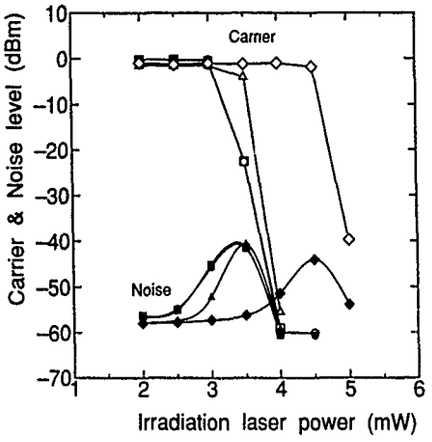

FIG. 4. Irradiation laser power dependence of carrier and noise level on Ar and Kr disks. ○●: dFeCo=9.0 Å; △▲: dFeCo=9.3 Å; □■: dFeCo=10.0 Å; ◇◆: Kr disk, dFeCo=9.6 Å. Read power=1.0 mW, resolution bandwidth=30 kHz.

measurement condition was the same as the Kr-disk measurement. Recording magnetic-field values, required for noise saturation, were similar for all Ar disks.

We defined recording magnetic-field sensitivity as a minimum magnetic-field saturating both carrier and noise level. Figure 3 shows the FeCo layer thickness dependence of the recording magnetic-field sensitivity for Kr and Ar disks. High recording magnetic-field sensitivity of 100 Oe was obtained at the 9.6 Å FeCo layer thickness for Kr disks. The recording magnetic-field sensitivities for the Ar disks were higher than those for the Kr disks. However, the highest recording magnetic-field sensitivity for the Kr disk was 100 Oe and was the same as that for the Ar disks. The Ar disks had a large margin for high recording magnetic-field sensitivity as compared with Kr disks. It was found that sputtering gas preparation for the magnetic layer affects the magnetic-field sensitivity.

Satoh *et al.* reported that the recording magnetic-field sensitivity had a tradeoff with relevance to readout stability.[3] Readout stability for Ar and Kr-disks was measured. Figure 4

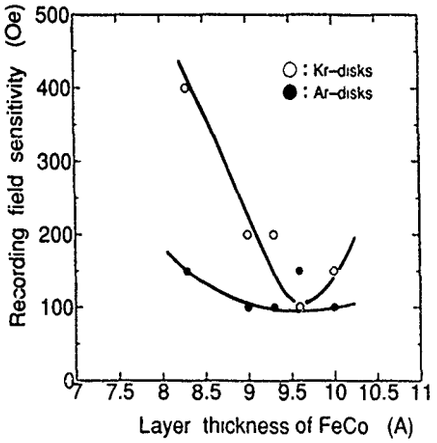

FIG. 3. FeCo layer thickness dependence of recording magnetic-field sensitivity.

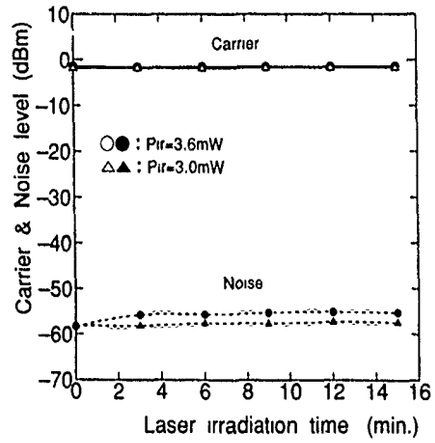

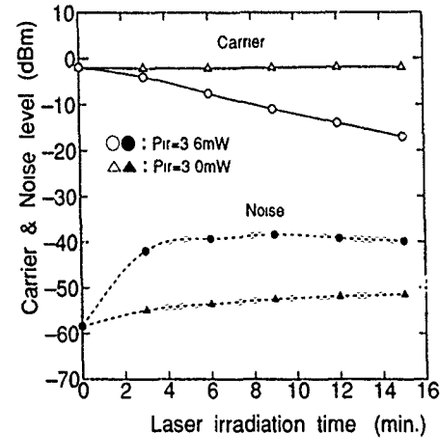

FIG. 5. Irradiation time dependence of carrier and noise level: (a) Kr disk, dFeCo=9.6 Å; (b) Ar disk, dFeCo=9.3 Å.

TABLE I. Wall coercivity for Kr and Ar disks at room temperature.

FeCo layer thickness (Å)	8.3	9.0	9.3	9.6	10.0
Kr disk (kOe)	>20	9.0	9.6	9.6	5.4
Ar disk (kOe)	6.9	3.0	10.8	6.0	4.8

TABLE II. The ratio of wall coercivity to nucleation coercivity.

FeCo layer thickness (Å)	8.3	9.0	9.3	9.6	10.0
Kr disk	···	0.67	0.70	0.63	0.61
Ar disk	0.39	0.57	0.53	0.65	0.54

shows the irradiation laser power dependence of carrier and noise level on Ar disks having 100 Oe recording magnetic-field sensitivity, whose FeCo layer thicknesses were 9.0 Å (disk no. 1), 9.3 Å (disk no. 2), and 10.0 Å (disk no. 3). Furthermore, Fig. 4 shows the irradiation laser power dependence of carrier and noise level for the Kr disk with 9.6 Å FeCo layer (disk no. 4). The recording was carried out at 400 Oe. The recording laser power was 7.5 mW. Then, the laser beam was irradiated with the 400 Oe magnetic-field applied in the erasing direction for 3 min. The readout laser power was 1.0 mW. Carrier levels did not change for less than 3.0 mW irradiation laser power. The carrier levels drastically decreased over 3.0 mW irradiation for disks no. 1 and no. 3. Over 4.0 mW power was required for complete erasure. On the other hand, carrier level for disk no. 2 did not change at 3.0 mW irradiation power. Increase in noise level for disk no. 2 was smaller than that for the other. Therefore, disk no. 2 had the highest readout stability in these three Ar disks. A comparison of readout stability between Kr and Ar disks was carried out. The recording magnetic-field sensitivity for disk no. 4 had the highest recording magnetic-field sensitivity and its value was 100 Oe. Recording laser power was 9.0 mW. The other measurement conditions were the same as for the above measurement. The Carrier level was constant up to 4.5 mW irradiation power. The readout stability for disk no. 4 (Kr disk) was more stable than that for disk no. 2 (Ar disk).

Figures 5(a) and 5(b) show the irradiation time dependence of carrier and noise levels for disk no. 4 (Kr disk) and disk no. 2 (Ar disk), respectively. The laser beam was irradiated with the 400 Oe magnetic field applied in the erasing direction. Irradiation laser power was 3.0 and 3.6 mW. The readout laser power was 1.0 mW. The noise level increased greatly through increasing the irradiation power and the irradiation time. Increase in noise level occurred at an initial irradiation time. Carrier level for disk no. 2 was decreased with increasing the irradiation stage, only when the irradiation power was 3.6 mW. Decrease in carrier level for disk no. 4 was not observed. Increase in noise level for Kr disk at the 3.6 mW irradiation power was smaller than that for disk no. 2 at the 3.0 mW irradiation power. Therefore, readout stability for disk no. 4 (Kr disk) is superior to that for disk no. 2 (Ar disk). Both high recording magnetic-field sensitivity and high-readout stability were obtained by Kr gas sputtering.

It was reported that large wall coercivity H_w was the key factor in achieving stable domains.[3] H_w and nucleation coercivity H_n were examined in order to clarify a relationship among the readout stability, H_w value, and H_n value. Table I shows H_w at room temperature for Kr and Ar disks. Table II shows the ratio of H_w to H_n, H_w/H_n. The authors find that high-readout stability for Kr disk cannot be explained by "only" the H_w value. The H_w value for the Ar disk with 9.3 Å FeCo layer thick (disk no. 2) was the largest in all Ar disks. However, the readout stability for the Ar disk with an 8.3 Å FeCo layer (disk no. 5) was almost the same as that for the Ar disk with a 9.0 Å FeCo layer (disk no. 1) in spite of the large difference of H_w. Furthermore, the H_w value for the Kr disk with 9.6-Å-thick FeCo layer (disk no. 4), whose read stability is superior to that for Ar disk, was smaller than that for disk no. 2.

The H_w/H_n value for disk no. 4 (Kr disks) was larger than for Ar disks (disks no. 1, no. 2, no. 3, and no. 5), except 9.6-Å-thick FeCo layer samples. Moreover, the H_w/H_n value for disk no. 1 was larger than that for disk no. 5. Thus, it seems that high readout stability for Kr disks is caused by the large wall coercivity and the large ratio of wall coercivity to nucleation coercivity.

In conclusion, recording magnetic-field sensitivity for Tb/FeCo multilayer MO disks by sputtering with Kr and Ar gas was studied. It was found that sputtering gas preparation for the magnetic layer affects the magnetic-field sensitivity. The 100 Oe recording magnetic-field sensitivity for Kr disks was obtained. Readout stability for the Kr disk was superior to that for the Ar disk. Both high recording magnetic-field sensitivity and high-readout stability were achieved by Kr gas sputtering. It seems that high-readout stability for Kr disks is caused by the large wall coercivity and the large ratio of wall coercivity to nucleation coercivity.

Double compensation point media for direct overwrite

T. K. Hatwar, D. J. Genova, and R. H. Victora
Imaging Research and Advanced Development, Eastman Kodak Company, Rochester, New York 14650-2017

Two magneto-optic media configurations are discussed that are suitable for direct overwrite by light intensity modulation using only one conventional bias magnet. One configuration consists of two magnetic layers (memory and reference having perpendicular anisotropy) exchange coupled through an intermediate soft magnetic layer. The second media configuration consists of only a memory layer and an intermediate layer. This scheme produced a respectable direct overwrite performance of 48 dB using a 3.5 μm mark size, 30 kHz bandwidth, and 7 m/s disk velocity. The major advantages of this scheme are simpler disk structures relative to a previously proposed quadrilayer scheme, and a wide range for Curie temperatures, thicknesses, and coercivities of the individual layers.

Direct overwrite (DOW) is vital for the new generation magneto-optic (MO) disk drives to achieve shorter access time and higher data rate. In recent years, substantial efforts have been directed to the development of an efficient and practical method for achieving direct overwrite on MO media. Following the limited success of DOW in a single-layer medium, schemes have been investigated based on both magnetic-field modulation and light intensity modulation.[1–7] Schemes based on light intensity modulation of the laser beam utilize multilayer media configurations and eliminate the field switching required in magnetic-field modulation. Some of these schemes have shown great promise, however, a large initializing magnetic field increases the complexity of the drive design and affects the stability of the written marks. The initializing field has been eliminated in recent direct overwrite schemes;[4–7] however, only the quadrilayer scheme proposed by Fukami *et al.* produced a respectable performance.[6] However, it is difficult to produce this scheme in large-scale manufacturing due to extreme constraints imposed on the large number of parameters of each layer. Further, defect density as well as the bit error rate increase tremendously as the number of layers increases in a disk structure. Therefore, a most desirable scheme that is manufacturable should have a simple disk structure, wide power margins, high writing sensitivity, and not require an IM. In this article we report a new type of direct overwrite scheme that eliminates some of the problems mentioned above. The static and dynamic performance, the underlying operational principle, and the future possibilities for this scheme are presented.

One configuration of this scheme is shown in Fig. 1 and consists of two magnetic layers (memory and reference) exchange coupled through an intermediate magnetic layer. The memory and the reference layers have a relatively large perpendicular anisotropy while the intermediate layer is magnetically soft. The memory layer has a Curie temperature T_{cm} that is greater than or approximately equal to the reference layer Curie temperature T_{cr}. The intermediate layer has a higher Curie temperature than either the memory layer or the reference layer. The room-temperature coercivity of the memory layer is higher than the room-temperature coercivity of the reference layer. The combined magnetization of the coupled layers exhibits two compensation points: This requires antiferromagnetic coupling between the memory and reference layers over at least part of the temperature range. The thickness and composition of the reference layer is chosen so that the combined system has a compensation temperature above the ambient temperature but below the write temperature.

Figure 2(a) shows the magnetization of the three layers of the trilayer scheme as a function of temperature, whereas Fig. 2(b) shows the magnetization for the combined system. The square symbol curve in Fig. 2(b) is obtained by considering the antiferromagnetic (AF) coupling between the memory and reference layers mediated though the control layer, whereas the other curve shows the experimental values of the remnant magnetization measured using the vibrating sample magnetometer. The combined magnetization curve has lower and upper combined compensation temperature T_{clc} and T_{cuc}, which are essential for the operation of this DOW scheme. An approximate location of the write temperature T_w is also indicated in Fig. 2(b). As shown below, T_w must exceed the highest temperature at which the coercivity for the domain-wall motion is above the bias field.

When such a medium is irradiated with the low- and high-power laser beam, the magnetization of the memory and reference layers change as shown in Fig. 3. The magnetization of the medium as it comes out of the vacuum coater points in random directions. As is common for conventional media, it is initialized once (presumably at the factory) using either a high dc field or a dynamic tester.

Writing at high power is aided by the applied field and the demagnetizing field; it is opposed by the energy of creating a domain wall and by the gradient in domain-wall energy caused by the Gaussian-shaped thermal profile. This

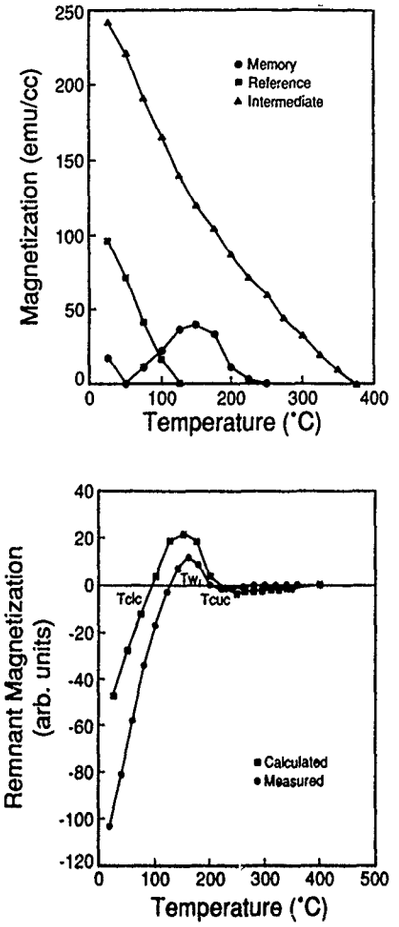

FIG. 2. (a) M_s vs temperature for the individual layer of the three-layer scheme; (b) M_s vs temperature for combined system.

profile makes a wall at small radius having a higher temperature and thus lower wall energy per unit area than a wall at a large radius. However, this profile dissipates rapidly and apparently leaves the domain wall pinned in place before the domain can vanish. Assuming that the memory layer has a larger magnetic moment at the write temperature (owing to greater thickness or other causes), the reference layer will be left with magnetization opposing the bias field, as illustrated in Fig. 3.

Erasing at low power is opposed by the applied field and the demagnetization field; it is aided by the domain-wall energy and particularly by the thermal gradient, which does not

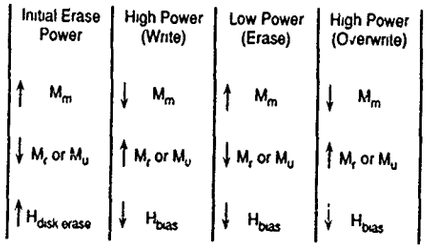

FIG. 3 Arrow diagram showing the write erase mechanism for a disk in which the memory and reference layers are antiferromagnetically coupled.

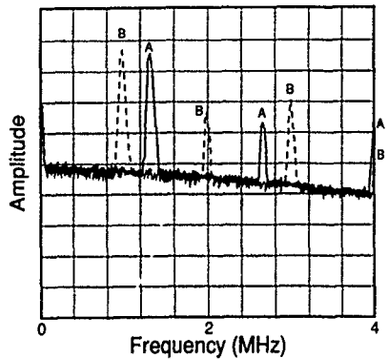

FIG. 4. Spectrum analyzer plot of the direct overwrite of the three-layer scheme. A and B correspond to original and overwritten signal, respectively.

dissipate until a much lower temperature than in the high-power case. Evidence for the proposed importance of the thermal gradient during erase is provided by the absence of a linear relationship between the measured erase power and the ambient temperature. The presence of such a relationship would allow the extrapolation of the erase temperature from the point where it crosses the temperature axis. (Such an extrapolation could be performed for the write temperature.) Its absence means that there is no one temperature at which erase occurs; erasure must depend on other variables such as the temperature gradient.

Samples containing the memory, reference, and intermediate layers were prepared on glass substrates. In one example, the memory layer comprised of $Tb_{24}Fe_{62}Co_9$ had a Curie temperature of 250 °C, compensation temperature of 30 °C, and room-temperature coercivity >13 kOe. The reference layer comprised of $Tb_{27}Fe_{64}Co_9Zr_{10}$ had a Curie temperature of 120 °C, and room-temperature coercivity <3 kOe. This layer did not have a compensation point below the Curie temperature. The intermediate layer, comprised of $Gd_{85}Fe_{22}Co_{43}$, had a Curie temperature of 400 °C. A trilayer disk was prepared using a 1300-Å-thick memory layer, 100-Å-thick intermediate layer, and 400 Å reference layer deposited sequentially on a 130-mm-diam glass substrate without breaking the vacuum in the sputtering chamber. A 5 mm band was erased dynamically using high power and an erase field of 600 Oe, thus initializing all the layers. A track was written by modulating the laser power at 6 mW (P_{low}) and 16 mW (P_{high}) levels, a frequency of 1.33 MHz (50% duty cycle), and using −400 Oe write bias field in the opposite sense to that of the erase bias field. The spectrum of the recovered signal is shown as curve A in Fig. 4 and shows the peaks at 1.33 MHz and higher harmonics as expected. The track was then overwritten while modulating the laser at 1.0 MHz. The spectrum of the recovered signal is shown as curve B in Fig. 4. The original signal at 1.33 MHz is completely overwritten with the 1.0 MHz signal and the new peaks appear corresponding to 1.0 MHz frequency.

The overwriting mechanism described earlier will become clearer from the Kerr hysteresis loop of the memory and reference layers measured at ambient and elevated temperatures. In this case memory and reference layers have

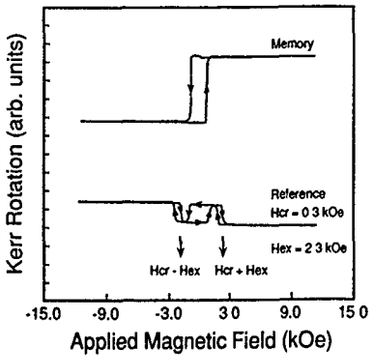

FIG. 5. Kerr hysteresis loops for the direct overwrite trilayer disk at 140 °C measured from both memory and reference layer side. Arrows on the hysteresis line indicate the direction for sweep of magnetic field.

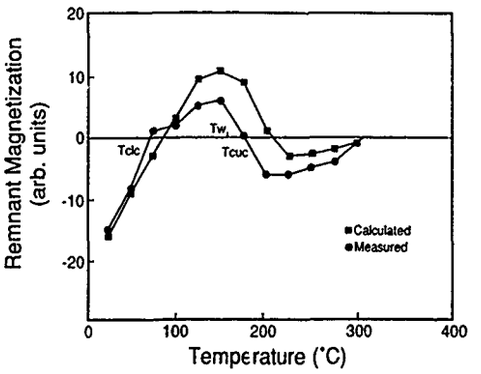

FIG. 6. Magnetization vs temperature for the two-layer scheme.

composition of $Tb_{24}Fe_{62}Co_9Zr_5$ and $Tb_{30}Fe_{60}Co_{10}$, respectively, and the same Curie temperatures of 175 °C. The two layers are exchange coupled (exchange field ~1.7 kOe) to each other at room temperature. The coercivity of the memory layer was high (>12 kOe) as in a single-layer sample. The high-temperature Kerr loops show interesting features. The coercivity of the memory layer has decreased to about 1000 Oe. The reference layer indicated three separate transitions in the magnetization as shown in Fig. 5. It is interesting to note that when the applied field is small (less than 1500 Oe), the magnetization of the memory and reference layers are always oppositely aligned and, in fact, switched simultaneously. This means both of the layers are written simultaneously. We found the exchange field between the memory and reference layers at this temperature to be 2.3 kOe.

To confirm our earlier observation that the reference layer is written along with the memory layer, we wrote tracks from the memory side but read from the reference side of the disk through the substrate. In fact, a large signal was recovered on the spectrum analyzer, indicating that reference layer and memory layer are written simultaneously.

The DOW performance was found to depend on the power levels, bias field, and disk velocity. By using suitable power levels we were able to obtain DOW CNR of about 48 dB at 3.5 μm mark lengths. We also investigated several combinations of disk structures to find the operating range for bias field and power levels of the direct overwrite process. DOW performance was similar as long as the combined system compensation point was 70–110 °C. Long-term reliability has not yet been evaluated: Limited testing (ten overwrites) shows no degradation in performance with repeated cycling.

The other configuration of this scheme consists of only a memory layer and a soft magnetic underlayer exchange coupled to each other. The Curie temperature of the underlayer is higher than the Curie temperature of the memory layer. This underlayer is the same as the control layer of the three-layer scheme of Fig. 1. Figure 6 shows the calculated and measured combined magnetization of the memory layer and underlayer. The combined magnetization curve has lower T_{clc} and upper compensation T_{cuc} temperatures that determine operation of the medium. This scheme also gave good dynamic performance but was about 2 dB lower than the first configuration. The mechanism of this structure is thought to be similar to that of the earlier configuration.

The CNR offered by either of the media configurations is below the desired value of 55 dB. Kerr microscopy has been used to examine the written and erased marks. It is found that if full width marks are written, then the erase power only thins the marks but does not completely remove them. This leaves a long chain of marks, modulated in width, and does not provide the desired CNR. If a lower write power is used, then marks can be fully erased, but the written areas do not have sufficient width to generate a full signal. Again, CNR is reduced. However, this scheme offers several possibilities for future improvements and exploitation. It has been found that relatively large marks can be erased if the marks occur in well-defined locations; this suggests use for fixed bit cell recording. More extensive optimization of media, particularly the domain-wall mobility, may allow larger areas to be erased and thus increase the CNR. Furthermore, the trend in MO recording is toward the smaller marks that we have no difficulty in erasing. Preliminary measurements indicate small mark (0.7 μm) performance only 4 dB lower than large mark performance. Finally, our measurements were made on a dynamic tester without high-frequency injection. This may have underestimated our performance by several dB.

We would like to acknowledge the help of A. C. Palumbo for Kerr microscopy, C. Brucker and J. Farruggia for vibrating sample magnetometer measurements, and Y. S. Tyan for several useful discussions and numerous suggestions.

The design philosophy and objectives for producing phase-optimized trilayer structures for magneto-optic enhancement of the polar Kerr effect is outlined. A number of alternative designs is presented based on glass/Co-Pt/SiO_2/Al. The performance of an actual device, as a function of the wavelength of the incident radiation, and of angle of incidence, for both of the principal polarization states, has been evaluated experimentally and theoretically. Results indicate excellent agreement and demonstrate the ease with which devices can be designed and fabricated.

I. INTRODUCTION

The magneto-optic (MO) Kerr effect in an absorbing medium can be enhanced by its incorporation into a suitable thin-film optical environment, usually a quadrilayer[1] or a trilayer system[2] which is designed to maximize the Kerr rotation for a given system reflectance. This has the effect of maximizing the signal-to-noise ratio (SNR) associated with the differential detection of the normal incidence polar Kerr effect and therefore with the readout of stored information in the MO storage disk system. Although improvements are significant, an additional and most desirable feature is the total elimination of parasitic Kerr ellipticity.[3] This has the effect of producing the maximum Kerr rotation while, at the same time, effectively dispensing with the need for MO phase correcting optics in the optical readout head.

In this article we report on the optical and magneto-optical performance of a trilayer structure designed around the use of Co-Pt multilayers (MLs) as the magnetic medium. We outline briefly the design philosophy[2] for MO phase correction and demonstrate the ease with which these systems may be fabricated. The performance of an actual device is demonstrated by a series of comprehensive measurements which demonstrate the dispersion and angular dependence of the most important properties compared with theoretical calculations.

II. EXPERIMENT

The trilayer structures consisted of Co-Pt MLs, as the magnetic component, together with a silicon dioxide dielectric spacer layer followed by an aluminium reflector as shown in Fig. 1. All layers were prepared by magnetron sputtering in a computer-controlled, UHV-compatible ($<10^{-8}$ mbar) multisource deposition system. Depositions of all materials were made at 3 mbar of argon onto glass substrates without breaking the vacuum. Individual layer thicknesses were determined from calibrated deposition times and in the case of the Co-Pt MLs, sublayer film thicknesses and bilayer periodicity were confirmed from low-angle x-ray diffraction. The Co-Pt consisted of 1.1 nm Pt/6(0.4 nm Co-1.1 nm Pt) giving a total thickness of 10.1 nm. The optical and MO properties were obtained using a variable-angle, spectroscopic Kerr polarimeter, operating with a rotating analyzer.

III. TRILAYER DESIGN

To maximize the SNR associated with the differential readout of the Kerr effect[4] it is necessary to satisfy three criteria. First, the MO disk reflectance R should be a specific value related to the magnitudes of the various noise sources of the detection system.[1] Typically this is likely to be within the range 0% to 33%. Second, the Kerr rotation θ_k should be a maximum. Third, the MO phase difference δ_k between the

TABLE I. Normal-incidence trilayer designs for glass/Co-Pt/SiO_2/Al $n=2.221+i4.532$ and $Q=-0.0103+i0.0104$ at a wavelength of 633 nm for Co-Pt.

R	$\cos\delta_k$	d_m (nm)	d_D (nm)	θ_k (deg)	η (%)
0.1	+1	7.3	162	1.35	90
0.2	+1	8.3	170	0.82	87
0.3	+1	9.4	176	0.56	83
0.1	−1	9.6	119	1.46	97
0.2	−1	12.1	110	0.93	98
0.3	−1	15.4	104	0.66	98

Kerr component and the isotropic amplitude reflectance vector must be either 0 or π. This gives rise to zero Kerr ellipticity ϵ_K.

The principle of the design may be understood by reference to the structure of the trilayer shown in Fig. 1. Given that the materials available for constructing the system are predetermined, there are essentially two variable parameters for satisfying the above three requirements: These are the thicknesses of the magnetic d_m and spacer layers d_D. At first sight the problem appears insoluble; however, it is important to realize that the maximization of the Kerr component is essentially determined by two factors. One is the need for d_m to be less than the optical skin depth. The other is that the complex amplitude reflectance of the underlying mirror system, into air, $\mathbf{r}_m(=|r_m|e^{i\rho m})$ (Ref. 5) be such that $|\mathbf{r}_m|>90\%$ and ρm is within $\pm 0.7\pi$. Satisfying this rather loose condition almost certainly guarantees that the Kerr component will be very close to its maximum value. Consequently, one may adjust d_m and d_D until R and δ_k attain desired values. The corresponding value of $\mathbf{r}_m$ usually ensures that the Kerr rotation is very close to its maximum value. The degree to which this is achieved is indicated by the efficiency parameter $\eta = \theta_k/\theta_{k\,\max}$.

Using this procedure we have designed a number of systems for $R=0.1$, 0.2 and 0.3, and for $\delta_k=0$ and π. The dielectric spacer layer was SiO_2 and the metal mirror was semi-infinite Al. The complex refractive index n and MO parameter Q for Co-Pt were deduced from Ref. 6 and the optical constants of SiO_2 and Al were taken from Ref. 7. The incident medium was assumed to be glass of refractive index 1.52.

IV. THEORETICAL RESULTS

As can be seen from Table I there are two designs for each reflectance value which will lead to zero Kerr ellipticity. The thickness of the Co-Pt layer is typically of the order of 10–15 nm, which is below the skin depth at this wavelength, and the SiO_2 layers are all less than 180 nm. Although the first three designs for $\cos\delta_k=+1$ are possible and would lead to zero Kerr ellipticity, they are not recommended for two reasons. First, the efficiency parameter η is not particularly high (≈85%). Second, the reflectance of the system is five times more sensitive to errors in the thickness of the magnetic layer than in the cases where $\cos\delta_k=-1$. For these reasons phase compensation with $\delta_k=\pi$ must be considered the most expedient design choice, since this will lead to systems whose reflectances are relatively insensitive to errors in film thicknesses and which have Kerr rotations that are within 97% of their absolute maximum values.

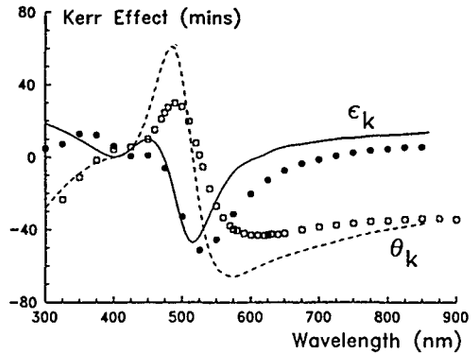

FIG. 2. Dispersion of the complex Kerr rotation $(\theta_k+i\epsilon_k)$ for a trilayer.

V. PRACTICAL PERFORMANCE

To demonstrate the feasibility of producing a trilayer of this type we have fabricated a structure based on the design for $R=0.1$ and $\delta_k=\pi$. In practice the Co-Pt had a total thickness of 10.1 nm which is slightly in excess of the design value of 9.6 nm. The SiO_2 layer thickness was 119 nm and that of the aluminium was greater than 200 nm. Measurements were made of θ_k, ϵ_k, and R over the spectral range 300–900 nm and the results are shown in Figs. 2 and 3 together with theoretical calculations based on the use of optical and MO constants for Co-Pt (0.65/1.8 nm) MLs.[8] Although these layer thicknesses are not exactly the same as those corresponding to the Co-Pt in the trilayer system they provide a useful means of assessing its performance. In addition, and because all practical MO disk systems will operate with a focused and therefore highly convergent light beam, we report on the variation of θ_k, ϵ_k, and $\cos\delta_k$ with angle of incidence. These are shown in Figs. 4 and 5 and are compared with theoretical calculations using the values of n and Q given in Table I.

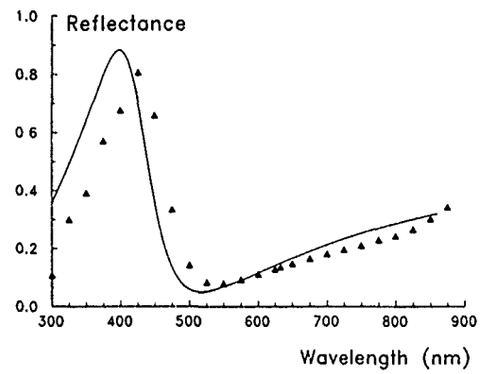

FIG. 3. Dispersion of the reflectance of a trilayer.

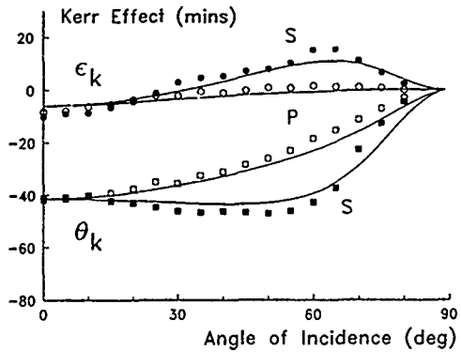

FIG. 4. Angular dependence of the complex Kerr rotation ($\theta_k + i\epsilon_k$) of a trilayer for the principal states of polarization.

When reading these figures it should be remembered that the design details were determined for a semi-infinite incident medium. In practice, measurements were taken through the substrate and as a consequence suffer from the complications of multiple incoherent reflections within the glass substrate. The theoretical curves shown in Figs. 2–5 have therefore been determined taking into account these extra reflections and should not be compared with data for R and θ_k in Table I.

At normal incidence, the rapid variation of θ_k and ϵ_k around 500 nm is associated with an antireflection condition which occurs for three-layer systems of the type being considered here. This reflectance minimum can be seen in Fig. 3. In fact, the reflectance minimum is very close to zero at the trilayer/glass interface and the corresponding Kerr rotation is very large indeed. However, the reflectance from the air/glass

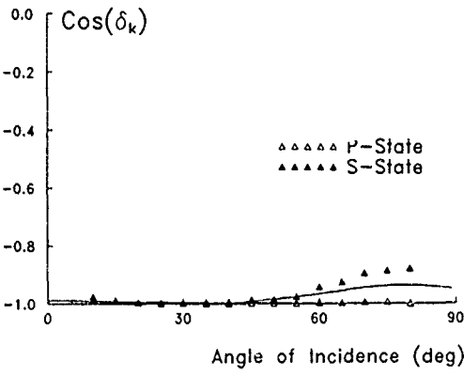

FIG. 5. Angular dependence of the MO phase function cos δ_k for the principal states of polarization.

interface remains finite and limits the measurable rotations to those values seen in the theoretical curves. Bearing in mind the uncertainties in the basic constants of the Co-Pt and in the actual layer thicknesses, the agreement between the theoretical and experimental curves is very good indeed. It may be noted that changing the value of d_m to about 14 nm produces even better agreement. The variation in the Kerr ellipticity is also as expected and can be seen to attain very small values in the vicinity of the design wavelength and is zero at about 700 nm.

The angular variations of θ_k, ϵ_k, and cos δ_k were measured in air and are labeled P and S corresponding to the MO component being polarized parallel or perpendicular to the plane of incidence, respectively. Theoretical curves have been calculated in the same way as before except that in this case the larger film thickness for the Co-Pt was used. This gives better agreement at normal incidence, by compensating for slight errors in actual film thickness or in the optical constants. It can be seen from these figures that the experimental behavior of the device is in accordance with expectations and that for angles of incidence up to about 30°–40° there will be little deterioration of performance resulting from the convergent nature of an optical readout beam. The effect which angle of incidence has on the MO phase term is illustrated dramatically in Fig. 5 where it can be seen that, for both polarization states, cos δ_k remains very close to unity up to nearly 60°. This confirms the achievement of the original design goal of producing a MO phase-corrected device.

VI. CONCLUSIONS

The design philosophy and objectives for producing trilayer structures for MO enhancement have been outlined. A number of alternative designs, giving $\epsilon_k = 0$, have been presented and actual structures based on glass/Co-Pt/SiO_2/Al have been fabricated successfully. The performance of one of these as a function of the wavelength of the incident radiation and as a function of angle of incidence for the principal polarization states has been evaluated experimentally and theoretically. Results indicate excellent agreement and demonstrate the ease with which devices such as this can be designed and fabricated.

Effect of substrate roughness on microstructure, uniaxial anisotropy, and coercivity of Co/Pt multilayer thin films

Chung-Hee Chang and Mark H. Kryder
Data Storage Systems Center, Carnegie Mellon University, Pittsburgh, Pennsylvania 15213-3890

We studied the microstructure and magnetic properties of Co/Pt multilayer thin films sputtered onto glass and Si substrates with different surface roughness caused by different methods of substrate preparation. The microstructure determined by high-resolution electron microscopy and x-ray scattering could be correlated to the observed magnetic properties. Better (111) texture and smoother layer structures produced on smoother glass substrate surfaces produced higher uniaxial anisotropy. Coercivity, on the other hand, was enhanced by either pinning of the domain walls caused by substrate surface roughness or stronger columnar structure. Although Si substrates exhibited slightly different roughness under the same preparation conditions, the dependence of magnetic properties on the substrate surface was consistent with the trends using glass substrates.

I. INTRODUCTION

Due to their intrinsic resistance to corrosion and a Kerr rotation which increases at short wavelength, Co/Pt multilayer films (MLF) are promising candidates for future high density recording.[1,2] Extensive studies of the film characteristics as a function of film fabrication parameters have been made of this multilayer system. It has been found that the magnetic properties such as uniaxial anisotropy and coercivity of these MLF are strongly dependent on the film fabrication method.

Since the layer thicknesses and total film thickness of Co/Pt MLF suitable for magneto-optical (MO) recording are ultrathin, it was expected that roughness of the interface and layer structure induced by substrate roughness would play an important role in determining the magnetic and magneto-optical properties. In this study, we investigated the effect of substrate roughness, introduced by various substrate preparation techniques, on the microstructure and correlated it to the magnetic properties.

II. EXPERIMENTAL DETAILS

Co/Pt MLF were fabricated by dc magnetron sputtering. A Leybold–Heraeus Z-650 system was configured so that two magnetron targets of 75-mm diameter could sputter simultaneously while substrates rotated underneath from one target to the other. A series of Co/Pt MLF consisting of ten bilayers with constant Pt layer thickness of 1 nm were deposited by sputtering with Xe onto 0211 Corning glass and oxidized (002) Si substrates. The substrate temperature during the deposition was ambient. The deposition rate of the Pt layer was 0.35 nm/s. The Co layer thicknesses were varied from 0.26 to 1.5 nm by changing the deposition rate from 0.12 to 0.6 nm/s. The base pressure of the chamber was less than 4×10^{-7} Torr and gas pressure during deposition was kept constant at 10 mTorr. Both glass and Si substrates were subjected to three different preparation procedures prior to film deposition as outlined below:

Procedure (A): (i) soaked in warm water 10 min;
(ii) cleaned with oxygen plasma 10 min.

Procedure (B): (i) ultrasonic cleaning for 10 min each with warm water, acetone, 2-propanol, and warm water sequentially;
(ii) cleaned with oxygen plasma 10 min.

Procedure (C): (i) Type (B) procedure;
(ii) sputter-etched at 500 V in 10-mTorr Xe 5 min.

Cross-sectional transmission electron microscopy (TEM) specimens were prepared following a method similar to that described by Bravman and Sinclair.[3,4] The specimens were prepared so that the layers and substrate–MLF interfaces could be viewed edge-on. A specimen consisted of two pieces of MLF on both glass and Si substrates glued face-to-face by epoxy thinner than 0.1 μm. The (111)-type fringes in the Si substrate were used to align the interfaces parallel to the electron beam direction.

The magnetic properties were measured with a DMS model 800 torque and vibrating sample magnetometer (VSM). The structure of the films was characterized by large and small angle x-ray scattering (LAXS and SAXS) using a Rigaku x-ray diffractometer. A JEOL 4000EX high-resolution electron microscope (HRTEM) operated at 400 kV was used to obtain images of the films and selected area electron diffraction (SAED) patterns.

III. RESULTS AND DISCUSSION

The effective anisotropy energy per unit volume K_{eff}, multiplied by the Co layer thickness t_{Co}, is plotted as a function of t_{Co} in Fig. 1 for the multilayers deposited on glass substrates prepared using the three different methods. The data follows the linear relation[5] $K_{\text{eff}}t_{\text{Co}}=2K_s+t_{\text{Co}}K_v$, where K_s is the interfacial anisotropy energy density and K_v is the volume anisotropy energy density of the cobalt. It is seen that the anisotropies of multilayers on sputter-etched substrates are the largest, and that the larger anisitropy for (A)- and (C)-type samples are due to the larger interfacial anisot-

 0021-8979/94/75(10)/6864/3/$6.00 © 1994 American Institute of Physics

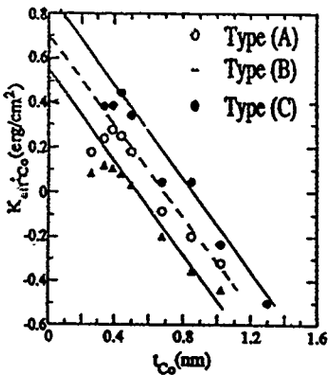

FIG. 1. Effective uniaxial anisotropy K_{eff} times the Co layer thickness as a function of Co layer thickness for Co/Pt MLF deposited on the glass substrates prepared using the three different cleaning procedures.

ropy while the volume anisotropy is constant. The larger anisotropy is attributed to a better-defined interface induced by a smoother substrate surface which agrees with a reported study made on MLF deposited on ZnO underlayers grown at different temperatures.[6] TEM micrographs in Fig. 2 show that the layer structure of the type (C) sample is the smoothest and most continuous, and that of type (B) is rough and discontinuous. The smoothness of the layers observed by TEM is found to be consistent with SAXS patterns shown in Fig. 3(a). It is seen that type (C) exhibits the most well-defined periodic structure and type (B) the worst. SAXS patterns for thicker t_{Co} showed a systematic increase in the number of diffraction orders for type (A) and (C).

High magnification HRTEM micrographs for the three different samples on glass are shown in Fig. 4. The surface of the type (B) substrate is the roughest. Although the depth of the roughness of type (A) and (C) samples were about the same, 0.8 nm, the wavelength of the roughnesses were quite different (10 and 1.5 nm, respectively). It is noticeable from the micrograph that the substrate surface region (~1.7 nm) of the film is amorphous for type (A) sample. On top of this amorphous layer, the multilayer was grown with less (111) texture. However, the grains in the type (C) sample start growing right from the substrate surface. This is probably due to increased nucleation sites for crystal growth helping to form the good lattice coherency as indicated by the satellite peak at $2\Theta=34°$ in the LAXS pattern shown in Fig. 3(b).

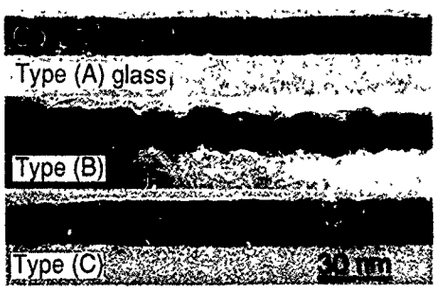

FIG. 2. Low-magnification cross-sectional HRTEM images of 10×(0.5-nm Co/1.0-nm Pt) MLF deposited on the three types of glass substrates. The type (C) sample has 11 Pt layers.

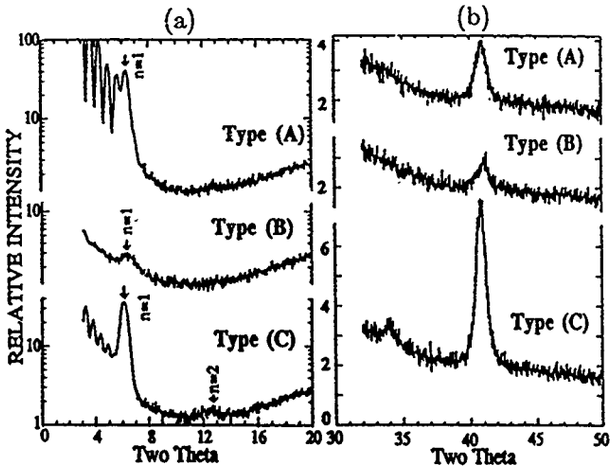

FIG. 3. (a) Small- and (b) large-angle x-ray scattering ($\lambda=0.154$ nm) measured from nominal (0.4/1.0)-nm Co/Pt MLF deposited on three types of glass substrates.

SAED patterns shown in Fig. 5 indicate that the (111) textured grains in type (C) samples are better oriented than those in type (A) and (B) samples. The relative intensity of the ring patterns from (111) textured crystallites are the strongest in the direction of film growth for type (C) and weakest for type (B) samples.

Magnetization hysteresis loops for the three types of samples are shown in Fig. 6. The squareness of the type (B)

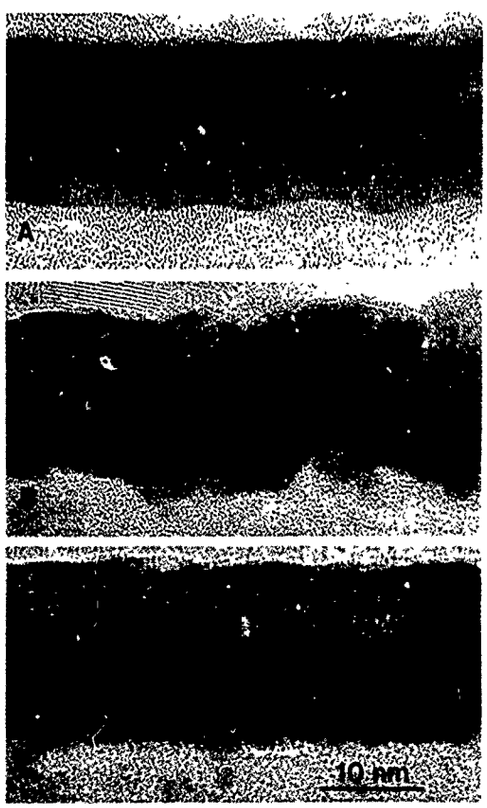

FIG. 4. High-magnification cross-sectional HRTEM images of the Co/Pt samples shown in Fig. 2

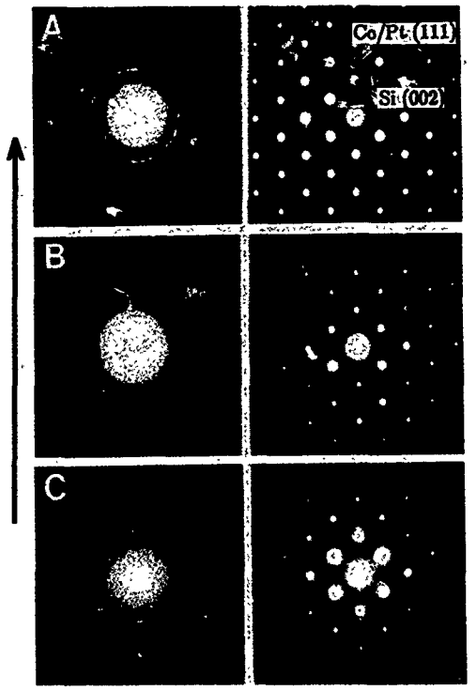

FIG. 5. Selected area electron diffraction patterns of the Co/Pt MLF samples shown in Fig. 4 and corresponding MLF deposited on Si substrates. The direction of film growth is indicated by the arrow.

sample is slightly lower than the others, but the coercivity is the largest. The large coercivity of the type (B) sample is attributed to the pinning of the domain walls caused by the surface roughness and thus by defects at the interfaces. This kind of coercivity enhancement was also observed in Co/Pt MLF deposited on a Si nitride underlayer.[7] Poorer squareness suggests that domain reversal in this sample is nucleation dominated.[8,9] The larger coercivity of sample type (C) as compared to sample type (A) can be attributed to more well defined grains (or columns) in type (C) samples. This may be seen in Fig. 4. Such isolated grains or columns were also reported to enhance coercivity in samples grown on a Pt underlayer.[10] Increased coercivity by sputter-etching were reported elsewhere.[11,12]

The microstructure and magnetic properties of samples prepared on Si with the same preparation procedure were

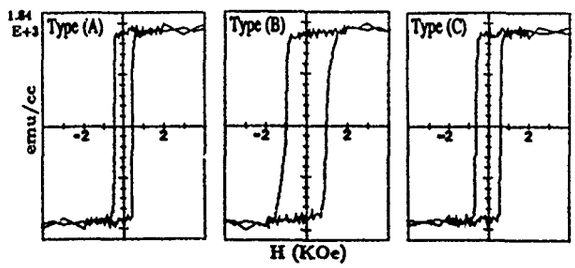

FIG. 6. Hysteresis loops of nominal (0.34/1.0)-nm Co/Pt MLF deposited on three types of glass substrates.

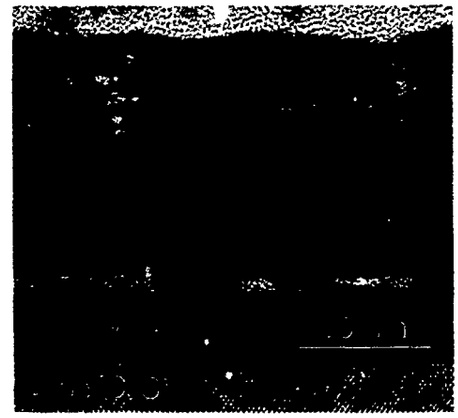

FIG. 7. HRTEM image of nominal (0.5/1.0)-nm Co/Pt MLF deposited on type (C) Si substrate.

approximately the same as those of glass samples. However, sputter-etching produced an amorphous layer about 5-nm thick on Si, which seems to further promote grain growth by providing a smooth surface underneath the 1-nm oxidized surface. Large grains measuring about 17.5 nm in the lateral dimension may be observed in Fig. 7, which is a HRTEM micrograph of a MLF grown on a type (C) Si substrate.

IV. CONCLUSIONS

The correlations between microstructure and magnetic properties of Co/Pt MLF deposited on substrates with different roughness were made. It was confirmed that the magnetic properties were very sensitive to substrate roughness. The roughness lowered the uniaxial anisotropy and raised the coercivity. The coercivity was also raised by stronger columnar structure produced by a smoother substrate surface.

ACKNOWLEDGMENTS

Polycarbonate substrates are the industry standard for optical storage. Optical anisotropy is frozen into the substrate as polymer orientation during mold flow and thermal stress during cooling. The substrate optical anisotropy degrades the readback of the data [carrier-to-noise ratio (CNR)] by increasing the noise level on Kerr rotation measurement. There are also synergistic effects of the disk optical properties with focus and tracking optics. For optimum CNR, the beam is focused on the magneto-optical (MO) film. For optimum tracking, the beam is focused to maximize track error signal (TES). For the disks considered the difference between the offset for optimum CNR and that for optimum TES was between 300 and 600 μm. This results in a compromise between optimum CNR and TES, which could limit MO storage density and performance. Conventional methods of bulk optical anisotropy measurement are unsuccessful in explaining this variance. These give an average or effective optical property. The optical properties are also known to vary with the depth in the substrate and especially near the mold walls as determined by optical polarizing microscope. A scanning micropolarimeter instrument is presented to rapidly measure the depth distribution of the optical properties. The interaction between the obliquely incident polarized beam with the microscopic variation in the index of refraction throughout the depth of the substrate is proposed as the source of the difference between the optimum focus offsets.

Polycarbonate (PC) substrates are the industry standard in magneto-optical (MO) recording from the mechanical, physical-chemical, as well as productivity and cost points of view. However, optical anisotropy which causes birefringence is frozen in the substrate as: polymer orientation during mold flow and thermal stress during cooling. Although injection molding techniques which minimize the in-plane birefringence in PC have been demonstrated, vertical birefringence which causes large retardation for marginal rays is an unsolved problem. Fluctuation around the average intensity distribution on the photodetector is attributed to vertical birefringence.[1] The substrate birefringence for an obliquely incident beam is very high, leading to degradation of the carrier-to-noise ratio (CNR).[2] Birefringence measurements are typically done by passing a beam through the substrate, for uncoated substrates,[3,4] or by reflecting the beam from a layer on one side of the substrate, for coated substrates.[5] These provide an average value for the optical property. A recent phenomenon observed with MO substrates that is attributed to birefringence but cannot be adequately explained in terms of the bulk average measurements is described. We developed an apparatus for rapidly measuring the microscopic variations of the index of refraction throughout the depth of the substrate in an effort to investigate this phenomenon.

When a MO disk is inserted into a drive, the focus servo-optics adjust the lens position vertically with respect to the disk substrate. In the case of an astigmatic focus servo system, the adjustment is done until the reflected spot is circular on the detector. This is considered to be focused through the substrate on the grooved surface covered by the reflective MO film structure. This is the point of zero focus offset. At this lens position both the track error signal (TES) and the signals of Kerr rotation of the data bits should be optimum, as the servo maintains the lens in focus by translating in response to disk vertical runout. The TES should be as large as possible to provide input to the radial positioning servo. Alternatively, if the track error signal is too low, the radial positioning servo system loses its ability to follow the runout of the tracking grooves. As the track pitch is decreased from 1.6 to 1 μm or less, the importance of obtaining the maximum TES increases. However, it is found that the maximum TES usually does not coincide with the optimum focus point. Some preliminary data are shown to illustrate this phenomenon. Typical data are shown in Fig. 1. The solid circles show the TES amplitude as a function of focus offset in nanometers. Here, the in-focus point determined by the servo system is the zero focus offset. The solid curve is the regression fit of the data which is employed to analytically determine the location of the maximum or minimum from the data. The data shown in Fig. 1(a) were measured on an amorphous polyolefin (APO) substrate. In this case, the optimum focus point nearly coincides with that for maximum TES. Figure 1(b) shows a larger focus offset measured on a PC substrate. From these data alone, it may appear sufficient to adjust the focus offset to obtain the maximum TES for the disk drive operating point.

The focus position for the best ability to read the MO data shows an offset which is different from that which provides the optimum TES. The best focus point for tracking is that which gives the maximum TES, while the best focus for data readback performance is that which gives minimum jitter. The jitter is a time-domain measurement of channel noise. In this example, the jitter of a square wave was used as a measure of data readback performance rather than CNR. The jitter is shown as a function of focus offset by the open squares in Fig. 1. The offsets for optimum TES and minimum jitter do not coincide. In fact, they are significantly

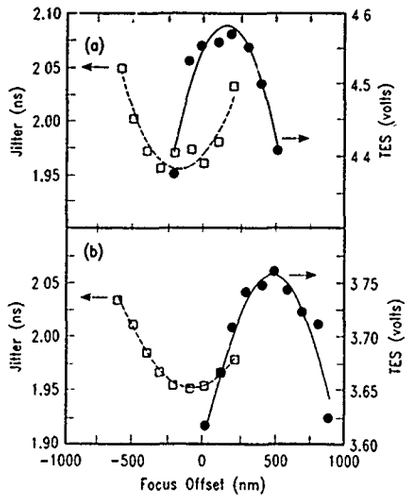

FIG. 1. The jitter (□) and the track error signal TES (●) for (a) an APO substrate and (b) a PC substrate.

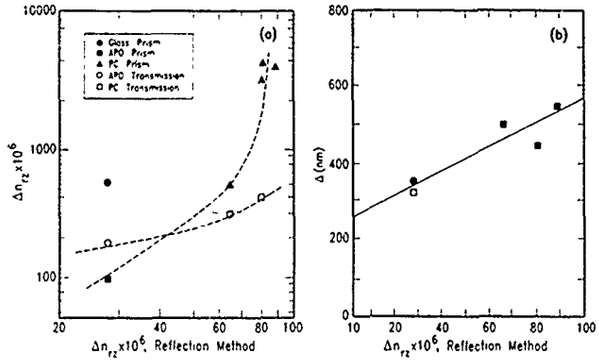

FIG. 2. A comparison of the vertical birefringence of MO disk substrates using three different types of measurement techniques. (a) The lines are drawn as an aid to the eye and (b) the distance between the two offsets Δ.

different, more so for the PC substrate in Fig. 1(b) than for the APO substrate in Fig. 1(a). This difference between the focus offset for maximum TES and minimum jitter represents a fundamental limitation in the ability to increase the data storage density on MO media by narrowing the track pitch and increasing the linear density. The difference between the offset for maximum TES and minimum jitter is defined as Δ. Ideally Δ=0. The nonzero Δ is the subject of the present investigation. Measurements attempting to relate the nonzero Δ with bulk and surface birefringence measurements are described below.

Several methods are available to characterize the vertical birefringence Δn_{rz}. Here subscript r denotes radial direction and z the vertical direction in the disk substrate. One technique is the transmission method.[3,4] Here, the birefringence is measured over a range of incident angles, and the data are extrapolated to a 90° angle of incidence. Another technique is called the prism method.[6] This approach utilizes the principle of total internal reflection. One feature of the prism method is that it is most sensitive to the optical properties near the surface of the disk substrate. There is also a novel reflection measurement method. The apparatus resembles that described in Otsuka *et al.*[7] The geometry of this method is closer to that found in the actual optical head of the disk drive than the transmission or prism methods.

Values of Δn_{rz} measured by the transmission and prism techniques are plotted as a function of that measured by the reflection method and shown in Fig. 2(a) for various MO disk substrates. Although the magnitudes differ, the trends are in qualitative agreement. The prism method is probably higher for PC because of the high surface layer optical anisotropy. In the APO, the surface layer contribution may be small due to the lower-stress optical constant. The glass is likely to have higher stress in the surface layer due to the chemical hardening which extends several microns into the bulk.[8]

The Δn_{rz} measured by each of these methods was examined to determine which correlates with the measured focus offsets. Among the three methods, the one most correlated with Δ was Δn_{rz} from the reflection method. Δ is plotted as a function of Δn_{rz} from the reflection method in Fig. 2(b). Δ increased with increasing Δn_{rz}. This suggests that overall it is preferable to have lower Δn_{rz} for lower Δ, although there is an additional contribution to the variation of Δ.

More detailed measurement of birefringence with respect to depth in an optical disk substrate has been done by counting fringes as a function of depth in a strip cut from the substrate using an optical polarizing microscope.[9] Since these measurements are manual and time consuming, they are impractical for studying large numbers of substrates.

In order to automate measuring the depth variation of the microscopic optical anisotropy, we have begun to develop a scanning micropolarimeter instrument. The polarimeter setup is similar to the conventional flow birefringence experiment. This apparatus is a modification of that used by Frattini and Fuller.[10] A schematic of the apparatus is shown in Fig. 3. The modifications in our apparatus are the focusing and collector lenses, and the translation stage which allows stepping the sample across the beam. Monochromatic light incident on a photoelastic modulator (PEM) perpendicular to the strain axis is modulated and experiences a time varying retardance given by $\delta_m = A_c \sin(\omega t)$. Here A_c is a function of the wavelength of light and the maximum voltage applied to the crystal, and ω is the resonant frequency of the optical element. The intensity of the light at the detector then contains a fundamental frequency ω, typically 50 kHz. Fourier decomposition of the voltage from the detector facilitates simultaneous determination of the birefringence Δn_{rz} and the extinction angle χ of the sample. The beam diameter was measured with the aid of the knife-edge technique. The knife-edge technique provides an accurate means to measure the diameter of a Gaussian beam. The beam diameter without the lens is 795 μm and the focused beam is 23 μm in diameter.

The micropolarimetry experiment is interpreted using Jones matrix algebra.[10] Taking the radial direction (flow field) as a reference, the incident polarizer is set at 90°, the PEM at 45°, and the analyzer at −45°. If δ is the unknown retardation of the sample, the intensity of the light at the detector is given by

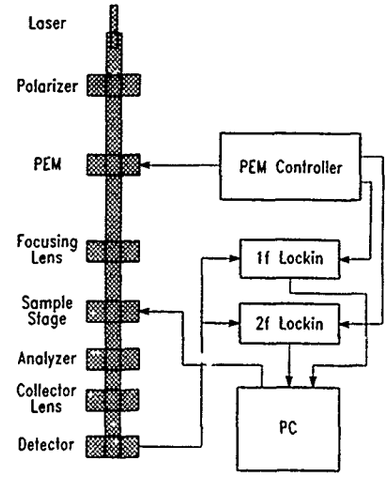

FIG. 3. A schematic of the scanning micropolarimeter apparatus using one PEM.

$$I=2I_{dc}[1+\cos 2\chi \sin 2\chi(1-\cos\delta)\cos\delta_m + \cos 2\chi \sin\delta \sin\delta_m]. \quad (1)$$

Here, $2I_{dc}$ is the light intensity emerging from the polarizer, and the birefringence is related to the retardation by $\Delta n_{rz}=-\lambda\delta/2\pi d$, with λ being the wavelength of the incident light and d the sample thickness. Equation (1) can be rearranged by recognizing that $\cos\delta_m=\cos[A_c \sin(\omega t)]$ to obtain

$$I=I_{dc}+I_\omega \sin(\omega t)+I_{2\omega}\cos(2\omega t)+\cdots. \quad (2)$$

Here, Fourier components I_ω and $I_{2\omega}$ are explicitly written as

$$I_\omega=2J_1(A_c)\cos(2\chi)\sin(\delta)I_{dc}$$

and

$$I_{2\omega}=2J_2(A_c)\cos(2\chi)\sin(2\chi)[1-\cos(\delta)]I_{dc}. \quad (3)$$

$J_m(A_c)$ is the Bessel function of the first kind with order m, and we set $J_0(A_c)=0$. The coefficients I_ω and $I_{2\omega}$ are measured in real time by two lock-in amplifiers tuned respectively to ω and 2ω. A phase-locked reference signal is provided to the amplifiers by the PEM control unit. I_{dc} is measured using a low-pass filter. The ratios I_ω/I_{dc} and $I_{2\omega}/I_{dc}$ are calculated in an IBM PC.

Defining $R_\omega=(I_\omega/I_{dc})/2J_1(A_c)$ and $R_{2\omega}=(I_{2\omega}/I_{dc})/2J_2(A_c)$, two equations with two unknowns δ and χ are obtained,

$$\cos 2\chi \sin\delta=R_\omega, \quad \sin 4\chi(1-\cos\delta)=R_{2\omega}. \quad (4)$$

Therefore, by measuring R_ω and $R_{2\omega}$, we can, in principle, obtain χ and δ.

Figure 4 shows the R_ω and $R_{2\omega}$ plots for a diamond-milled section cut from a PC disk substrate. These profiles reflect the variation of the optical anisotropy with depth in the substrate. Although R_ω and $R_{2\omega}$ are a function of depth, careful analysis is required to convert the R_ω and $R_{2\omega}$ plots into Δn (or δ) and χ profiles. Note that δ and χ cannot be uniquely determined from Eq. (4) due to the multiple solutions for the angles. Observation of the R_ω profiles as a function of depth, Fig. 4, shows considerable variation in R_ω as the beam is traversed across the depth of the substrate. The extinction angle ($\sim R_{2\omega}$) also varies considerably, indicating that the commonly used assumption of uniform Δn_{rz} and $\chi=0$ throughout the depth of the substrate is clearly invalid.

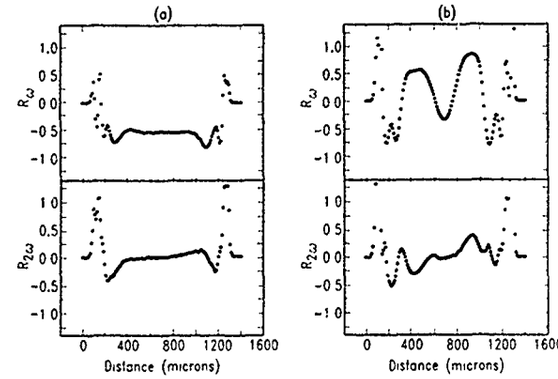

FIG. 4. The measured R_ω and $R_{2\omega}$ in scanning across a 1-mm-thick strip cut radially from a PC substrate that was diamond milled; (a) 10 mm and (b) 25 mm.

The differential propagation Mueller matrix[11,12] can be employed to calculate the actual integrated optical matrix for the disk in response to the convergent Gaussian beam used in the optical disk drive. Rigorously, $dS/dz=mS$ where S is the Stokes vector, z is the depth in the substrate, and m is a 4×4 real matrix containing the optical properties of the medium at depth z.

Depth variation in the MO substrate optical anisotropy is believed to cause focus offset differences so that both the MO signal and the TES cannot be simultaneously optimized. Automated measurement of the depth profiles of Δn_{rz} can be done using the scanning micropolarimeter instrument. The geometry using one PEM does not provide a unique value of birefringence and extinction angle for PC substrates. Future apparatus for determining Δn to within one wavelength of the retardation should include an additional PEM below the sample to act as a programmable quarter-wave plate.

The authors are grateful to R. Wimberger-Friedl of Philips Research Laboratories for providing the diamond-milled section from the PC substrate. We thank T. McDaniel of the IBM Optical Storage Laboratory for technical guidance. Growth and subsequent relaxation of the anisotropic structure of amorphous Tb-Fe (abstract)

F. Hellman, M. C. Robson, and M. T. Messer
Physics Department, University of California, San Diego, 0319 La Jolla, California 92093-0319

The large, growth-induced magnetic anisotropy in amorphous rare earth-transition metal alloys such as Tb-Fe are shown to depend strongly on the deposition temperature and only weakly on deposition rate or deposition technique (e.g., sputtering versus electron beam co-evaporation). These dependencies can be well fit with a thermally activated form involving minimization of surface energy *during the growth* by a re-orienting of adatom configurations over potential energy barriers. In this model, the growing film lowers its surface energy by a partial alignment of local clusters, presumably such as to maximize the number of in-plane bonds, although chemical effects undoubtedly also play an important role. These effects are somewhat analogous to a surface reconstruction which becomes trapped into the growing film by low bulk diffusion rates. In particular, a two-level model with a flat distribution of energy barriers is here shown to provide an excellent fit to the observations. Such a model leads to a $\ln(t)$ dependence on deposition rate and an exponential dependence on deposition temperature. We have also studied the subsequent irreversible relaxation of the anisotropy upon annealing. This relaxation is *strongly* influenced by the original growth temperature. In particular, the higher the original growth temperature, the more resistant the film is to subsequent relaxation. This result has important technological implications. As is commonly observed, the relaxation is well fit by a two-level model, again with a flat distribution of energy barriers over a range of energies, producing a $\ln(t)$ dependence on annealing time and a thermally activated dependence on annealing temperature. In annealing, of course, the lower energy state is isotropic, unlike the surface-induced anisotropic state produced during growth. The influence of the growth temperature on this relaxation implies that the actual *process* of creating the anisotropic state during the growth has the consequence of eliminating free volume in the sample, thereby raising the energy barriers to subsequent relaxation.

Macroscopic ferrimagnets as magneto-optic media (abstract)

Richard J. Gambino,[a] Ralph R. Ruf, and Nestor Bojarczuk
IBM, T. J. Watson Research Center, Yorktown Heights, New York 10598

We have discovered a class of phase separated materials in which the two phases couple antiferromagnetically across the phase boundary. A prototypical example is cobalt containing ≈100-Å-diam precipitate particles of EuS with the NaCl structure. These materials show many of the properties of ferrimagnets such as compensation points so we have adopted the term "macroscopic ferrimagnet" to distinguish them from ferrimagnets in which the antiferromagnetic exchange couples individual atoms. As a result of the ferrimagnetic exchange between the Co and the EuS the net magnetization of the composite is low in the vicinity of compensation so the anisotropy field is high. Electron beam evaporated thin films have a perpendicular easy axis as a result of growth induced anisotropy. Another effect of the exchange between the Co and EuS is to order the EuS well above its normal Curie point of 16 K. A film with 80 mole % Co and 20 mole % EuS has a compensation point of 55 K showing that the Eu^{2+} has essentially its full moment of $7\mu_B$ at this temperature in order to compensate the $1.65\mu_B$ of Co. The EuS even shows evidence of magnetic order at room temperature. The wavelength dependence of the sign of the magneto-optic Kerr effect can only be explained if the EuS has sufficient rotation at high photon energies to be larger than the rotation of the Co. We have prepared more complex alloys that show square loop properties at room temperature, for example, Tb-Co-EuS and Tb-FeCo-EuO. X-ray diffraction analysis shows that these films consist of an amorphous matrix (Tb-Co or Tb-FeCo) with precipitates of a NaCl structure phase (e.g., defect solid solutions[1] like $Eu_{1-x}Tb_xS_{1-x}\square_x$). Both atomic and macroscopic ferrimagnetism are operating in these compositions. Films with high remanence and coercivitics over 4 kOe at room temperature have been obtained. Some of these compositions may be useful as magneto-optic storage media.

High-resolution magneto-optic measurements with a Sagnac interferometer (invited)

A. Kapitulnik, J. S. Dodge, and M. M. Fejer
Department of Applied Physics, Stanford University, Stanford, California 94305

A technique for measuring the Faraday effect and the magneto-optic Kerr effect has been developed. In a Sagnac interferometer, two optical beams follow identical paths in opposite directions. Effects which break time-reversal symmetry, such as magneto-optic effects, will cause destructive interference between the two beams. By measuring the phase shift between circular polarization states reflected from a magnetized sample, the polar magneto-optic Kerr effect is measured to an accuracy of 3 μrad, with a spatial resolution of 2 μm. The interferometric technique provides a number of advantages over conventional polarizer methods, including insensitivity to linear birefringence, the ability to completely determine the magnetization vector in a region, and the ability to sensitively measure magneto-optic effects without an external field. It is also shown that this device has great potential if incorporated into a near-field optical device. Some of the considerations for the design of a near-field Sagnac magneto-optic sensor are introduced and the advantages of the device are discussed. Some preliminary experiments are shown.

I. INTRODUCTION

Magneto-optic studies of magnetic films and of surface magnetism in bulk materials is very common.[1] In particular the surface magneto-optic Kerr effect (SMOKE)[2] has recently been refined to a state where selected systems can be studied to a submonolayer level. The Kerr effect, like all other magneto-optic effects,[3] originates from spin-orbit coupling. Its net effect is to produce a rotation of the polarization axes as well as a slight ellipticity in linearly polarized light reflected from a magnetized surface. The amount of Kerr rotation is directly proportional to the magnetization in the film, and thus provides an excellent method to study magnetism. In bulk materials, Kerr rotation and ellipticities can be as high as 10^{-2} rad (for a measurement of a metal using visible light with an optical penetration depth of $\sim$100 Å, this implies a specific rotation of $\sim 10^4$ rad/cm). For very thin films, the effect can be reduced substantially, hence restricting the materials and configurations that can be studied.

Magneto-optics is also discussed in the context of high-density data storage, where bits are represented as domains in a magnetic film which has strong perpendicular anisotropy. Data are written optically by locally heating the film above its Curie temperature with a laser, and aligning a domain with an applied magnetic field. The data are then read by means of the polar Kerr effect. A diffraction-limited optical device is capable of handling cell sizes as low as (1 μm)^2. In this limit, detailed imaging of the domain structure is beyond the capabilities of conventional polarized light microscopy, and currently we must turn to electron microscopes for high-resolution images. Near-field optical microscopy, operating in reflection with magneto-optic contrast, may be particularly useful in guiding the engineering of such storage materials. We might further imagine a near-field magneto-optic read-write system, which could push the minimum cell size down to the order of $\sim$(500 Å),[2] hence increasing the storage density to more than 10^{10} bits/in.^{2}; however, to date there are no magneto-optic devices which are working both in reflection and in the near-field region.

Recently we have demonstrated[4–7] the use of a Sagnac interferometer for the measurement of Faraday and Kerr effects. Three instruments were built to operate at 1060, 672, and 840 nm. One important advantage of these instruments over conventional SMOKE is that they are sensitive only to broken time-reversal symmetry effects while completely rejecting linear birefringence and optical activity. Our first instrument was built using an existing fiber-optic gyroscope (λ=1060 nm). For measurements of the Faraday rotation angle, the sensitivity achieved was 3 μrad/$\sqrt{\text{Hz}}$. We have since built instruments (λ=672 and 840 nm), designed more specifically for magneto-optic studies, which are slightly modified from the original with a shorter Sagnac loop. These instruments work in both transmission and reflection to measure both the Faraday and Kerr effects. The sensitivity achieved has been 2 μrad/$\sqrt{\text{Hz}}$. The Sagnac magneto-optic sensor (SMOS) was first developed in the search for anyon superconductivity in high-temperature superconductors;[4] we are currently giving more attention to its use for characterization of magnetic materials. An important measurement was the observation of free radicals in biological molecules.[7] In this experiment we showed the versatility of SMOS. The sensitivity found was comparable to electron-spin resonance (ESR), the only other technique used to look for free radicals; however, the sensitivity is not the only advantage of SMOS. As we explain below, SMOS is able to measure absolute magnetization, hence avoiding the need for external field modulation. Moreover, we show that SMOS is capable

 0021-8979/94/75(10)/6872/6/$6.00 © 1994 American Institute of Physics

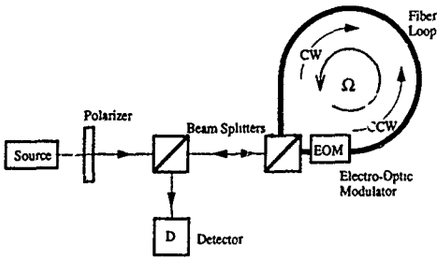

FIG. 1. Basic configuration of a Sagnac interferometer. Ω is the angular frequency of rotation of the loop.

of fully determining the state of magnetization in a sample region, and should provide a unique way to probe surface anisotropies.

II. SAGNAC INTERFEROMETER

Figure 1 shows a schematic of a basic Sagnac interferometer. The beam of light from the source enters a beam splitter, which sends half of the light clockwise (CW) and the other half counterclockwise (CCW) around a fiber loop. The two beams will come to the beam splitter after one turn and combine to constructively interfere at the detector. This is the Sagnac loop at rest and if we assume that the fiber allows one and only one path through the loop, it is completely reciprocal. If the loop is now rotated at a constant angular velocity Ω, reciprocity is no longer preserved. The rotation creates a difference in path length between the two counterpropagating beams, so that there will be a slight phase shift, the so-called Sagnac effect, introduced between them. This phase shift is translated into an intensity change when the two beams interfere at the detector. The phase shift will be proportional to the area enclosed by the loop, so with a fiber-optic loop the sensitivity to mechanical rotation can be increased by adding more windings.[8]

As described above, small changes in path length will lead to intensity changes proportional to the phase difference squared, which will in turn lead to poor sensitivity to small phase shifts. Typically the interferometer will be biased onto the linear portion of the interference curve to increase the sensitivity. In principle, this can be done by introducing a nonreciprocal element into the loop which creates a stable $\pi/4$ phase shift between the two beams. However, in practice, a dynamic biasing system is easier to engineer. In Fig. 1 we show one common bias technique, in which an electro-optic phase modulator is placed at one end of the loop. Although the phase modulator is a reciprocal device, we take advantage of the finite time it takes light to travel around the loop to create a nonreciprocal phase shift between beams which pass through the modulator at different times. With a sinusoidal phase modulation, the first-harmonic component of the detected intensity may be measured with a lock-in amplifier. For a small nonreciprocal phase shift $\Delta\phi_s$ and an average detected intensity I_0, the first harmonic is proportional to $k_1 I_0 \sin(\Delta\phi_s)$, where k_1 is a constant which depends on the phase modulation amplitude. Maximum sensitivity is achieved for a modulation frequency of $f=c/2L$, where L is the path length of the loop. Additionally, parasitic effects due to imperfections in the phase modulator will be significantly reduced near this frequency. Consequently, although the SMOS is not designed for mechanical rotation measurements, we must maintain a finite loop length of about 30 m in order to keep the modulation frequency in the MHz range.

To achieve sensitivity to magnetic substances, one would like to measure the asymmetry between the CW and the CCW beams induced by the nonreciprocity (broken time-reversal symmetry) resulting from magnetism. To do this, we "break" a (completely reciprocal) Sagnac loop, then introduce bulk optics into the optical path to allow us to probe a sample. More specifically, we use wave plates to create two polarization states which will lead to the maximum nonreciprocal phase shift upon interaction with a magnetized sample. The simplest geometries for describing the operation of the SMOS are those in which the sample exhibits no linear birefringence, and the direction of beam propagation is both collinear with the magnetization and normal to the sample surface. This corresponds to the polar Kerr effect in reflection and the Faraday effect in transmission. Choosing the z axis as the direction of beam propagation, the conductivity tensor for the material may be written in the form

$$\sigma(\mathbf{M}\|\hat{\mathbf{z}})=\begin{pmatrix} \sigma_{xx} & \sigma_{xy} & 0 \\ -\sigma_{xy} & \sigma_{xx} & 0 \\ 0 & 0 & \sigma_{xx} \end{pmatrix}. \tag{1}$$

For both of these geometries, circular polarization states are the appropriate basis for describing magneto-optic effects.[9] Transforming the electric-field vector to a circular basis diagonalizes the conductivity tensor and gives slightly different diagonal elements $\sigma_{\pm}=\sigma_{xx}\pm i\sigma_{xy}$ for the two basis states. The reflectance and the transmittance of the material is affected similarly, so that we may measure a difference in both the relative phase shift and the absorption between the two states. It is important to note here that this phase shift is nonreciprocal, unlike the phase shifts induced by linear birefringence or optical activity, since the magnetization breaks time reversal symmetry. It is precisely this nonreciprocity which allows us to measure magneto-optic effects using SMOS.

The most common way to measure these effects is to direct linearly polarized light at the sample and measure the polarization state of the returning light, so the literature commonly refers to the phase shift as "rotation," denoted by θ, and the differential absorption as "ellipticity," denoted by ϵ. We refer to the nonreciprocal phase shift (NRPS) throughout this article, and denote it by $\Delta\phi$. In the perpendicular geometries described above, $\Delta\phi=2\theta$, but in general the phase shift is a function of both the rotation and the ellipticity. To measure the NRPS, we compare two states with opposing angular momentum vectors, so that one is parallel to the magnetization and the other antiparallel. In transmission, this corresponds to states of the same handedness, and in reflection the appropriate states have opposite handednesses, where handedness is defined with respect to the direction of propagation [Fig. 2(a)]. When configured in this way, the SMOS is sensitive only to Faraday or Kerr rotation, not el-

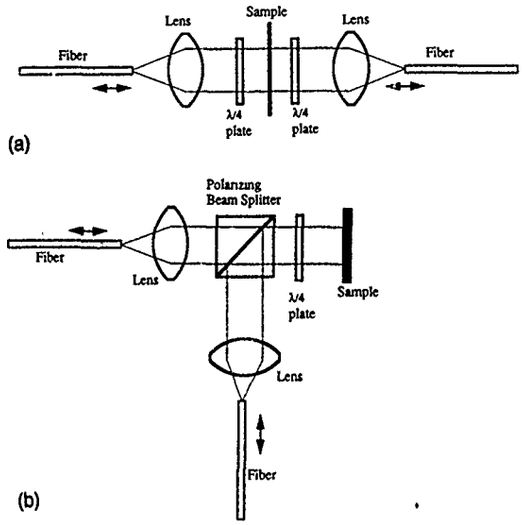

FIG. 2. Bulk optics inserted in the loop for (a) transmission and (b) reflection measurements.

lipticity, because magneto-optically induced ellipticity arises from nonreciprocal absorption, and consequently does not lead to a NRPS but to a small asymmetry in the absorption for the two polarization states.

We first describe the configuration which is used to measure the Faraday effect.[4] As explained above, we add in succession [see Fig. 2(a)] a quarter-wave (λ/4) plate, the sample holder, and another λ/4 plate, which comprise the bulk optics. Lenses are also added to focus the beams into the fiber. The polarization state in the fiber is linear, and the two λ/4 plates are arranged such that both beams are given circular polarization of the same handedness. We choose right-handed polarization states for the sake of discussion. With no sample, the clockwise propagating light is converted into right-handed circularly polarized light by the first λ/4 plate and converted back to the original linear state of polarization by the second λ/4 plate, and the counterclockwise propagating light will do the same, in the reverse direction. Assuming that no nonreciprocal phase shift occurs in the central portion of the bulk optics, then both clockwise and counterclockwise beams will emerge with no relative phase shift. If, however, a nonreciprocal phase shift occurs in the central portion of the bulk optics, one beam will be advanced in phase while the other will be retarded in phase, and the phase difference will be detected as an intensity change at the output of the interferometer.

To modify the apparatus for reflectance measurements, only one quarter-wave plate is needed, together with a polarizing cube beam splitter [Fig. 2(b)]. We set the linear polarization state in one fiber end to be parallel to the optical table, with the other orthogonal to it, and we use the beam splitter to selectively redirect one beam to overlap with the other. Each beam is given a different handedness upon passing through the λ/4 plate, which again is set to produce circular polarization states at the sample. If a perfect mirror is used as a sample, the handedness of each polarization state is switched upon reflection and the linear polarization which results from passing through the λ/4 plate a second time will

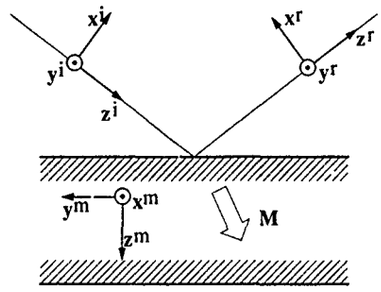

FIG. 3. Basic notations for components of incident and reflected beams from a magnetized surface.

be orthogonal to the original. Thus, the incident beam which is transmitted by the beam splitter is reflected by the beam splitter upon return, and vice versa, and a complete loop is established.

For the more general problem of measuring magneto-optic effects in the presence of linear birefringence, for arbitrary magnetization directions, and away from normal incidence, circular polarization states will no longer be eigenstates of the optical system, and we must search for the two polarization states which will lead to the largest signal. We describe the electric field of a plane wave as

$$\mathbf{E}(z,t)=\mathrm{Re}\{E_0\exp[i(\omega t-\phi)]\exp(-ikz)\}, \tag{2}$$

where $\mathbf{E}_0=E_x\hat{\mathbf{x}}+E_y\hat{\mathbf{y}}$ is the complex vector amplitude, and E_x and E_y are complex. We may then define the Cartesian Jones vector $\mathbf{E}$ as[10]

$$\mathbf{E}=\begin{bmatrix}E_x\\E_y\end{bmatrix}. \tag{3}$$

The action of optical elements on the polarization state may be described by complex 2×2 matrices acting on this vector, assuming that the wave retains its planar character. In Fig. 3 we define the coordinate systems which we shall use to describe the reflection of a plane wave from a magnetic surface. One of these, denoted by the superscript m, refers to the orientation of the magnetization vector in the medium, and the other two refer to the incident and reflected waves, $\mathbf{E}_1^i$ and $\mathbf{E}_1^r$.

The reflectivity matrix for a magnetized reflector, defined by the equation $\mathbf{E}^r=\mathbf{r}(\mathbf{M})\mathbf{E}^i$, is

$$\mathbf{r}(\mathbf{M})=\begin{pmatrix}\mathbf{r}_{pp}+a\mathbf{M}\cdot\mathbf{x}^m & b\mathbf{M}\cdot\mathbf{y}^m+c\mathbf{M}\cdot\mathbf{z}^m\\ -b\mathbf{M}\cdot\mathbf{y}^m+c\mathbf{M}\cdot\mathbf{z}^m & r_{ss}\end{pmatrix}, \tag{4}$$

where a, b, and c are complex coefficients which depend on the optical properties of the material and the experimental geometry, and are generally of order 10^{-3} or less, r_{ss} and r_{pp} are the diagonal elements of the reflectivity matrix for an unmagnetized material, and s and p refer to the usual s- and p-polarization convention. When the magnetization is oriented normal to the plane of incidence, which is the geometry of the transverse Kerr effect, we see that this matrix is diagonal and that the magnetization induces a small linear birefringence. This birefringence is linear in the magnetization, and is a truly nonreciprocal effect. For an appropriate choice of counterpropagating polarization states, the trans-

verse Kerr effect will lead to a nonreciprocal phase shift Magnetization in the plane of incidence leads to nonzero off-diagonal terms, which are responsible for the well-known longitudinal and polar Kerr effects. In particular, the reflectivity matrix will be antisymmetric for magnetization oriented in the plane of the sample surface, and symmetric for magnetization oriented normal to the surface. Again, with the proper choice of polarization states, the nonreciprocal phase shift due to either one of these effects can be maximized. In fact, the symmetry properties of the reflectivity matrix are such that a measurement which is sensitive to the longitudinal effect is completely insensitive to the polar effect, and vice versa, whereas the transverse effect appears in both. By making measurements with three different sets of polarization states, we can completely determine the phase shift associated with each of these effects. In this way we may completely determine the magnetization vector, with no modification of the experimental geometry other than changing the orientations of the wave plates. Detailed analysis of the measurements required to make such a determination will appear in a subsequent publication.

III. NEAR-FIELD SAGNAC MAGNETO-OPTIC SENSOR

Resolution beyond the diffraction limit can be achieved with optical microscopy by operating in the near-field regime, where the evanescent components of the electromagnetic field strongly depend on the environment, i.e., the boundary conditions set by the sample with respect to the source.[11] In this near-field scanning optical microscopy mode (NSOM),[12] a subwavelength source and/or detector of visible light is placed in close proximity (of order of the size of d, the source) to a sample and raster scanned to generate images. The coupling of the near-field radiation to the far field is typically quite weak; the transmission coefficient at normal incidence has been calculated to be[11]

$$T=\frac{P_{\text{trans}}}{P_{\text{inc}}}\approx 10\left(\frac{d}{\lambda}\right)^6. \tag{5}$$

This is for the ideal case of a circular aperture in a perfectly conducting, infinitely thin screen, with diffraction-limited focusing of the radiation illuminating the pinhole; the problem is analogous to Rayleigh scattering (the additional factor of λ^{-2} comes from the illumination spot size). In general, the finite conductivity and thickness of the screen, as well as inefficiencies in the method used to deliver the incident light to the aperture, will lead to a reduction in this value. Recently, Betzig *et al.*[12] have demonstrated such a microscope with a spatial resolution of 120 Å, using as a light source a tapered optical fiber coated with aluminum. Polarization contrast has also been achieved by creating a polarized source and introducing a polarizer between the sample and the detector.[13] By orienting the polarizer near the extinction position, magneto-optic contrast with a resolution of 30–50 nm was observed in thin, transparent magnetic films.[14] Although some progress has been made in imaging opaque materials by using NSOM in reflection,[15–18] serious technical barriers impede similar studies of opaque magnetic samples, and to our knowledge none have been made.

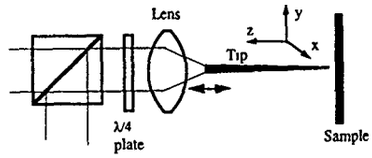

FIG. 4. Arrangement for near-field scanning in conjunction with reflection mode [Fig. 2(b)].

Many of the difficulties in achieving magneto-optic contrast NSOM in reflection are related to the crossed polarizer method for creating the contrast. Moreover, analysis of light scattered away from the normal of the sample is complicated by polarization state changes which are generally dominated by effects which have nothing to do with its magnetic state, such as the shape of the aperture, the direction of radiation in the far field, and the conductivities of both the sample and the tip. Light which reflects back through the aperture from which it came might carry fewer of these spurious polarization effects, but the problem of distinguishing the signal from an overwhelmingly large background becomes significant, since most of the light incident on the aperture is reflected without ever interacting with the sample. In other words, a large amount of "reciprocal" light is expected that will completely mask the real signal. We may expect the intensity which carries the signal to be a factor of 10^{-6} smaller than the incident intensity, and if we are to measure magneto-optic effects by analyzing this light with a crossed polarizer, we may expect a further reduction of 10^{-2}, so this is a formidable problem. One group[16,17] has succeeded in modulating the distance between the tip and the sample and using synchronous detection to attempt to solve this problem, but their resolution is not yet better than the diffraction limit and they have they have not yet addressed polarization effects.

The selective sensitivity of SMOS to nonreciprocal effects has led us to explore the possibility of using it as a detection scheme for NSOM with magneto-optic contrast in reflection. If we introduce an aperture between the focusing optics and the sample in Fig. 4 only the light generated in the near field of the magnetic sample will receive a nonreciprocal phase shift, and the enormous amount of background light which passes through reciprocal optics will go undetected. In fact, the presence of this more intense reciprocal radiation can actually serve to amplify the intensity change due to the small magneto-optic phase shift by means of an optical homodyne effect. Let us decompose the fields in the fiber loop into two components for each of the two counterpropagating waves,

$$E_1=A\,\exp(i\theta)+\alpha_+\,\exp(i\phi_+) \tag{6a}$$

and

$$E_2=A\,\exp(i\theta)+\alpha_-\,\exp(i\phi_-), \tag{6b}$$

where A and θ are the amplitude and phase of the reciprocal part of the fields, and $\alpha_\pm$ and $\phi_\pm$ are the amplitudes and phases of the nonreciprocal part. The nonreciprocal phase shift which we measure upon interfering these two waves will be

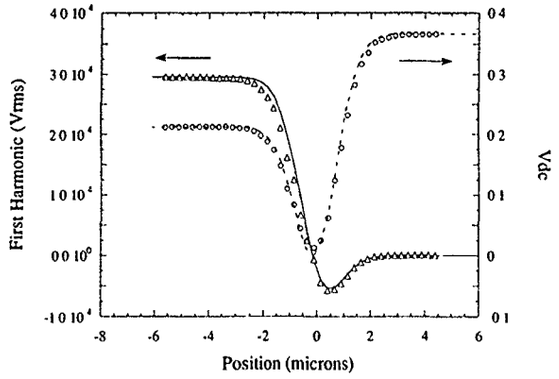

FIG. 5. First-harmonic and dc components of the detector voltage as the edge is traversed with the beam. The edge is at the center of the beam at a position of 0 and the beam is centered on the gold for positive values of the position. Solid and dashed lines represent the fit using Fourier optics analysis.

$$\Delta\phi = \arg\left(\frac{E_1}{E_2}\right) \cong \frac{2\alpha_{\text{avg}}}{A} \sin(\phi_+ - \phi_-)\cos(\phi_{\text{avg}} - \theta), \qquad (7)$$

where $\alpha_{\text{avg}} \equiv (\alpha_+ + \alpha_-)/2$, $\phi_{\text{avg}} \equiv (\phi_+ + \phi_-)/2$, and we have neglected higher-order terms. The signal which we measure is then

$$I_\omega \propto A^2 \Delta\phi = 2\alpha_{\text{avg}} A \sin(\phi_+ - \phi_-)\cos(\phi_{\text{avg}} - \theta), \qquad (8)$$

which is proportional to the field amplitude of the light reflected from the aperture, not the intensity. As a consequence, we may expect our signal to be orders of magnitude larger than NSOM in transmission, where the magneto-optic signal is proportional to the square of both the transmitted field amplitude and the magneto-optic phase shift, both small numbers. For a system which is limited by shot noise, this increase in signal will naturally be accompanied by a corresponding increase in noise, so that the signal-to-noise ratio will not change. However, the dramatic increase in signal strength allows us to move away from photomultiplier tubes to noisier but more convenient photodiode detection schemes.

To verify our analysis, we have deposited 2400 Å of TbFeCo on a silicon wafer, capped it with 200 Å of silicon nitride, then deposited 2000 Å of gold on top as a reflecting layer. We then etched 25 μm lines in the gold to expose the magneto-optic (MO) material, and scanned our beam across the edge dividing the gold from the MO material. The results of this scan are shown in Fig. 5, together with the response which we have calculated using standard Fourier optics techniques.[19] The first-harmonic signal, proportional to the NRPS, as well as the dc detector voltage, proportional to the average intensity, are plotted as a function of beam position on the sample, with the edge at zero. Note that as the edge approaches the center of the beam, both signals drop to zero. This is because the thickness of the gold plus the optical thickness of the nitride cap sum to almost exactly a quarter of one wavelength, so that there is a 180° phase shift between light reflected from the gold and light reflected from the MO material. When the edge is near the center of the beam, the reflected mode is almost fully antisymmetric about

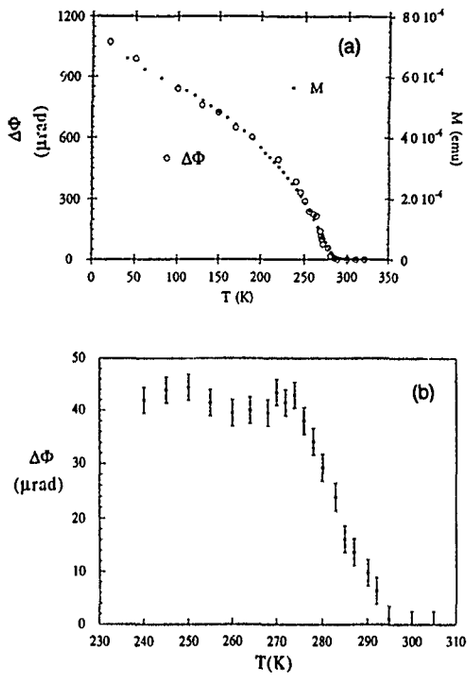

FIG. 6. (a) Transmission (Faraday) measurements and SQUID magnetometry on 480-Å-thick Gd film in an applied field of 30 Oe as a function of temperature. (b) Reflection phase shift using an applied field of 70 Oe.

the plane of the edge and the optical axis, and the single-mode fiber rejects it. As the beam is moved onto the gold, the average intensity increases with the symmetric part of the reflected mode, and the first-harmonic signal crosses zero to become negative. This is exactly the optical homodyning effect described above: Although the bare MO signal is positive, when the wave reflected from the MO material is mixed with the stronger field reflected by the gold, the sign changes because the two waves are shifted relative to each other. In the theoretical fit, we have neglected aberrations in the focusing lens as well as the finite aperture of the lens. There is only one free parameter in the model, the beam radius, which takes a value of 2.2 μm in the curves shown; by simply calculating the magnification of our optics and assuming perfect lenses we obtain a radius of 1.7 μm. The agreement between theory and experiment is quite good, especially considering the limitations of a scalar theory in treating polarization properly.

IV. ADVANTAGES OF SMOS

As explained above, SMOS may achieve high sensitivity and high common-mode rejection for reciprocal effects. The ultimate limit on our sensitivity will be set by the shot noise of the laser. For optical powers of ~1 mW at the detector, the shot-noise-limited sensitivity is ~50 nrad/$\sqrt{\text{Hz}}$. In Fig. 6(a) we show Faraday and superconducting quantum interference device (SQUID) magnetization measurements from 400 Å Gd film. The magnetization lies in the plane, and the Faraday effect measurements have been made in zero field with the sample oriented at 45° to the optical beam. However, the most striking example of the current sensitivity of the appa-

ratus is shown in Fig. 6(b), where the Kerr effect of this 400 Å Gd film is measured through the ferromagnetic transition (T_c=270 K) with only a 70 Oe applied field, with a measurement time of 10 s per point. Currently, we have achieved a NRPS sensitivity of 2 μrad/$\sqrt{\text{Hz}}$ in transmission and 4 μrad/$\sqrt{\text{Hz}}$ in reflection. The sensitivity may be increased toward the shot-noise limit with some improvements in the construction of the apparatus and in particular the power and spectral characteristics of the source.

An important feature of the Sagnac loop is its immunity to reciprocal effects such as linear birefringence or optical activity. This immunity comes from the fact that two beams are experiencing the same optical path, and phase shifts that do not come from broken time-reversal symmetry will exactly cancel each other. This immunity may be particularly important for evaluation of anisotropic materials where birefringence may be difficult to differentiate from Kerr or Faraday effects if not analyzed properly.

Based on the advantages of the SMOS, it is clear that many of the difficulties with doing magneto-optic contrast NSOM in reflection may be eliminated. If SMOS is used, the background light, as much distorted as it may be, will not lead to a background signal. On the contrary, this light serves to amplify the magneto-optically induced signal by orders of magnitude. Moreover, the high sensitivity allows for relatively easier detection of the very small signals. We believe that this method provides an excellent scheme for expanding the potential applications of NSOM.

The advantages of the near-field SMOS (NFSMOS) microscope over other spin-polarized devices are evident. First is the possible high sensitivity, in particular for materials with large magneto-optic coefficient. The second is the spatial resolution. Current near-field optical microscopes reach a spatial resolution of 120 Å. This is smaller than a typical superparamagnetic size and thus extremely useful for the detection of magnetism. Moreover, since the detection is made with light, the relevant probing thickness is of order of optical penetration depth, hence information from deeper than the first few atomic layers can be obtained. Finally, the accumulation of data can be obtained much faster with improvements in efficiency. Thus, one may envision using this method for high-frequency measurements.

V. SUMMARY

The above instrument opens for us new avenues in the research of magnetic materials. In particular we believe that because of the complete rejection of any reciprocal optical effects, the instrument is ideal for use in reflection mode in a near-field configuration. In this way, it may be possible to do magneto-optics on a scale of ~200 Å (current near-field microscopy using tips that preserve polarization may go to a length scale of ~120 Å). This could potentially lead to new opportunities in high-density magnetic recording and magneto-optic readout.

ACKNOWLEDGMENTS

We would like to thank Michael Farle for equipment and useful discussion, as well as Federico Sequeda for fabricating the TbFeCo wafer. We would also like to acknowledge the fruitful collaborations along many phases of this work, in particular with S. Spielman and T. Geballe. Parts of this work were supported by AFOSR, by NSF through the Center for Materials Research at Stanford University, by a special grant from IBM, and by a grant from Stanford Office for Technology Licencing.

dc magnetic force microscopy imaging of thin-film recording head

Paul Rice, John Moreland, and Andrzej Wadas
Electromagnetic Technology Division, National Institute of Standards and Technology, Boulder, Colorado 80303

Using a new form of magnetic force microscope (dc MFM) magnetic force images of a thin-film recording head have been made. Using dc MFM, atomic force microscope images are presented of the surface topography and magnetic forces taken simultaneously, allowing direct correlation of magnetic fields to the pole pieces. Magnetic force images of the head at typical head-to-disk spacings are presented. The tips used for these images had two different magnetic coatings.

I. INTRODUCTION

Recently magnetic force microscopy (MFM) has been used to study the field patterns of thin-film recording heads.[1–5] There are two fundamental modes of MFM. In one method, a vibrating cantilever is used to detect the force gradient between the sample and sensing tip attached to the cantilever. This method referred to in this article as ac MFM, in principal, has high sensitivity.[6] The ac-MFM data can be integrated to obtain the force profile. The other type of MFM detects the deflection of a nonvibrating cantilever due to the magnetic interaction between the tip and the sample. We refer to this as dc MFM. In dc MFM the force profile can be directly obtained by multiplying the tip displacement by the cantilever spring constant. This article describes our results for applying a new form of dc MFM to thin-film recording heads.

II. EXPERIMENT

Traditionally dc MFM was difficult to apply, because there was no sensing mechanism to position the tip from the sample. Early dc-MFM attempts would scan the entire section of the sample to be imaged, saving slope information or manually adjusting the sample slope, then scan the sample again with the tip raised off the sample.[7] There were problems with the tip-to-sample distance varying due to piezopositioner creep or hysteresis, and also surface roughness. Since the force profile is dependent on distance, the magnetic force map was not uniform and there were problems preserving the tip-sample separation.

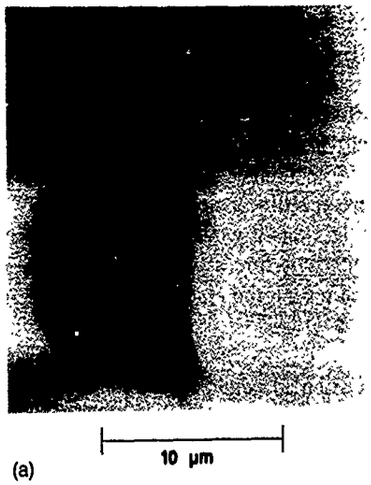
Recently a new dc-MFM operating technique that is based on these previous efforts was developed, although with one major modification:[8] instead of scanning the entire image and storing the slope, the sample is scanned one line at a time. First a line scan is performed using atomic force microscopy (AFM) contact mode. The topographical and slope information is stored. The tip is then lifted and scanned using the stored topography and slope information to position the tip from the surface. On this second scan the deflection of the tip is recorded as the magnetic signal. This allows for accurate tracking of the sample surface during the magnetic scan since the tip is away from the surface for only one scan line, thus minimizing error due to piezo drift. This also allows for simultaneous imaging of topography and magnetic force. While holding the tip steady, we estimate our cantilever vibration noise to be less than 0.1 nm and therefore conclude that we can detect forces less than 1×10^{-10} N when using tips with less than 1 N/m spring constant. Also, lateral resolution in many cases is not limited by force sensitivity, but more often limited by the shape and magnetic domain structure at the end of the MFM tip.

Two thin-film heads were measured. These were standard thin-film heads with two pole pieces that were approximately 9×3 μm^2 as measured by the AFM. The separation of the poles (gap length), also measured with the AFM, varies from 300 to 500 nm. The nonuniform gap length can be attributed to polishing. On one of the heads imaged, the pole pieces were vertically offset by 200 nm. This was visible in the optical microscope and appeared to be a fracture. Although apparently flawed, the head still wrote magnetic bit patterns and produced a strong magnetic field as measured by the MFM. Separation between disk and head, or flying height, is typically between 50 and 100 nm. Saturation current for these heads was reportedly 40 mA.

The heads were removed from the flexures and mounted in the MFM with the trailing edge of the slider to the left-hand side relative to the images presented. The head was driven with a dc current source. The tips for these measurements were standard 100 μm Si_3N_4 microfabricated cantilevers. The images presented were from two tips. One was coated with 20 nm Fe base layer and a 5 nm Au cap layer. The spring constant for this tip was 0.38 N/m as reported by the supplier. The second tip was coated with 10 nm Fe base layer and a 10 nm Au cap layer with a spring constant of 0.58 N/m. The Au coating was to minimize oxidation of the Fe. It was calculated that the change in spring constant due to these coatings was less than 5%.

III. RESULTS

Figures 1(a) and 1(b) are top-view images of the unfractured head. The second tip as described above was used for this measurement. Figure 1(a) is magnetic and Fig. 1(b) is topographic. In the magnetic image, attractive forces are indicated by dark contrast. The tip is constrained to flexing vertically, so the forces imaged are primarily vertical. The current to the head was 10 mA dc. The gap in the magnetic image can be seen as a bright line accented by the dark contrast of the pole pieces. For the magnetic image, the tip was scanned 100 nm above the surface. The maximum tip deflection is 30 nm. Multiplying this by 0.58 N/m gives a force of 17.4×10^{-9} N. Decreasing the tip height above the sample increases the magnetic contrast due to the increasing field gradient, but no additional magnetic microstructure ap-



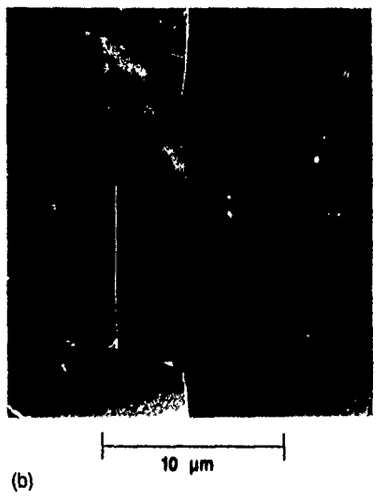


FIG. 1. (a) Magnetic force image of the air bearing surface of a thin-film head, taken as it was driven with a current of 10 mA, with a tip-to-head separation of 100 nm. The head is oriented with the trailing edge of the slider to the left-hand side. The arrow indicates the magnetic gap. (b) Corresponding topography of the thin-film head taken simultaneously with the magnetic force image. The dark rhombus is the leading pole piece, which is recessed 20 nm due to polishing effects. The arrow indicates the gap between the pole pieces.

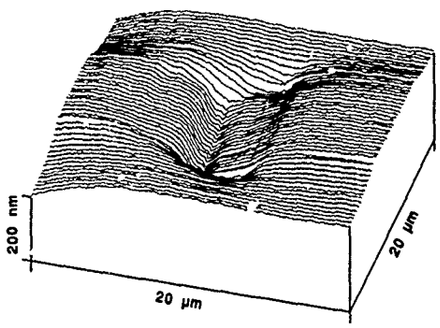

FIG. 2. Magnetic force image line scan taken of the head as it was driven with a current of 30 mA, with a tip-to-head separation of 100 nm. The gap is located at the lowest area on the scan. In the bottom of this depression, the gap can be distinguished as small rise in the scan lines. The attraction of the pole pieces is evident on both sides of the gap.

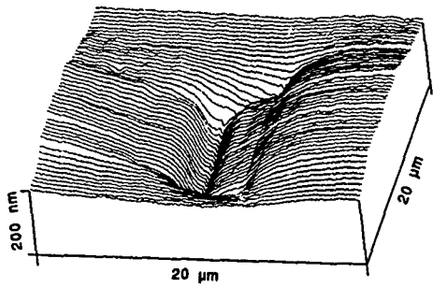

FIG. 3. Magnetic force image line scan taken of the head as it was driven with a current of 30 mA, with a tip-to-head separation of 50 nm. Notice the increase of the depression due to the increased magnetic force.

pears. Pole recession of 20 nm caused by polishing can be seen in Fig. 1(b) (topographical image of the head). Comparing the magnetic image to the topographical image shows that the magnetic contrast trails off, shadowing the edge of the pole piece. These fields compare closely with calculations of thin-film head field profiles by Zhu, Ye, and Arnoldussen.[9] Figure 2 is a line scan of the magnetic image taken with the tip height at 100 nm and a head drive current of 30 mA. The magnetic gap is more clearly visible in the line scan image, as is the attraction due to the pole pieces. Varying the head drive current increased tip deflection linearly with current. Tip displacement for this image is 85 nm with a corresponding force of 5×10^{-8} N. With the tip-to-head spacing again at 100 nm and the head current increased to 100 mA, the tip continually snapped onto the sample. This is attributed to the soft spring constant of the cantilever.

Figure 3 is taken with the tip height at 50 nm and a head drive current of 30 mA; this technique can explore the head field at heights comparable to typical head-to-disk separations. For this image, a tip displacement of 120 nm corresponds to a magnetic force of 7×10^{-8} N.

The arrows in Fig. 4 point to two small depressions. These are the edges of the pole pieces where the field diverges most rapidly. Below the scan line, the pole pieces are indicated as blocks. This image shows that the tip is magnetically soft, since it is attracted to the pole pieces regardless of polarity. A magnetically soft tip minimizes force variations due to domain switching that can occur in high-

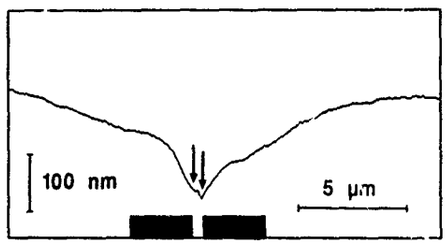

FIG. 4. An individual magnetic scan taken through the center of the head. The head was driven with a current of 30 mA and imaged with a tip-to-head separation of 100 nm. The pole piece positions are indicated as blocks below the magnetic scan line. As seen here both pole pieces attract the tip which indicates that the tip is magnetically soft.

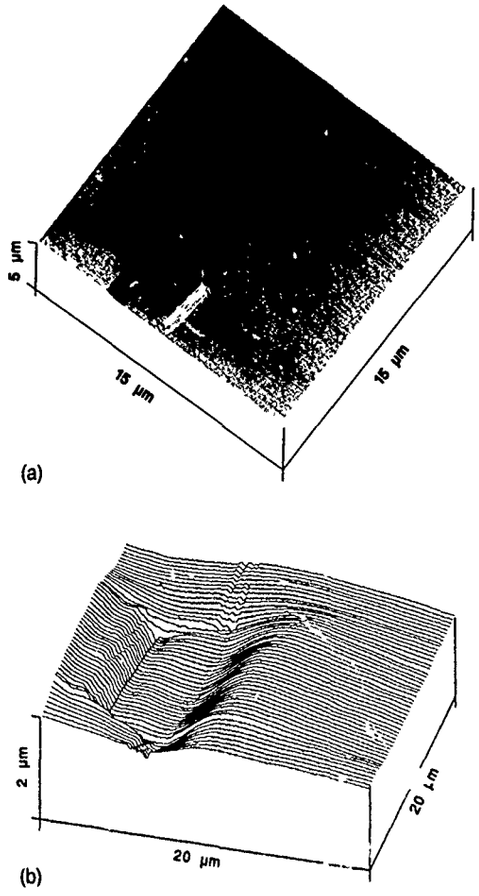

FIG. 5. (a) Topographic image of a flawed thin-film head. The step height is 200 nm. Notice the depression at the base of the step, this appears to be a crack in the head. (b) The corresponding magnetic force image, displayed as a line scan, demonstrates the ability of this MFM to image even very rough magnetic samples. For this image the head was driven with a current of 30 mA and tip-to-head separation was 187 nm. The tip used had a 20 nm coating of Fe.

coercivity (magnetically hard) tips. In the gap the magnetic field gradient is low and deflects the tip less. The asymmetry of the image is likely due to the pole recession. Scanning direction and tip angle can also make the image asymmetrical. In this case the offset seems to be comparable to the pole recession height.

As measured in air, the tip-to-head spacing for good magnetic imaging appears to be a function of surface roughness and tip spring constant. If the surface is rough or the cantilever is very flexible, the tip snaps onto the surface often. This is attributed to the difficulty of maintaining the head-to-tip separation as force deflections cannot be anticipated during the AFM scan. With proper selection of cantilever spring constants and magnetic tip coatings, rough surfaces with large magnetic fields can be imaged. Figure 5(a) shows a topographical surface view of the head with the 200 nm vertical offset defect. The trailing pole piece is 200 nm higher than the leading one, as measured by the AFM. There is what looks like a crack at the gap making it difficult to measure the gap length. Figure 5(b) is a line scan display of the magnetic force image. The magnetic image presented was taken with a tip-to-head separation of 187 nm. When the tip was closer than this it would contact the surface and van der Wals or meniscus forces would keep the tip in contact with the surface during the rest of the scanline.

IV. SUMMARY

We have presented magnetic force images of dc current driven thin-film heads that were taken with a dc-operated magnetic force microscope. This has allowed us to study the fringing fields above thin-film heads at different driving currents and tip-to-head separations. Comparison of surface topography and magnetic forces has shown that there are magnetic fields associated with the ends of the pole pieces. These fields could possibly contribute to off-track failures of the drive if they are strong enough. With coatings of 10 or 20 nm Fe the tips are magnetically soft, while they scan the head with currents of 10–30 mA. Simultaneous imaging of surface topography and magnetic force is an advantage of this newly developed dc-MFM technique. A further advantage is that the tip-to-sample separation can be more accurately monitored, allowing much rougher samples to be imaged. In contrast, ac MFM measures the magnetic force gradient whereas dc MFM measures the magnetic force which is obtained by simply multiplying the tip deflection by the spring constant. Also, the sensitivity of dc MFM is comparable to ac MFM (in air) and detection of tip deflection is less complicated than phase shifts or amplitude changes of a vibrating tip.

ACKNOWLEDGMENT

We thank Jim Brug of Hewlett-Packard Corp. for providing the thin-film heads and for helpful discussions.

Proposed antiferromagnetically coupled dual-layer magnetic force microscope tips

John O. Oti, Paul Rice, and Stephen E. Russek
Electromagnetic Technology Division, National Institute of Standards and Technology, Boulder, Colorado 80303

A magnetic force microscope tip designed from dual-layer magnetic films of antiferromagnetically coupled magnetic layers is proposed. A theoretical analysis of the possible advantages of such a tip over conventional single-layer tips is given, using an extension to dual layers of a previously described micromagnetic model of single-layer tips. In contrast to single-layer tips, the magnetic domains of dual-layer tips are less sensitive to the fringing fields of the specimen, and the tips' stray fields are greatly reduced, thus minimizing the likelihood of erasure of the sample magnetization. These properties of dual-layer tips should lead to improved resolution of magnetic force microscopy images.

I. INTRODUCTION

The imaging component of a magnetic force microscope (MFM) system is a probe in the form of a sharp tip mounted at the end of a soft cantilevered spring and positioned near the surface of the specimen. The MFM image is obtained from the force interactions between the tip and specimen. Traditionally, MFM tips have been made from a single magnetic material, and a variety of tip shapes and materials have found practical application.

A MFM tip should remain uniformly magnetized as it interacts with a specimen and not generate large stray fields that inadvertently alter the magnetization pattern of the specimen. The first property helps the interpretation of images, while a contravention of the second property defeats the aim of the imaging process, which is to obtain an image of the magnetization of the specimen without destroying it. In this regard, traditional MFM tips have limited capabilities. Traditional soft magnetic tips, such as nickel with a coercivity H_c of about 40 A/m and a saturation magnetization M_s of about 500 kA/m, are, by virtue of their low coercivities, unsuitable for imaging high-moment films. Their magnetization is usually rendered unstable by the large fringing field of the film surfaces. A hard magnetic tip such as iron ($H_c \approx 160$ kA/m, $M_s \approx 1700$ kA/m), although largely immune to effects of fringing field, can itself generate high enough stray fields to alter the magnetization of soft magnetic films. All this limits the range of applicability of the tips.

We propose a new MFM tip that overcomes these limitations. The new tip is a dual-layer magnetic film, with strongly antiferromagnetically coupled ferromagnetic layers separated by a nonmagnetic layer. Each magnetic layer and the separation layer are a few nanometers thick. Strong antiferromagnetic coupling maintains the stability of oppositely directed domains in the magnetic layers. The resulting magnetic-field-flux closure at the tip edges reduces the tip's stray fields. The tip's stray field pattern leads to improved resolution of MFM images.

We have developed a micromagnetic MFM model to analyze the dual-layer tips. An analysis of the effects of the antiferromagnetic coupling on the response of dual-layer tips is presented in this article. Traditional MFM tips are called simply single-layer tips in the article.

II. MICROMAGNETIC MODEL

The micromagnetic model of the proposed tip is an extension of our previously described single-layer model.[1] The geometry of the dual-layer model for a triangular tip is shown in Fig. 1(a). The tip is scanned at a fixed distance d_0 above the sample from point A to point B. Other tip shapes

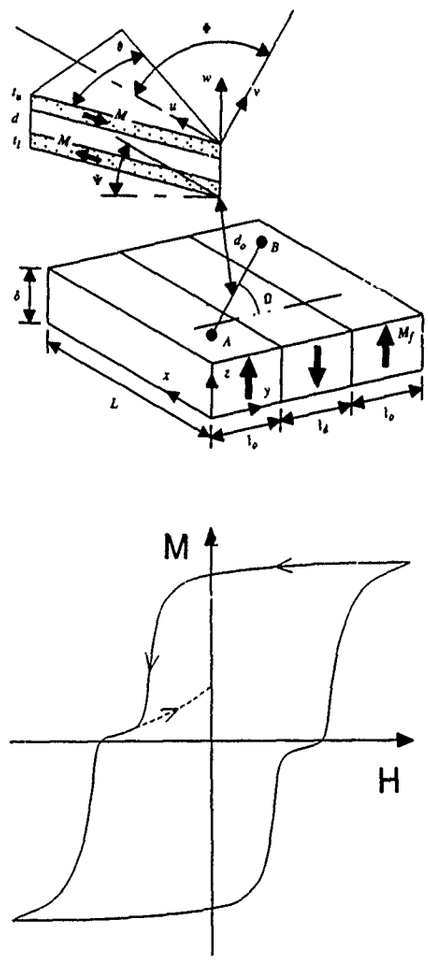

FIG. 1. (a) Geometry of micromagnetic model, showing defining dimensions and two abrupt Bloch walls. (b) Illustration of the field sequence for obtaining antiferromagnetic coupled bilayers. Arrows indicate the path traversed in the major hysteresis curve of the tip in the v direction.

such as bars are possible. A way of traversing the major hysteresis loop which results in the antiparallel orientation of magnetization in the ferromagnetic layers is illustrated in Fig. 1(b). The humps that are formed in the branches of the hysteresis loop are due to the difference in the switching fields of the magnetic layers that is enhanced by the antiferromagnetic coupling between them. Subscripts u and l are used to distinguish between quantities of the upper and lower magnetic layers of the tip in Fig. 1(a). The upper and lower magnetic layers have thicknesses of t_u and t_l, and are separated by a nonmagnetic layer of thickness d. Each magnetic layer is modeled using closely packed discrete elements with rectangular parallelipiped shapes that have square cross sections in the plane of the probe [the u-v plane of Fig. 1(a)]. The elements represent the grains of the tip medium. The grains interact with each other by nearest-neighbor exchange and long-range magnetostatic interactions. The magnetization of the tip can vary, but that of the film is assumed unaffected by its interaction with the tip. A detailed account of modeling the magnetic layers and calculating forces acting on the tip is given in Ref. 1. Antiferromagnetic coupling between the magnetic layers is simulated by introducing a negative interlayer exchange-interaction parameter. The effective exchange interaction field acting on a grain of the upper layer is given by[1,2]

$$H_u=\frac{2A_u}{(M_uD)^2}\sum M_u+\frac{2A'}{(M_uD)^2}M_l, \tag{1}$$

where $A_u \geq 0$ is a phenomenological ferromagnetic exchange parameter for the top layer, $A' \leq 0$ is a phenomenological interlayer antiferromagnetic-exchange parameter, D is grain size, and M_u, M_l are the magnetization of grains of the upper and lower layers. The first term on the right-hand side of Eq. (1) represents the exchange interactions among grains of the upper layer; the summation is over the nearest neighbors of the grains. The second term of Eq. (1) represents exchange interactions of the upper layer with grains of the lower layer. Interlayer exchange interactions are assumed to occur between grains in corresponding positions in the layers. Positive values of A' could be used when ferromagnetic exchange coupling between the layers is intended. For simplicity it is assumed that the magnetocrystalline anisotropic properties, the magnetization and grain size D are identical for both magnetic layers. The expression for the exchange interaction field in the lower layer is obtained from Eq. (1) by interchanging the roles of the subscripts u and l.

III. SIMULATION RESULTS

The stray field patterns of the dual-layer and single-layer tips, in the active regions of the tips, are compared in Fig. 2. The stray field of the single-layer tip radiates outwardly from the tip toward the sample surface and thus is more likely to affect the magnetization of the sample. The stray field of the dual-layer tip, on the other hand, is localized about the active region due to magnetization flux closure stemming from the proximity of the opposite magnetic poles in the magnetic layers. The force sensitivity of the dual-layer tip is affected by the choice of the layer thicknesses t_u and t_l. In a region of

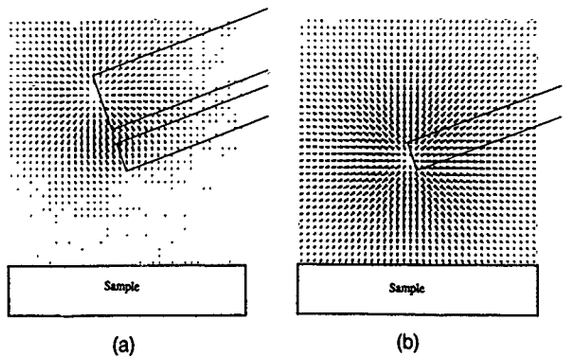

FIG. 2. Longitudinal section (in the u-w plane of Fig. 1) of stray fields for triangular tips for (a) dual-layer tip and (b) single-layer tip.

constant fringing field of the sample, the force acting on a tip of equally thick magnetic layers with a small separation between them is vanishingly small; however, when the layers have the same thicknesses, the tip is sensitive to field gradients. When the tip distance d_0 is less than the layer spacing d, these gradient forces can be nearly as large as the forces acting on a single-layer tip in a uniform field.

Force profiles from a single scan of two abrupt Bloch walls [Fig. 1(a)], for three different antiferromagnetic exchange parameters A', are plotted in Fig. 3. A tip magnetization of $M=1430$ kA/m and first-order anisotropy constant of $K=4.3\times10^5$ J/m^3, corresponding to those of cobalt,[3] were used in the calculations; magnetic layer thicknesses $t_u=10$ nm and $t_l=15$ nm and an interlayer separation $d=2$ nm were used. An intralayer exchange constant $A=4\times10^{-10}$ J/m, corresponding to a maximum exchange field of 2343 kA/m, was used. The tip was inclined at an angle $\psi=30°$ to the sample and separated from it by $d_0=5$ nm. The tip was scanned normal to the domain wall [$\Omega=0°$ in Fig. 1(a)]. The same grain sizes, linear dimensions of the tips, and gyromagnetic parameters as in Ref. 1 were used. Each cobalt grain is characterized by a uniaxial magnetocrystalline anisotropy; the anisotropy directions were assigned randomly among the grains in the calculation. The sample

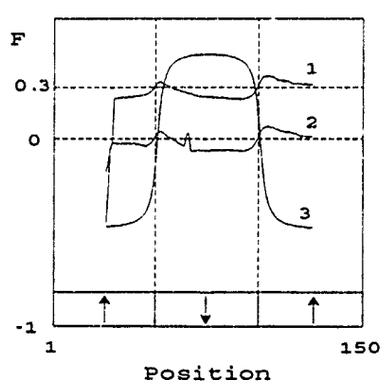

FIG. 3. Profiles of reduced force F as functions of interlayer antiferromagnetic coupling A' for $A'=-4\times10^{-11}$ J/m equivalent to an antiferromagnetic coupling field $H_{AF}=468.5$ kA/m (curve 1), $A'=0$, $H_{AF}=0$ (curve 2), and $A'=-2\times10^{-10}$ J/m, $H_{AF}=2343$ kA/m (curve 3). Curve 1 is displaced vertically by 0.3 for clarity.

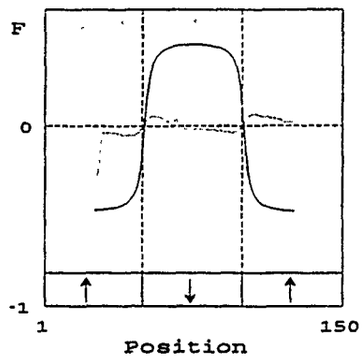

FIG. 4. Force profiles of dual-layer tip with $A' = -2\times10^{-10}$ J/m (solid curve) and single-layer tip (dotted curve).

properties were chosen to correspond to those of a magnetic garnet film described in Ref. 1. The following linear dimensions of the sample were used in the calculations [see Fig. 1(a)]: δ=2000 nm, $l_d = l_0 = 500$ nm, and $L = 1000$ nm.

The antiferromagnetic-coupled state of the magnetic layers is a low-energy state, which requires an external field greater than the antiferromagnetic coupling field to move it away from this state. The force profile is greatly distorted for $A' = 0$ and -4×10^{-11} J/m (curves 1 and 2) because the fringing field surpasses the antiferromagnetic coupling field and leads to instability of the magnetic domains. With increasing A' the magnetic domains of the tip gradually stabilize, the force increases, and the force transition regions sharpen (curve 3). Stable tip domains also lead to larger force amplitudes. The calculation was repeated for a single-layer tip using the same shape and mutual orientation of the tip and sample as for the dual-layer tips. The single-layer tip had a thickness equal to the combined thickness of the magnetic layers of the dual-layer tips, and the magnetic properties were the same as those of the magnetic layers of the dual-layer tips. The calculated force profile of the single layer tip is compared with that of a dual-layer tip having $A' = -2\times10^{-10}$ J/m in Fig. 4; the dual-layer tip produces a larger force with a sharper transition region which is better centered and more nearly symmetrical relative to the domain walls. These properties, due to the stability of domains, in the magnetic layers lead to a better spatial resolution of the final MFM image.

IV. DISCUSSION

Strongly antiferromagnetically coupled multilayer magnetic films that are currently receiving a lot of attention in the literature in connection with their giant magnetoresistance properties would make good candidate materials for constructing the dual-layer tips.[4] The range of interlayer separation d corresponding to antiferromagnetic coupling between the magnetic layers is material dependent. An Fe-Cr-Fe system reported in Ref. 4 has a coupling field of 1600 kA/m. The magnitude of the fringing field close to the surface of the film is bounded by the value of the saturation remanent magnetization. The saturation remanent magnetization of metallic recording films,[3] for example, ranges from 400 to 1000 kA/m, which is smaller than the coupling field of the Fe-Cr-Fe system. Thus, a Fe-Cr-Fe probe is expected to remain stable while imaging such films or films with lesser saturation magnetization values. Other coupled multilayers such as Co-Cr-Co, Co-Ru-Co, and Co-Cu-Co multilayers with coupling fields of comparable magnitudes to the Fe-Cr-Fe system have also been reported.[5,6]

Anisotropy and magnetostriction measurement by interferometry

Peter S. Harllee III, George H. Bellesis, and David N. Lambeth
ECE Department, Data Storage Systems Center, Carnegie Mellon University, Pittsburgh, Pennsylvania 15213

Extending the use of a laser-Doppler interferometer that measures magnetostriction by measuring the deflection of a thin-film cantilever sample to also measure the anisotropy is reported. When the sample is driven with a rotating magnetic field of constant magnitude, a number of harmonics of twice the rotating field frequency are evidence of the magnetization vector lagging and leading the drive field around the sample. Altering the magnitude of the drive field so that the H vector traces out an ellipse is found to null the harmonic signals. This ellipse has its major axis aligned with the hard axis. Using the Stoner–Wohlfarth single-domain-particle model, it is shown that a rotating field will cause the magnetization to rotate around the particle uniformly only if the difference in magnitude between the fields along the major and minor axes is equal to the anisotropy field. Measurements on isotropic and anisotropic samples confirm the theory.

I. INTRODUCTION

In the beam deflection method of measuring saturation magnetostriction λ_s a magnetically soft thin-film material deposited on a nonmagnetic substrate is subjected to a rotating magnetic field.[1-3] As the magnetization rotates, the thin film expands (or contracts for $\lambda_s<0$), creating a stress on the substrate, which causes the substrate and film to bend. Typically, a rectangular cantilever sample is clamped on one end and the deflection of the free end is measured. This deflection is measured using a laser Doppler interferometer.[3] A laser beam is reflected off the sample and off a nearby stationary mirror, and is interfered with a second beam whose frequency is shifted by 50 kHz. This produces two sinusoidal signals that differ in phase by 2π times twice the distance between the sample and the nearby mirror divided by the laser wavelength. An inplane rotating field is used to avoid the ambiguity of the demagnetized state; only the difference in deflection is measured as the saturation magnetization is rotated from alignment along the length of the cantilever to alignment perpendicular to the cantilever.

As no difference in the field-induced strain along the cantilever occurs for a 180° change in magnetization direction, magnetization rotating at a frequency f will produce a deflection that oscillates at a frequency $2f$. However, a number of higher harmonics have been observed,[3] which were partly attributed to the magnetization not rotating uniformly with the applied field. Here we describe how the elimination of these harmonics can be used to determine the anisotropy field of the sample.

II. PHYSICAL MODEL

Even though the sample is polycrystalline, for analysis purposes the magnetization of the thin-film sample is assumed to behave as that of a Stoner–Wohlfarth single-domain particle, as illustrated in Fig. 1.

The total energy of this particle when saturated is

$$E_t=K_u \sin^2 \theta - HM_s \cos(\alpha-\theta), \tag{1}$$

where θ is the angle between the magnetization and the easy axis, α is the angle between the applied magnetic field and the easy axis, M_s is the saturation magnetization, H is the magnitude of the applied field, and K_u is the anisotropy constant. An expression for the magnetization direction θ is found by minimizing this energy,

$$\frac{\sin(\alpha-\theta)}{\sin(\theta)\cos(\theta)}=\frac{2K_u}{HM_s}. \tag{2}$$

Straightforward algebraic manipulation yields the following equation for the position of the magnetization for a given applied magnetic field:

$$\frac{\sin(\alpha)}{\sin(\theta)}-\frac{\cos(\alpha)}{\cos(\theta)}=\frac{H_k}{H}, \tag{3}$$

where $H_k=2K_u/M_s$.

If two sets of Helmholtz coils orthogonal to each other generate the rotating field, an expression for the applied field is

$$H(t)=h_x \cos(\omega t)\hat{\mathbf{x}}+h_y \sin(\omega t)\hat{\mathbf{y}}, \tag{4}$$

where the first term is generated by one coil pair and the second term is generated by the other, and where **x** is along the easy axis as shown in Fig. 1. We refer to the case where $h_x=h_y$ as a "circular field," and the case $h_x\neq h_y$ as an "elliptic field."

Substituting Eq. (4) into Eq. (3) gives an expression for the time-dependent magnetization position,

$$\frac{h_y \sin(\omega t)}{\sin(\theta)}-\frac{h_x \cos(\omega t)}{\cos(\theta)}=H_k. \tag{5}$$

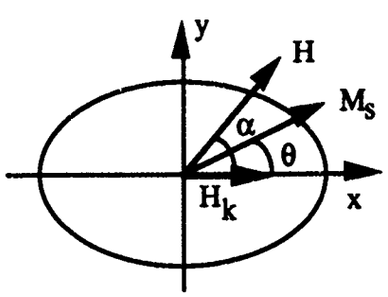

FIG. 1. Stoner–Wohlfarth single-domain particle.

 0021-8979/94/75(10)/6884/3/$6.00 © 1994 American Institute of Physics

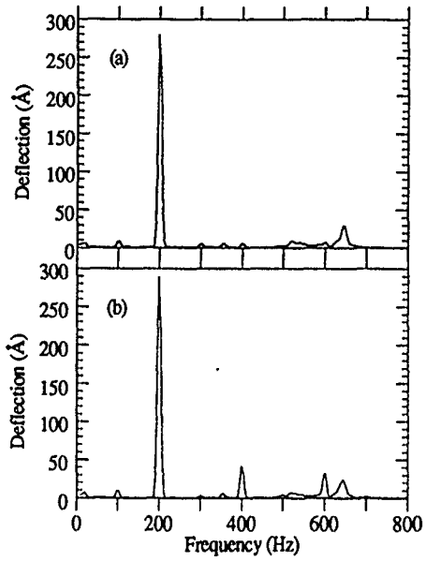

FIG. 2. Round, isotropic sample subjected to (a) a 28.3 Oe circular rotating field, and (b) an elliptic field with $h_y=35.4$ Oe and $h_x=28.3$ Oe.

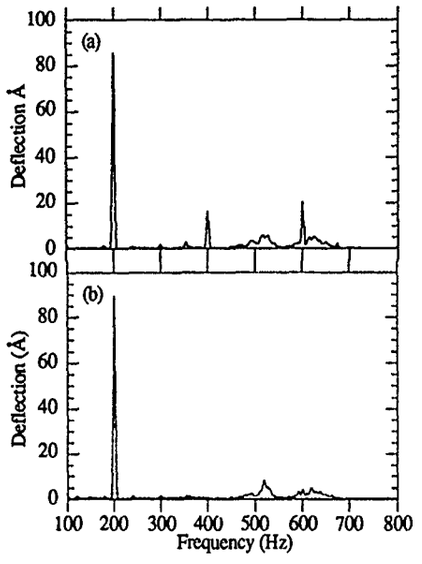

FIG. 3. Round, anisotropic sample subjected to (a) a 28.3 Oe circular field, and (b) an elliptic field with $h_y=36.2$ Oe and $h_x=28.3$ Oe.

In order for the magnetization to rotate uniformly around the sample, θ must equal ωt, yielding

$$h_y - h_x = H_k . \tag{b}$$

This means that when the deflection of the sample occurs at a single frequency, the difference between the field along the hard axis and the field along the easy axis is equal to the anisotropy field of the sample.

The cantilever deflection frequency ϑ (Hz) will be twice the frequency of the magnetization. In a circular field, an isotropic, round sample would have a uniform demagnetization and hence the magnetization would rotate at the field angular frequency ω and the cantilever deflection frequency would be $\vartheta=2\omega/2\pi$. A sample with crystalline anisotropy or a noncircular shape would produce higher harmonics of ϑ. Hence, by Eq. (6), obtaining the h_y and h_x values required to eliminate the higher harmonics yields the sample anisotropy.

III. RESULTS ON PERMALLOY FILMS

The signal spectrum of a 21-mm-diam, 0.5-μm-thick, isotropic FeNiZr film subjected to a 28.3 Oe field rotating at 100 Hz is shown in Fig. 2(a). The peak at 100 Hz is due to a number of causes, including mechanical vibration and metal in the sample holder.[3] A number of harmonics of 60 Hz is observed, and the signal from 580 to 640 Hz is due to the mechanical resonances of the sample. The 200 Hz peak is the magnetostrictive signal ($\lambda_s=2.68\times10^{-6}$). This value is determined from the deflection and the physical properties of the sample: glass substrate thickness is 229 μm, film thickness is 0.5 μm, cantilever length is 0.495 in., and the ratios of the Young's modulus and Poisson's ratio of the substrate and film are 1.611.[3] This spectrum closely matches what the theory predicts, namely for the circular field the only significant deflection due to the sample magnetostriction is at 200 Hz. Only a very weak 400 Hz peak of 5.5 Å is observed.

Figure 2(b) shows the signal spectrum of the same sample when the applied field is changed from circular to an elliptic field with a major axis magnitude of 35.4 Oe and a minor axis magnitude of 28.3 Oe. The 200 Hz peak has risen from 280 to 289 Å because the average field applied to the sample has risen and the sample is not fully saturated at 28.3 Oe. The 400 Hz peak has jumped from 5.5 to 38.1 Å. A 600 Hz term is also apparent, but its magnitude is nonlinearly amplified by the mechanical resonance of the cantilever.

The signal spectrum of a 21-mm-diam, 0.5-μm-thick, anisotropic Permalloy film on a 229 μm glass substrate subjected to a 28.3 Oe field, rotating at 100 Hz, is shown in Fig. 3(a) ($\lambda_s=7.72\times10^{-7}$). It is apparent that this spectrum is very similar to that of the isotropic sample subjected to the elliptic field. Figure 3(b) shows the signal spectrum of the sample when subjected to an elliptic field with a major axis magnitude of 36.2 Oe and a minor axis magnitude of 28.3 Oe. The 400 Hz term has almost vanished, dropping from 16.4 to 0.7 Å. The difference in the fields along the two axes, 7.9 Oe, is equal to the anisotropy field. Figure 4 is a plot of

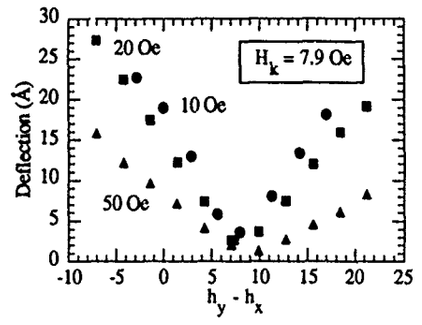

FIG. 4. 400 Hz deflection vs difference in field for several values of easy-axis field.

the 400 Hz deflection as the field along the hard axis is varied for various constant values of field applied along the easy axis. The point at which the 400 Hz term is minimized is the value of the anisotropy field. For this sample the anisotropy field is approximately 7.9 Oe. The uncertainty in the value arises from misalignment of the easy axis of the sample and the axis of the coils, and the value of the field can only be resolved to 0.2 Oe. It is worth noting that as the average field is increased the harmonic strength decreases since the magnetization more closely follows the applied field.

The anisotropy of this sample was also measured using a M-H looper built by SHB industries. The value obtained by the M-H looper was 7.1 Oe. This value differs from that measured using the magnetostriction instrument because in the M-H looper, the film is driven with a field much lower than that needed for saturation, therefore the value of H_k obtained by this method is suspect.[4]

The round isotropic film used to obtain Fig. 2 was cut into a rectangular shape and measured in the instrument. The anisotropy of this sample is almost totally due to shape demagnetization effects. Strictly speaking, the demagnetizing field is nonuniform in the rectangular sample; however, its effect was estimated by considering the sample to be a general ellipsoid with the same axial dimensions as the rectangle. From this approximation the anisotropy due to demagnetization effects was estimated to be 0.5 Oe. The measured value of anisotropy was 1.4 Oe. The difference between the measured and estimated values is most likely due to the difference in the actual demagnetization of a rectangle as opposed to an ellipse.

IV. CONCLUSION

The high sensitivity of the rotating field interferometric magnetostriction instrument has allowed multiple harmonics of the deflection of magnetostrictive cantilevers to be measured. By employing a Stoner–Wohlfarth model it has been shown that these harmonics are directly related to the sample's anisotropy. By creating an elliptical rotating field the harmonics are eliminated and the anisotropy field determined. Measurement of the anisotropy field of a permalloy sample was demonstrated.

New complex permeability measurement device for thin magnetic films

S. Hayano, I. Marinova, and Y. Saito
College of Engineering, Hosei University, Kajino, Koganei, Tokyo 184, Japan

Previously, we have proposed a strategic dual image (SDI) method to obtain the finite element solution of open boundary magnetic field problems. Also, we have derived a complex permeability from a Chua-type magnetization model. Combination of this complex permeability with the SDI method is now applied to exploit a new high frequency characteristic measurement device for thin magnetic films. Numerical simulation suggests that our new measurement method yields far superior results compared with those of the conventional one.

I. INTRODUCTION

At high frequency, the peak flux density in the magnetic materials is sufficiently small that both the flux density and field intensity are sinusoidally time varying. This makes it possible to employ a complex permeability representing the magnetization characteristics. Previously, we proposed a Chua-type magnetization model based on the magnetic domain theory.[1–5] Also, this Chua-type model was successfully applied to derive a complex permeability.[6]

In the present paper, we propose one of the novel methods for measuring the complex permeability of thin magnetic films. The measurement principle of the conventional method is that the mean flux density B in a specimen is obtained from a difference linkage flux between the detection and correction coils; and the field H is obtained from linkage flux of the detection coil. Each of the coils of the conventional measurement method is that the detection and correction coils are arranged in parallel in the exciting coil. In the new method, the detection, correction, and exciting coils are coaxially arranged in each other, and the flux density B is similarly obtained as those of the conventional one, but field intensity H in a specimen can be obtained by extrapolating the field intensities in the outer and inner detection coils. According to the simulation in the two-dimensional (2D) as well as axisymmetric coordinate systems, it is suggested that the new method yields the extremely higher accurate results compared with those of the conventional one.

II. FINITE ELEMENT SOLUTION OF OPEN BOUNDARY HYSTERETIC FIELDS

A. Complex permeability

At high frequency, it is possible to assume that both the flux density and field intensity are sinusoidally time varying. This is because the peak flux density in the magnetic materials is sufficiently small. Thus, it is possible to employ a complex permeability representing the magnetization characteristics. Previously, we proposed a Chua-type magnetization model based on the magnetic domain theory.[1–5] Also this Chua-type model was successfully applied to derive a complex permeability.[6] A Chua-type magnetization model is given by

$$H+(\mu_r/s)dH/dt=(1/\mu)B+(1/s)dB/dt, \tag{1}$$

where H, B, μ, μ_r, and s are the field intensity, flux density, permeability, reversible permeability, and hysteresis coefficient, respectively.[1–5] These parameters can be assumed to take the constant values when the flux density B as well as the field intensity H are sinusoidally time varying. When we employ a complex notation $d/dt=j\omega$, the complex permeability $\mu(\omega)$ is derived from Eq. (1) as

$$\mu(\omega)=B/H=\mu_R(\omega)-j\mu_I(\omega)=\mu[(s^2+\omega^2\mu\mu_r)/(s^2+\omega^2\mu^2)]-j\mu\omega s[(\mu-\mu_r)/(s^2+\omega^2\mu^2)], \tag{2}$$

where $j=\sqrt{-1}$; $\omega=2\pi f$ (f:frequency). Figure 1 shows an example of the frequency characteristics of the complex permeability.

B. Strategic dual image method

For simplicity, let us consider a 2D magnetic field problem having an open boundary. The key idea of the strategic dual image (SDI) method is that any vector fields and their field sources, respectively, can be divided into two components: rotational and divergent.[7–10] Thereby, it is possible to exploit a method by which the rotational and divergent components can be obtained by imposing the rotational and divergent field source images, respectively. In magnetic field problems, the rotational and divergent field sources correspond to the current i and magnetic charge m so that the rotational field component can be obtained by imposing the corresponding image current as shown in Fig. 2(a). In this case, the condition

$$\sum_{p=1}^{q}(i_p/r_p)=0 \tag{3}$$

must be satisfied at the center of a circular hypothetic boundary to reduce the net image to zero. In Eq. (3), q and r_p denote the number of source currents and the distance from a center of the hypothetic boundary to the current i_p, respectively. Equation (3) and the image in Fig. 2(a) mean that the total currents in the problem region must be zero, and the vector potentials at the center as well as on the circular hypothetic boundary must be zero. Therefore, the calculation of the rotational field component can be reduced to the solution of a vector potential problem having zero boundary conditions at the circular hypothetic boundary and the center of its

hypothetic boundary. Similarly, it is possible to show that the calculation of the divergent field component can be reduced to the solution of a scalar potential problem having zero boundary conditions at the circular hypothetic boundary and the center of the hypothetic boundary, as shown in Fig. 2(b). Obviously, the zero boundary condition of scalar potential U at the hypothetic boundary corresponds to the symmetrical boundary condition of vector potential A. This means, if we employ the vector potential A to represent the open field, then the calculation of the divergent field component may be reduced to the solution of a vector potential problem having the symmetrical boundary condition at the circular hypothetic boundary and the zero boundary condition at the center of the hypothetical boundary. Thus, the open boundary field calculation can be reduced to the solution of zero and the symmetrical boundary problems having the circular hypothetic boundary for two dimensions and the elliptic hypothetic boundary having an axial ratio of 1.8 for axisymmetrical dimensions.[7-11] According to Ref. 11, the axial ratio 1.8 in axisymmetrical dimensions could be determined by considering the demagnetization factor of the elliptic solid. Further, the zero condition must be set at the center of the hypothetic boundary by Eq. (3) for both zero and symmetrical boundary problems.

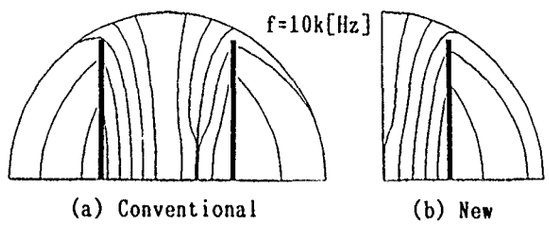

FIG. 4. Field distributions in 2D models. Specimen: TDK H5c2, thickness: 10 (μm), length: 10 (mm), frequency $f=10k$ (Hz).

C. The high frequency measurements for the thin magnetic films

Figure 3 shows the 2D models of a high frequency characteristic measurement device for the thin magnetic films. The measurement principle of the conventional method is that the mean flux density B in a specimen is obtained from a linkage flux difference between the detection and correction coils; and the field H is obtained from the linkage flu ... the detection coil. The principle may be correct if the fields in the correction and detection coils distribute in parallel to each of the correction and detection coil axes. However, this condition is not always held but the reasonable field distribution is distorted by the specimen in the detection coil. In order to overcome this difficulty, we propose here a new method. In this new method, the flux density B is similarly obtained as in the conventional one, but the field intensity H in a specimen can be obtained by extrapolating the field intensities in outer and inner detection coils.

Figure 4 shows the examples of the field distribution in 2D models. Obviously, a field of the conventional measurement method becomes asymmetrically distributed, caused by

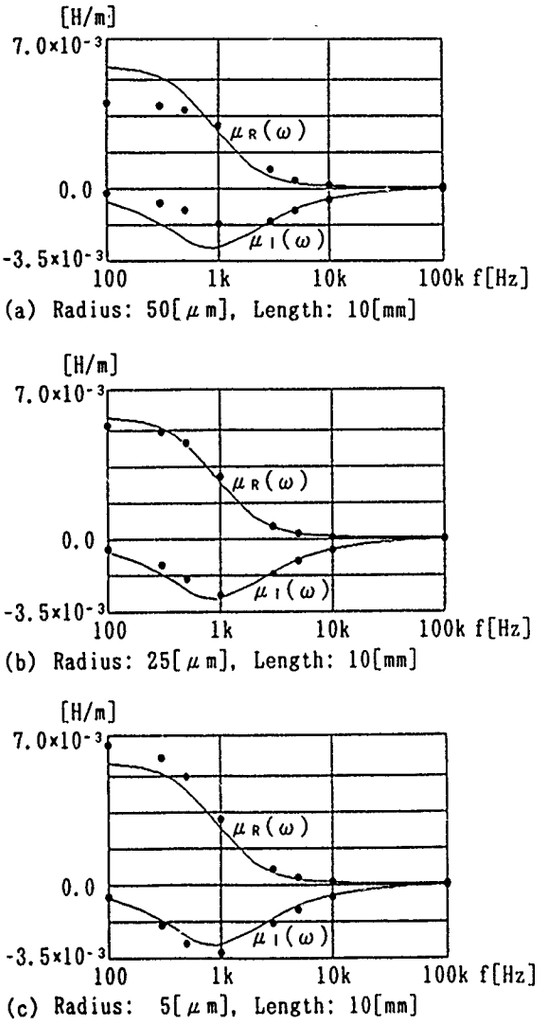

FIG. 6. Frequency characteristics of the complex permeability. Solid lines: exact, solid dots: simulated in the axisymmetrical dimensions assuming the slender magnetic bars instead of thin magnetic films. Specimen: TDK H5c2.

the specimen in the detection coil. On the contrary, a field of the new method becomes symmetrically distributed. This means that it is possible to extrapolate the field intensity H in the material with fairly good accuracy.

Figure 5 shows the comparison between the simulated and exact hysteresis loops in two dimension. The results in Fig. 5 suggest that the new method makes it possible to measure the high and low frequency characteristics of the thin films with higher accuracy.

As shown in Fig. 6, even if the axisymmetrical coordinate system assumes the slender magnetic bars instead of thin magnetic films, it is obvious that the new method provides fairly good results. Also, it is revealed that the measured accuracy becomes higher for slender magnetic bars. This is because the magnetic field distribution in the specimen becomes not uniform for thicker magnetic bars due to the skin effect.

III. CONCLUSION

As shown above, we have shown that the finite element solutions of open boundary hysteretic field problems could be evaluated by combining the SDI method with complex permeability. As an application of our method, the new high frequency characteristic measurement device for the thin magnetic films has been developed to get more accurate results compared with those of the conventional one.

We have used the magnetic circular x-ray dichroism (MCXD) technique to image magnetic domains with a spatial resolution of 1 μm. The experiments employed circularly polarized soft x rays near the edges of the three-dimensional (3d) transition metals Co ($\simeq$780 eV) and Ni ($\simeq$850 eV) and a photoemission microscope based on an electrostatically imaging lens system. Element specific contrast is obtained by tuning to a specific L edge resonance ("white line") and imaging the number of secondary electrons created locally near the surface of the sample. The magnetic contrast arises from the fact that the white line intensity depends on the relative orientation of the photon spin and the local magnetization direction. The obtained contrast is remarkably large ($\simeq$20%) such that images can be recorded without background subtraction. Images taken at the L_3 and L_2 resonance energies give reversed contrast, as expected. Because of the long x-ray and secondary electron mean free paths, images can be recorded for buried magnetic layers which makes this new technique especially valuable for technological applications.

High spatial resolution spin-polarized scanning electron microscopy (abstract)

Spin-polarized scanning electron microscopy (spin SEM) to observe magnetic domains has the potential for spatial resolution as high as 10 nm. The best resolution from spin SEMs attained so far, however, is around 50 nm. In this talk, we report a newly developed spin SEM with 20 nm resolution. The major factor determining the resolution of a spin SEM is probe diameter. A smaller probe diameter, however, results in lower probe current. This is a serious issue in spin SEM because the efficiency of a spin detector is very low. Thus, to get high resolution with a reasonable signal/noise (S/N) image, higher efficiency in the spin detector and/or higher probe current are needed in addition to get a smaller probe diameter. The higher probe current has been attained by using a thermal assisted field emission cathode in an electron gun. The higher efficiency in the spin detector was achieved by increasing the acceptance angle of electron detectors inside the spin detector and optimizing both a secondary collector and transport optics. Obtaining a smaller probe diameter required a low aberration objective lens and a short working distance. Those were achieved by computer calculation so that there was no interference between the objective lens and the secondary collector. This achieved both a short working distance of 20 mm and high secondary collection efficiency. As a result, magnetic images of 20 nm resolution with a 25 keV and 1 nA probe beam have been attained. We have applied this spin SEM to observing recorded bits of longitudinal thin film media at high recording densities.

An analysis of magnetization patterns measured using a magnetic force scanning tunneling microscope (abstract)

E. R. Burke
Laboratory for Physical Science, College Park, Maryland 20740

R. D. Gomez and I. D. Mayergoyz
Department of Electrical Engineering, Institute for Advanced Computer Studies, University of Maryland, College Park, Maryland 20742

In a previous paper,[1] we made a complete analysis of the interaction between the probe tip of a magnetic force scanning tunneling microscope (MFSTM) and the magnetic fields emanating from a typical recorded pattern. In this paper we show how the magnetization distribution in the recorded media can be determined from the measurements by obtaining expressions for the magnetic fields from a Fourier series expansion for the recorded magnetizations. We have used these techniques to find the magnetic fields from many different distributions, including all those we could find in the literature. The probe tip displacement, which is the quantity measured using the MFSTM, can be calculated using these magnetic fields. The results can then be compared to the experimental data. For one set of experiments on high density recording we have found that the best fit is with a magnetization that has a modified arctan transition. The modification eliminates the discontinuity in the slope of the transitions as they are joined together, giving a more realistic representation of the magnetic distribution. The transition width can then be used as an adjustable parameter to find the best fit to the data. The MFSTM can, therefore, be used as a quantitative tool to find the magnetic recording transition widths. These theoretical techniques are not necessarily restricted to the use of a MFSTM, but can be applied to other problems in magnetic recording. For instance, we show how the probe tip displacement corresponds to the flux picked up by a conventional read head. The response of the head as a function of different magnetization patterns can then be studied and compared to experimental results. The measurable quantities are expressed in Fourier series but we show how these series can be easily evaluated with a PC and the appropriate software.

The micromagnetic domain structure of a magnetite (Fe_3O_4) single crystal has been studied using a magnetic force microscope (MFM). The MFM responds to the perpendicular component of the stray field above the magnetite surface. The sample was polished in the (011) plane. In this case, there are two easy magnetic axes parallel to tne surface. Surface domains observed near cracks and edges have a complex closure structure (see Fig. 1), while walls seen far from such boundaries have a sinusoidal structure. Of particular interest is the presence of walls with either even or odd symmetry of the perpendicular stray field component across the transition. These can be conventionally modeled as Bloch or Neel walls, respectively. Both types of walls have been modeled and compared with the experimentally observed structures. We find the Bloch domain walls to be about 300 nm wide, nearly twice the value expected from bulk wall calculations. This distinction is consistent with a surface broadening of the domain wall due to magnetostatic effects.[1]

Interpretation of magnetic force microscopic images (abstract)

Atsushi Kikukawa, Hiroyuki Awano, Sumio Hosaka, Yukio Honda, and Ryo Imura
Central Research Laboratory, Hitachi, Ltd., 1-280 Higashi-koigakubo, Kokubunjishi, Tokyo 185, Japan

The authors have developed a magnetic force microscope (MFM) which works in a vacuum. By detecting the cantilever resonance frequency directly, it takes full advantage of the improved cantilever resonance quality, lowered noise level, and improved resolution, due to reduction of the air resistance that the cantilever suffers. Detailed observations on various magnetic recording media were made employing this instrument. An obstacle in interpreting the MFM images is that they contain both the magnetic image and the surface corrugation (directly related to the atomic force) since the cantilever detects both magnetic and atomic force at the same time. One solution for this is to compare the images of the same region observed at different tip to sample spacings because the contrast due to the magnetic force decreases as the tip to sample spacing reduces. We confirmed that this decrement in magnetic contrast occurs due to the effects of the atomic force by predicting the MFM image theoretically, utilizing a model which has taken in the effect of the atomic force estimated by an experiment. An example among the analyses on various magnetic recording media is the analysis of the magneto-optical (MO) disks which have undergone the heat cycle test. The MFM revealed the existence of irregular shaped domains, which were not observed with the conventional methods (Kerr effect microscopes) in the badly damaged regions. This information was helpful in detecting the deterioration that occurred to the magnetic layer. The authors are convinced that MFM would become a powerful and convenient tool for analyzing magnetic recording media.

Determination of para- and ferromagnetic components of magnetization and magnetoresistance of granular Co/Ag films (invited)

Mary Beth Stearns and Yuanda Cheng[a)]
Department of Physics and Astronomy, Arizona State University, Tempe, Arizona 85287

Several series of thin films (~3000 Å) were fabricated by coevaporation of Co and Ag in a dual *e*-beam UHV system at substrate temperatures, T_S, between 300 and 500 K. The composition was varied between 23 and 54 at. % Co. The maximum measured magnetoresistance was 31% at room and 67% at nitrogen temperature. Magnetization and Rutherford backscattering measurements showed that the Co and Ag atoms are completely segregated for films deposited at $T_S \geq 400$ K. The magnetoresistance (MR) and magnetization curves have been analyzed taking into account both the paramagnetic (PM) and ferromagnetic (FM) contributions that are observed to be present. The films having ≤32 at. % Co are entirely paramagnetic. The fraction of Co atoms in the ferromagnetic component increases monotonically with increasing T_S and/or at. % Co. The average radii of the PM granules in the films having an MR effect of 25%–31% are ~20–22 Å with a minimum average separation of ~10 Å. The large MR values attained in both the PM and FM components are attributed to the small effective domain sizes, ~40–50 Å. The MR values are large because the MR effect varies inversely as the mean-free-path for magnetic boundary scattering which is the average distance between domain boundaries. The variation of the resistive and magnetic behavior of the films was also studied as a function of the annealing time for an annealing temperature of 300 °C. A striking behavior seen in these films is the long relaxation times when a FM component is present.

INTRODUCTION

The Co_xAg_{1-x} system has been found to be an ideal prototypical system to study in order to examine the origin of the "giant" room temperature magnetoresistance (GMR) effect which has been seen to occur in a wide variety of multilayer and granular nanostructures. The feature that makes this system ideal is that the Co and Ag segregate essentially completely under the proper fabrication conditions. This segregation occurs because the surface free energy[1] of Co (2.71 J/m^2) is more than twice that of Ag (1.30 J/m^2) causing the Co to cluster. There is a very poor lattice match since fcc Ag has a lattice parameter that is 15% larger than that of fcc Co. The heat of formation between Co and Ag is positive (+26 kJ/g atom) so that there is no tendency for formation of the compound CoAg or for alloying.[2]

The Co_xCu_{1-x} system is less favorable for complete segregation since all three of these effects are smaller; the surface free energy of Cu (1.93 J/m^2) is closer to that of Co, the lattice mismatch is only 2%. and the heat of formation CoCu is +13 kJ/g atom.

We have found that the Co/Ag evaporated films that are codeposited at substrate temperatures that are high enough so that the adatoms have appreciable mobility are completely segregated[3] as Co globules embedded in a Ag matrix.

Ironically, the granular structures are simpler and more amenable to modeling than the complex structures obtained when alternately depositing layers of nonlattice-matched materials. TEM micrographs of many such multilayer systems have shown that usually only the first few bilayers are layered and that strong columnar growth and severe intermixing occurs farther from the substrate. Thus, in general, multilayer structures are intermediate between layered and granular structures which causes them to be difficult to model in a credible manner.

At concentrations of less than ~35 at. % Co the Co/Ag granular structures can be thought of as pure superparamagnet single domain Co globules embedded in a Ag matrix. The large magnetoresistance values (31% at room temperature and 67% at 77 K) are due to the same mechanism responsible for the low field (<20 kOe) magnetoresistance in pure ferromagnets.[4] Namely, the conduction electrons of Co are predominately highly polarized itinerant *d* electrons that are strongly scattered at the magnetic boundaries between regions of different magnetization directions. In the granular and layered structures the room temperature MR is much larger than that of the pure ferromagnets because the domain size has been greatly reduced from the micrometer range, typical of pure ferromagnets, into the nanometer range.

The other proposed mechanism for the origin of the GMR, spin-dependent scattering from solutes of the nonmagnetic material in the magnetic component,[5] is inapplicable to the Co/Ag system, since there is a negligible concentration of Ag atoms in the Co globules. Moreover, since the spin-dependent resistivities of the transition metals are similar for Fe, Co, and Ni hosts,[6] the spin-dependent scattering rates of Ag solutes are likely to be about the same as for Cu solutes in Ni. When properly analyzed by taking into account that the conduction electrons of the FM transition metals are predominately highly polarized *d* electrons it is

a)Presently at Akashic Memories Corporation, San Jose, CA 95134.

 0021-8979/94/75(10)/6894/6/$6.00 © 1994 American Institute of Physics

found that for Cu the spin-up and -down scattering rates are essentially the same.[7]

We have previously analyzed the magnetization and MR behavior of the Co/Ag system in terms of the Co globules being mainly superparamagnetic.[3] However, at Co concentrations >35 at. % this system also clearly has a ferromagnetic component. The maximum room temperature MR values are found at Co concentrations where the films are just beginning to exhibit a ferromagnetic component. In this paper we determine and take into account the ferromagnetic component in the films.

A striking effect seen in the MR behavior when a ferromagnetic component is present is very long relaxation times; sometimes several minutes. This is due to the many different energy states available by connecting the globules through different paths. Therefore, upon changing the applied field the time needed to establish the minimum energy configuration becomes very long.

II. EXPERIMENTAL DETAILS

Several series of Co_xAg_{1-x} and pure element films were prepared by coevaporation of Co and Ag in a dual *e*-beam gun UHV deposition system. The nominal thickness of the films was ~3000 Å. High purity single crystal Si wafers with an oxidized surface layer were used as the substrates. The deposited samples consisted of a square of ~2 cm on a side and a dumbbell pattern with a small neck of ~0.2 mm×5 mm for resistance measurements. The exact dimensions were determined by profilimeter measurements. In order to study changes in the microstructure the substrate temperature, T_S, was varied from room temperature (RT) to 500 K. The deposition rate of Co was kept constant at 0.6 Å/s while the Ag rate was varied from 0.5 to 2 Å/s in order to change the composition of the films.

A Rigaku D/Max-IIB x-ray diffractometer with Cu $K\alpha$ radiation was used to study the grain size and crystal orientation of the films. The Co and Ag were found to be fcc with preferential growth in the ⟨111⟩ direction. The atomic compositions were deduced from the evaporation rates and were further confirmed by Rutherford backscattering (RBS). RBS also measures the areal densities, which when combined with the measured film thickness (from profilimeter measurements), allowed an evaluation of the fraction of voids in the films. Studies of the morphology of the films were made using cross-sectional electron microscopy. Irregular globular structures containing many voids (consistent with the conclusions from the magnetic, resistance, and RBS measurements) were observed but in general the images were not very informative because of the random nature of granular structures.

The magnetization curves were measured on small rectangles using a vibrating sample magnetometer whose maximum field was 10 kOe. The magnetoresistance was measured on the dumbbell shaped samples using the four-probe method in a field varying up to 14 kOe. The four probes were gold plated stop balls which were connected to a digital voltmeter supplying a constant current of 10 mA. The resistivity was found to be independent of the size of the current. Resistance measurements were made at both room and liquid

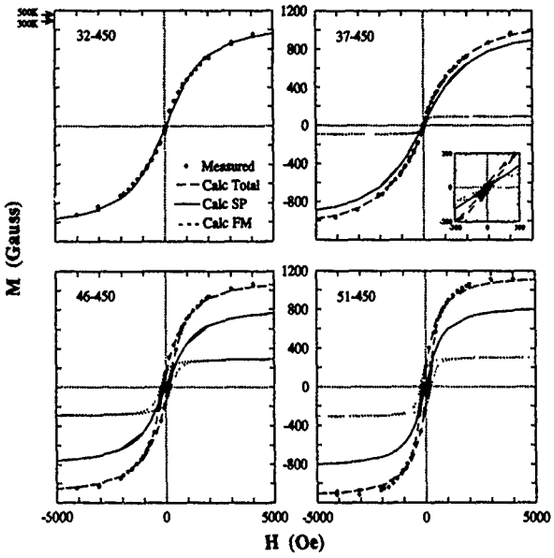

FIG. 1. Deconvolution of the measured total magnetization curves into their ferromagnetic and superparamagnetic components for the series deposited at 450 K. The insets show total and FM magnetizations near $H=0$. Note that the H_c values of the ferromagnetic components are larger than those of the total curves.

N_2 temperatures (NT). The magnetoresistance (MR) measurements were made for the applied field, H, in-plane and perpendicular to the film and with the current both transverse (TMR) and parallel (LMR) to the field.

III. MAGNETIZATION BEHAVIOR

At room temperature a ferromagnetic (FM) component began to appear in the magnetization curves of the films with ≥35 at. % Co. With increasing Co concentration the FM component and the coercive field, H_c, increased. Excellent fits were made to the magnetization curves, $M_T(H)$, using the general fit procedure of Kaleidagraph with a function made up of a FM and a superparamagnetic (SP) part as follows:

$$M_T(H)=\frac{2M_F^s}{\pi}\tan^{-1}\left[\frac{(H\pm H_c)}{H_c}\tan\left(\frac{\pi S}{2}\right)\right]+N_g\bar{\mu}\left[\operatorname{ctnh}\left(\frac{\bar{\mu}H}{kT}\right)-\left(\frac{\bar{\mu}H}{kT}\right)^{-1}\right]. \quad (1)$$

The first term is the usual function used to represent a FM hysteresis curve. The second term is the usual expression for an SP component. $M_{\rm FM}^s$ and $M_{\rm SP}^s = N_g\bar{\mu}$ are the saturation magnetization of the FM and SP parts. S is the squareness of the ferromagnetic loop, i.e., the ratio of the remanent magnetization, M_R, to $M_{\rm FM}^s$. The average moment per globule, $\bar{\mu}$, and number of Co globules/cm^3, N_g, in the SP fraction are obtained from the second term. Typical fits to the magnetization curves are shown in Fig. 1 for the series deposited at a substrate temperature of 450 K. The films are identified by the notation at. % Co-substrate temperature.

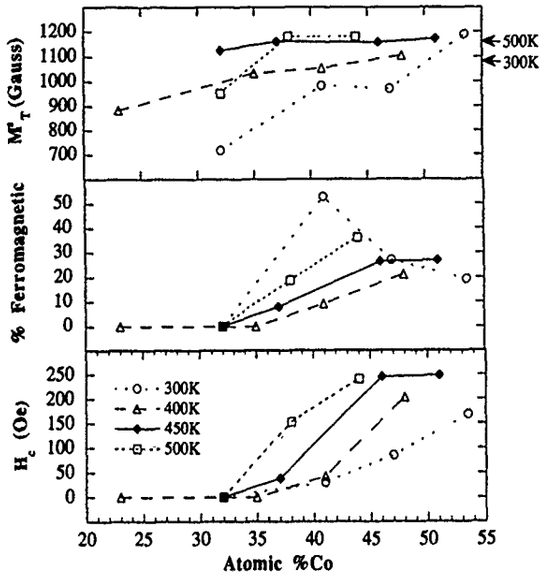

FIG. 2. Variation of total saturation moment, M^s_T, the ferromagnetic fraction of the total moment in %, M^s_{FM}/M^s_T, and the coercive field, H_c, with at. % Co. The saturation magnetization values for pure Co films deposited at 300 and 500 K are indicated on the upper right side of the graph.

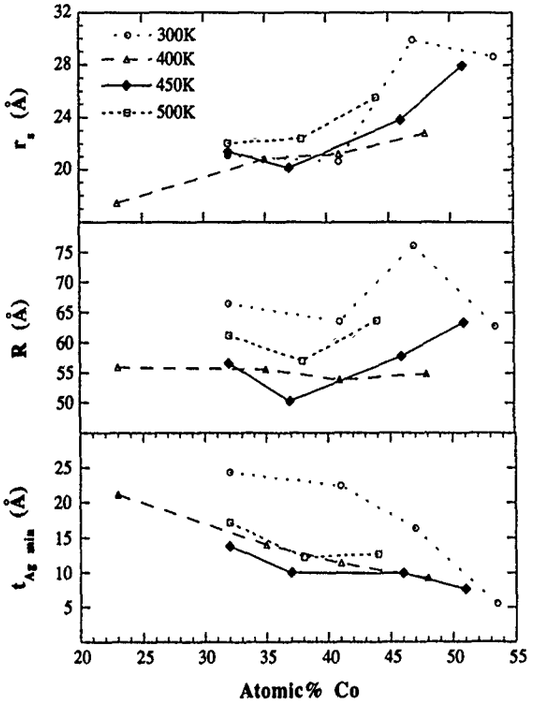

FIG. 3. Variation with Co concentration of the average globule radii r_S; side R of a cubical volume containing the globule and the average minimum distance between globules, $t_{Ag\,min}$, for films coevaporated at various substrate temperatures.

A. As-prepared films

The variation of the total saturation magnetization M^s_T, the ferromagnetic fraction in %, and H_c with at. % Co are shown for each of the substrate temperatures in Fig. 2. From high resolution TEM images of many metallic multilayer systems we have found that evaporated films deposited at a substrate temperature of 300 K are composed of small, jumbled crystallites giving rise to very poorly defined structures.[8] This is due to the adatoms not having sufficient mobility to form well-ordered structures. We see here that this causes low M^s_T values and erratic behavior in the FM fraction. The M^s values for pure Co films of the same thickness as the granular films deposited at 300 and 500 K are indicated on the right-hand side. As has been discussed previously[3] all of these evaporated films contain about 20% voids. This was determined from magnetization saturation measurements, Rutherford backscattering measurements, profilimeter film thickness measurements, and the known deposition rates. Such a void fraction is not unusual for evaporated films of a thickness of ~3000 Å. From such considerations we conclude that for films with sufficient mobility of the adatoms ($T_S \geq 450$ K) essentially all the Co is in the globules with each Co atom having a full bulk moment of $1.72\mu_B$. Discounting the anomalous behavior of the films deposited at 300 K we see that the ferromagnetic fraction of the films increases with increasing Co content. The H_c values also increase with increasing Co content with the values obtained from the deconvolution of the magnetization curves naturally being larger than the $M=0$ values of the raw data.

The number of Co atoms per globule, N_{Co}, in the SP fraction is given by $N_{Co}=\tilde{\mu}/\mu_{Co}$. Typical values for the films showing the larger MR values were 3000–4000 Co atoms per globule. The average volume per globule, V_g, is given by $V_g=N_{Co}V_{Co}$. We use the bulk volume per Co atom (11.1 Å^3) for V_{Co} since, although the voids alter the average density of the films, the Co globules and Ag matrix are assumed to have essentially their bulk densities. As a first approximation let us model the system by assuming that the globules are spherical. We can then obtain the average radius of the globules, r_S, from V_g. The average number of globules per cm^3 is given by $N_g = M^s_{SP}/\tilde{\mu}$. Since the Co and Ag only occupy ~80% of the volume of the films the average volume that a globule occupies is $0.80/N_g$. Assuming a cubic shape for this volume we obtain an average value for a side of this cube, R. A quantity of interest is the average minimum thickness of Ag between the globules; given by $t_{Ag\,min}=R-2r_S$. We show the variations of r_S, R, and $t_{Ag\,min}$ with Co concentration in Fig. 3. We see that r_S tends to increase with increasing Co content while R is quite constant. This results in $t_{Ag\,min}$ decreasing as the fraction of Co increases. Whereas the films deposited at $T_S \geq 400$ K are quite similar in their $t_{Ag\,min}$ variation the films deposited at 300 K are again anomalous. Since the globules are more likely to touch as the at. % Co increases the FM component also increases. Thus, the observed behavior of the FM component agrees well with the globular sizes and separation which are derived from the SP parameters.

In order to investigate the assumption that the globules are spherical we considered the effect of the globules being ellipsoids of revolution with a eccentricity of 10%; i.e., the minor axes are 0.9 of the major axis. For this case the variation of the major axis is only 7% greater than the radius of a

TABLE I. Parameters obtained from fitting the magnetization curves of the annealed films. The last column is the ratio of the ferromagnetic volume of the film to the total volume.

	M_T^s (G)	M_{FM}^s/M_T^s	H_c (Oe)	N_{Co}	r_S (Å)	R (Å)	V_{Co}^{FM}/V^T

sphere. This would cause little difference to the average distance between globules. However, in the ellipsoidal case there may be geometric effects due to the ellipsoids aligning as flat discs parallel to the plane of the film.

B. Annealed films

The effects of annealing were studied by heating a few selected films at 300 °C for one-half hour intervals. We chose two films deposited at 300 K (32–300 and 41–300) which we knew were composed of small jumbled crystallites. Thus, for these the annealing should markedly improve the structure and segregation of the Co and Ag. For comparison we also annealed the film showing the largest MR effect, 37–450. The results are listed in Table I. It can be seen that in general for the films prepared at 300 K all the parameters listed tend to increase with annealing. This indicates that the main effect of annealing is to better segregate the Co and Ag. The annealing of the optimum film 37–450 causes little change in M_T^s but an increase in the FM fraction and all the other parameters. However, as is seen in the next section, there is little change in the MR value of this film with annealing.

IV. MAGNETORESISTANCE BEHAVIOR

The variation of the resistance with applied field, H, was measured at RT and NT with H in-plane and perpendicular to the films. For the superparamagnetic films the transverse magnetoresistance (current $\perp H$, TMR) was of the same magnitude but slightly broader for H perpendicular to the film. For an in-plane field the longitudinal magnetoresistance, LMR (current $\| H$) was slightly different than that of the TMR. This difference, the anisotropic magnetoresistance AMR=LMR−TMR, was essentially the same for all films and had a maximum value of about the same magnitude as for pure Co films; i.e., ~1%. The behavior of this difference is in agreement with the proposed mechanism for its origin, namely, that it arises because of the anisotropic shape of the electronic density of the d electrons due to the spin-orbit

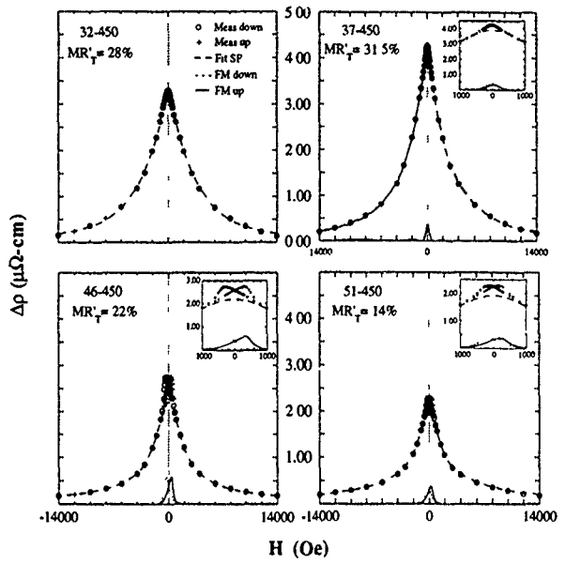

FIG. 4. Typical deconvolutions of the TMR curves into their FM and SP components for the 450 K series. The insets show the FM components near $H=0$.

coupling.[9,10] This causes the cross-sectional area for scattering at high H to be larger for the LMR geometry than for the TMR geometry.

The magnetoresistance is here defined to be $MR = [R(H)-R_{min}]/R_{min} = [\rho(H)-\rho_{min}]/\rho_{min} = \Delta\rho/\rho_{min}$. Since our maximum field of 14 kOe was not sufficient to reach R_{min} for these granular films we determined its value in the following manner: For films that were entirely superparamagnetic the whole curve was fit with the sum of two Lorentzian functions using KaleidaGraph. Only the part of the wings that had no hysteresis was fit in the same manner for MR curves having an FM component. The entire SP component was then calculated using the parameters determined from the wings and the FM component obtained by subtracting the SP component from the total measured MR curve. It was required that the FM component be positive. Deconvolutions of the 450 K series TMR curves into their FM and SP components are shown in Fig. 4. Also shown are insets of the FM components.

It was found that all the films that had a FM component in the magnetization curves also had a FM component in the MR curves. Some of the parameters characterizing the MR curves are listed in Table II. In order to compare the various films we have converted the R values into resistivities, ρ. In Table II we list ρ_{min}, the $\Delta\rho$'s ($\Delta\rho_{(T,FM,SP)} = \rho_{max}^{(T,FM,SP)} - \rho_{min}$), the maximum MR values $MR_T' = \Delta\rho_T/\rho_{min}$), and the fields corresponding to the peak of the total TMR curve H_p^T and the ferromagnetic component H_p^{FM}. Unless otherwise noted the data are for room temperature measurements and the SP contributions are fit to the portion of the data for $H \geq |2000|$ Oe.

The full-width at half-maximum of the total MR curves for films deposited at ≥400 K were ~6000 Gauss for 30–35 at. % Co and decreased with increasing Co content. The largest decreases were seen in the films deposited at higher tem-

peratures, e.g., the 44–500 film had a half-width of ~3000 Gauss. As seen in Fig. 4 the half-widths of the FM components are much smaller, ~400–1000 Gauss, and decrease as the fraction of FM component (or at. % Co) decreases.

The poor, ill-defined structure of the films prepared at a substrate temperature of 300 K is evident in the low MR′ values of these films. All the MR curves for as-prepared films for $T_S = 300$ K that did not peak at $H = 0$ (i.e., had a non-SP component) had a double-peaked behavior. Upon annealing them for $\frac{1}{2}$ h at 300 °C the MR curves became single peaked and the segregation increased causing higher M_S and

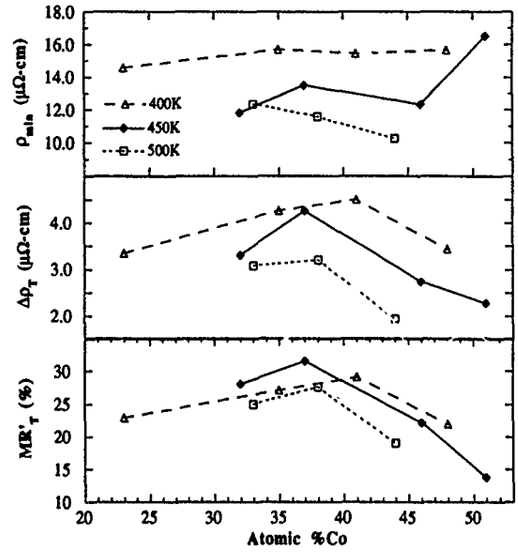

FIG. 5. Variations of ρ_{min}, $\Delta\rho_T$, and MR'_T with at. % Co for the as-prepared films deposited at $T_S \geq 400$ K.

MR′ values. The magnetization curve for the 53.5–300 film also had a peculiar shape that could not be fit well with Eq. (1). Thus, the 300 K films give quite anomalous MR behavior that is attributed to their poor structure and we will not consider these films further.

V. DISCUSSION AND CONCLUSIONS

It was found that for the as-prepared films that were deposited at $T_S \geq 400$ K, the ratios of MR'_{FM}/MR'_T were very similar to the fractions of the FM component, M^s_{FM}/M^s_T.

In Fig. 5 we show the variations of ρ_{min}, $\Delta\rho_T$, and MR'_T for the as-prepared films deposited at $T_S \geq 400$ K. We see that with the exception of the 51–450 film ρ_{min} is quite constant for each value of T_S. However, $\Delta\rho_T$ is seen to have a maximum between 37–41 at. % Co which gives rise to the maximum in the MR'_T values. From Fig. 3 we see that the maximum MR′ values are obtained when the globular diameter is near its minimum of ~40 Å and the minimum separation between the globules is ~10 Å. It was shown[4] that for a pure ferromagnet the resistivity due to magnetic boundary scattering, $\Delta\rho_{MB}$, has the form

$$\Delta\rho_{MB} = A(K/\eta D), \tag{2}$$

where A is a factor depending on the magnetic alignment of the domains in the magnetic material. A sample with a net magnetization of zero has $A = 1$ for domains that are only aligned antiparallel and $A = \frac{1}{2}$ for randomly oriented domains. K is a constant that depends on the band structure of the magnetic material. For fcc Co we estimate K to be ~0.6 $\mu\Omega$ cm when the average domain size D is given in μm. ηD is the mean free path for the magnetic scattering causing the magnetoresistance. For fcc Co $\eta \sim 2$. For pure ferromagnets D is a few micrometers, while for granular films, $D \sim R$, the linear size of the box occupied by the granule, which is seen to be a few nm. These values lead to an estimate for $\Delta\rho_{MB} \sim 30$ $\mu\Omega$ cm for a pure ferromagnetic with domains of

TABLE III. Room temperature contribution of the resistivity $\rho_{p,m}$ due to scattering by phonons and magnons.

Sample	32–450	37–450	44–500	–400	48–400 (1 ann)	51–450
$\rho_{p,m}$ ($\mu\Omega$ cm)	4.2	4.5	4.5	4.6	5.6	7.5

5 nm. However, in materials containing a nonmagnetic material, $\Delta\rho_{MB}$ is reduced because the memory of the spin direction in the magnetic region from which the conduction electrons emerge is lost as the electrons traverse the nonmagnetic region. Thus, for granular films we multiply Eq. (2) by an attenuating factor and obtain

$$\Delta\rho_{MB}=A(K/\eta R)F\ \exp(-t_{Ag}/l_0). \tag{3}$$

F is a factor decreasing the magnetic resistivity due to the scattering caused by the variation in the potentials at the interfaces between the magnetic and nonmagnetic regions. Since a conduction electron must traverse two such interfaces we estimate[3] that $F\sim\frac{1}{2}$. The factor $\exp(-t_{Ag}/l_0)$ is the reduction of the magnetic resistivity caused by the loss of polarization of the conduction electrons in passing through the nonmagnetic region. t_{Ag} is the average thickness of nonmagnetic material that a conduction electron travels between two sequential magnetic regions and l_0 is the mean free path or spin diffusion length for the d-conduction electrons to lose their spin memory in the nonmagnetic region. For the 37–450 film we found that $R\sim50$ Å and we take l_0 to be ~35 Å at RT[11] and t_{Ag} to be ~30 Å (between the maximum Ag distance, $\sqrt{3}R-2r_S$ and $t_{Ag\,min}$). Putting in these values we obtain that $\Delta\rho_{MB}\sim6\ \mu\Omega$ cm; in good agreement with the measured value of ~4.2 $\mu\Omega$ cm. From Eq. (2) we see that the highest MR′ values are obtained when R is a minimum and $t_{Ag\,min}$ is small but not so small that the globules are ferromagnetically coupled. When they touch or are close enough to couple indirectly via the RKKY exchange interaction an FM component occurs that then effectively increases the value of D. We see that indeed these are just the condition under which we obtain the maximum MR′ values in the granular structures. As can be seen from Eq. (3), $\Delta\rho_{MB}$ is sensitive to both the magnetic and physical structure of a film.

From Table II and Fig. 5 we see that ρ_{min} is quite independent of the Co content and decreases slightly with increasing T_S. This is expected because of the higher mobility of the adatoms in the films deposited at higher T_S. ρ_{min} is composed of all the nonmagnetic scattering contributions. We separate these contributions into two categories depending on their temperature dependence: (1) Scattering from phonons and magnons, $\rho_{p,m}$, which varies as $1/T$; (2) scattering from structural imperfections and voids, ρ_i, which should be independent of T and decrease with annealing. Interfacial scattering, ρ_{if}, at the step potential between the Co and Ag interfaces. The measured decreases in ρ_{min} at NT for the as-prepared films are thus attributed to the decrease in $\rho_{p,m}$ with temperature. Using the RT and NT values of ρ_{min} and a $1/T$ dependence for $\rho_{p,m}$ we evaluate $\rho_{p,m}$ and $\rho_i+\rho_{if}$, for the films deposited at $T_S\geq400$ K. The RT values obtained for $\rho_{p,m}$ are listed in Table III. We see that the values tend to increase slightly with at. % Co and vary from 4.2 to 7.5 $\mu\Omega$ cm. These are very reasonable values since these thin films are expected to have somewhat larger resistivities than an intermediate value between the bulk RT resistivities of 1.6 and 5.8 $\mu\Omega$ cm of pure Ag and Co, respectively. The decrease in ρ_{min} with annealing is mainly due to a decrease in ρ_i.

In Table II it can be seen that the FM component of the films is considerably larger at NT than at RT. This occurs because in order to obtain magnetic alignment between the Co globules the effective coupling between them must be $\geq kT$. Thus the requirement of weaker coupling at NT gives rise to a greater fraction of the sample being FM.

The relaxation effects observed in these films deserve more study. In the region of the MR curves that had an FM component an appreciable time was required to reach equilibrium after changing field, from a few seconds to several minutes in various parts of the MR curve. These relaxation effects likely occur because when an appreciable fraction of the globules are close enough to couple there are numerous closely spaced energies states available to the system so it takes considerable time for the system to reach the ground state.

The authors wish to thank C.-H. Lee for measuring the hysteresis curves of the samples.

The microstructure and magnetic properties of phase-separated Fe-Ag and Co-Ag granular alloy films, grown epitaxially on (001) NaCl substrates and exhibiting giant magnetoresistance (GMR), have been investigated. Surprisingly, two Fe-Ag films of similar composition grown under identical conditions are found to have substantially different microstructures yet display similar GMR. The microstructure of the films is characterized by Fe-rich or Co-rich regions, respectively, 350–700 nm in extent, surrounded by a Ag-rich matrix. Within the Ag-rich regions, the Fe concentration varies from 20 to 25 at % and the Co concentration is ≃16 at %. Within these regions essentially pure fcc Co particles and bcc Fe particles are in parallel and rotated epitaxial alignment respectively with the fcc silver matrix. The Co and Fe particles are ≃15–25 Å in diameter. It is these small particles which most likely account for the giant magnetoresistance exhibited by these alloys. This suggests that a size distribution of magnetic particles, sharply peaked at the optimum size with limited bulk segregation, might give rise to larger GMR values.

I. INTRODUCTION

Enhanced or giant magnetoresistance (GMR), is exhibited by a variety of different inhomogeneous metallic magnetic systems comprising of magnetic layers or particles separated by nonferromagnetic material. In magnetic multilayers the largest GMR has been found in systems comprised of thin ≃8 Å-thick Co layers separated by thin (≃8 Å) Cu layers.[1,2] In magnetic granular alloys the largest GMR has been reported in $Co_xAg_{1-x}(x \simeq 0.2)$.[3–5] A variety of models have been proposed to account for the origin of the GMR effect.[6–8] Of particular interest is the relationship of GMR to the detailed microstructure of the magnetic multilayer or alloy. The basic assumption of most models of GMR is the existence of spin-dependent scattering of the conduction electron either within the interior (bulk) of the magnetic particles or layers or at the interfaces between the magnetic and nonmagnetic entities. Recent experiments strongly suggest the predominant role of interfacial scattering in accounting for the GMR of both multilayers[9–11] and granular alloys.[3,5,12] For the latter this means that the size of the magnetic particles is a key parameter in determining the magnitude of GMR.

Typically magnetic granular films deposited by sputtering techniques at room temperature display little GMR. However, GMR is obtained with appropriate post-growth annealing. In contrast, it has been shown recently that slow coevaporation using electron beam or thermal evaporation sources under ultrahigh vacuum (UHV) conditions at moderate substrate temperatures of ≃250 °C (less than required for post-growth annealing of sputtered films, i.e., ≃400 °C) yields GMR in the as-grown films in Co-Ag, Co-Cu, and Fe-Ag.[5,12,13] In this paper, we report observations of the microstructure of Fe-Ag and Co-Ag thin films grown epitaxially on NaCl(001) substrates from transmission electron microscopy (TEM) studies.

II. EXPERIMENTAL PROCEDURES

Fe-Ag and Co-Ag films were grown by slow coevaporation of Fe or Co, respectively, and Ag in a molecular beam epitaxy (MBE) system. The nominal compositions of Fe-Ag and Co-Ag thin films were ≃29 at % Fe and ≃21 at % Co, respectively. The NaCl substrates were cleaved in air and cleaned *in situ* at 300 °C in ultrahigh vacuum (UHV) before growth. Thin films (≃500 Å thick) highly oriented in the (001) direction were then grown at a substrate temperature of 250 °C. No post-growth annealing was required to observe the GMR effect. Details of the growth and the magnetoresistance measurements of these and similar films grown on sapphire (0001) substrates are reported elsewhere.[5] For TEM studies, the films were lifted onto Cu grids by dissolving the NaCl substrate in water and the Pt cap layer was then removed by gentle ion milling. Energy-dispersive x-ray microanalysis, and standard bright-field and dark-field TEM imaging techniques were used to analyze the microstructure of the films.

III. MICROSTRUCTURE OF Fe-Ag AND Co-Ag GRANULAR ALLOY FILMS

A typical low-magnification through-foil bright-field TEM image of the microstructure of a $Fe_{29}Ag_{71}$ film is shown in Fig. 1(a). Also included in the inset to the figure is the corresponding diffraction pattern which demonstrates the epitaxial growth of the film. The composition of the film was analyzed locally using energy-dispersive x-ray microanalysis. Electron probe sizes of 100 and 200 Å were used. The film microstructure is clearly inhomogeneous. The micrograph shows a distribution of dark (pure Ag, 350–500 nm), gray (25 at % Fe, matrix), and light (88 at % Fe, 350–700 nm) regions. The microstructure also varies locally, indicating variations in metal film nucleation on the NaCl surface. Where the NaCl surface has a large local density of (001) steps, the microstructure contains about equal amounts of

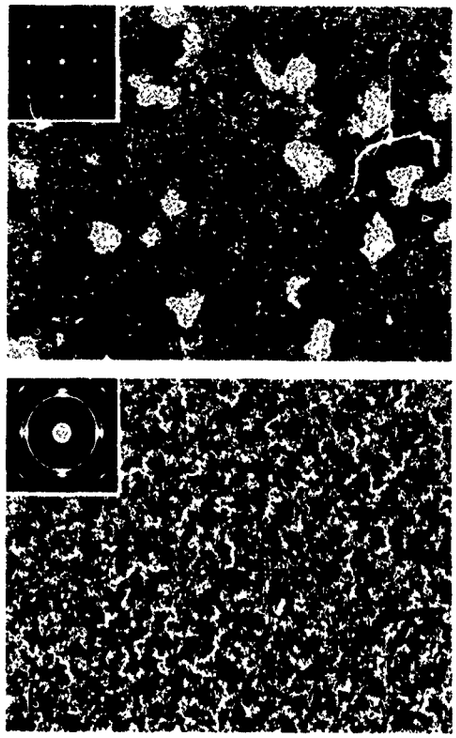

FIG. 1. (a) Microstructure of an as-deposited $Fe_{29}Ag_{71}$ grown on NaCl(001). The micrograph shows bulk segregation of Fe in the light region, pure silver particles in dark contrast, and the gray region with 25 at % Fe. The diffraction pattern shown in the inset indicates the (001) epitaxy of the film with the (001) NaCl substrate. (b) A second Fe-Ag film prepared under almost identical growth conditions shows a more uniform microstructure with a polycrystalline structure

Ag-rich (gray) and Fe-rich (light) regions. The orientation relationship is clearly $(100)Fe\|(100)Ag$ and $[01\bar{1}]Fe\|[00\bar{1}]Ag$, i.e., the reflections from the bcc Fe and the fcc Ag are in exact coincidence but rotated 45° (the lattices have only 0.8% mismatch in this arrangement). The presence of the fcc (γ) phase of Fe in the post-annealed Fe-Ag sample, as reported by Tsoukatos *et al.*[14] was not found in our Fe-Ag samples. Another $Fe_{25}Ag_{75}$ deposition on NaCl under similar conditions unexpectedly resulted in a fine-grained polycrystalline film with slight (001) texture [Fig. 1(b)]. For this film the particle size distribution is highly uniform with the Fe concentration varying locally from 10 to 20 at %. However, a few isolated grains have a higher (30 at %) Fe concentration. For both samples, dark-field imaging obtained from (200) Ag did not yield any information about the distribution and size of the phase-separated Fe particles because of the overlapping of Fe and Ag reflections.

The microstructure of the $Co_{21}Ag_{79}$ films [Fig. 2(a)] is similar to the epitaxial $Fe_{29}Ag_{71}$ film [Fig. 1(a)] and consists of about 10% "Co-rich" light regions where the concentration varies from 32 to 64 at % Co. In contrast, the gray regions contain about 16 at % Co and these regions dominate the microstructure. However, where the Co-Ag film nucleates near steps on the (001) NaCl, the volume fraction of Co-rich light regions increases and reaches about 50% [Fig. 2(b)]. The (001) electron diffraction pattern obtained from

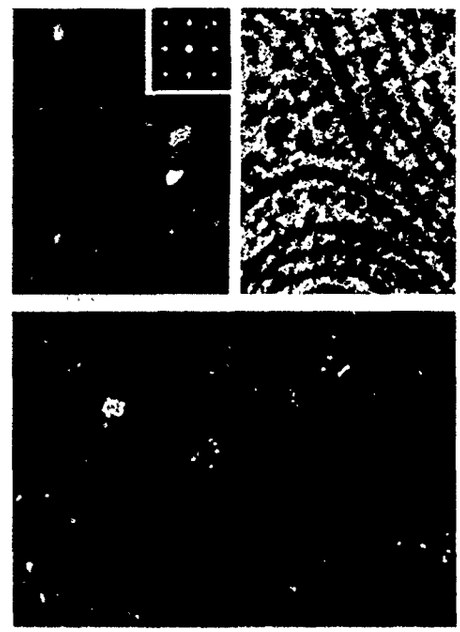

FIG. 2. Microstructure of a $Co_{21}Ag_{79}$ sample showing (a) segregated Co-rich light regions grown on the flat NaCl surface and (b) regions of the film grown on the (001) NaCl steps. The inset in Fig. 1(a) is the electron diffraction pattern showing spot-splitting (arrow) due to Co-phase segregation and parallel epitaxial alignment of Co particles with Ag. (c) Dark-field micrograph obtained using (220) Co reflection showing distribution of 20 Å Co particles in the gray region.

the same area [Fig. 2(a), inset] confirms epitaxial growth of the Co-Ag films on NaCl(001). This pattern also shows distinct spots corresponding to phase separated fcc Co. Even though the Co_{fcc} and Ag_{fcc} have 13% lattice mismatch in the cube-cube orientation, the Co grows in epitaxial alignment with the Ag presumably due to high adatom mobility in this growth mode. Co particles within the Ag matrix retain their bulk lattice parameter and thus the 13% lattice mismatch between the Co and the Ag must be mostly accommodated at the interfaces. Dark-field imaging using the (220) Co reflection clearly shows the Co particle distribution and size [Fig. 2(c)]. The Co particle size varies from 15 to 25 Å, the mean "diameter" being 20 Å. The inter-particle distance [Fig. 2(c)] appears similar to the particle size but this is not conclusive since the particles contained in the 500 Å-thick film are in projection. This measurement agrees with earlier studies[5] using grazing incidence small-angle x-ray scattering (GISAXS) for a Co-Ag film grown on sapphire (0001) which showed comparable mean Co particle size (≃25 Å) but a different mean interparticle distance (≃76 Å).

IV. MAGNETIC CHARACTERIZATION OF Fe-Ag AND Co-Ag GRANULAR ALLOY FILMS

Although the microstructures of the two Fe-Ag films shown in Figs. 1(a) and 1(b) are quite different, the films exhibit similar MR (Fig. 3). Both films show decreases in resistance (for applied fields of up to 16 kOe) of about 4%–5% at room temperature and 15% at 4.2 K. Similar values have also been reported for post-annealed sputtered

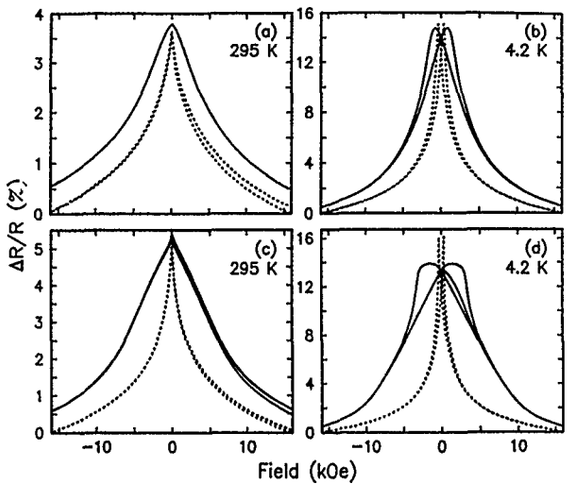

FIG. 3. (a) and (b) magnetoresistance data at 295 and at 4.2 K for the Fe-Ag film shown in Fig. 1(b). (c) and (d) show the magnetoresistance data for the Fe-Ag film shown in Fig. 1(a). The dashed lines are for the field aligned in the plane of the film and the solid lines are for the field perpendicular to the film plane. The data show significant perpendicular magnetic anisotropy.

Fe-Ag samples.[14] However, the GMR reveals distinct magnetic anisotropy for field applied perpendicular and parallel to the film as shown by the solid and dashed curves respectively in Fig. 3. A similar result has previously been found in MBE-deposited Co-Ag alloy films for which various possible mechanisms were discussed.[5] The magnetoresistance data for the Co-Ag film measured at room temperature are given in Fig. 4. A resistance change of 22% under a field of 60 kOe was observed. By varying Co composition, GMR of 40% at room temperature and 71% at 4.2 K has been observed for similar films grown on sapphire substrates.[5]

V. DISCUSSIONS AND CONCLUSIONS

If spin-dependent electron scattering at the interfaces between the magnetic particles and the host nonferromagnetic metal is the dominant scattering mechanism for GMR, then it follows that the magnitude of the GMR will scale approximately as the inverse particle size. Thus, maximum GMR is expected for small magnetic particles. Annealing studies on MBE-grown Co-Cu granular alloys show that the GMR is significantly reduced by annealing resulting from growth of the Co particles.[12] The TEM studies presented here show that a significant fraction, ≈50%–90%, of the Co-Ag alloy sample is comprised of small Co particles, ≈20 Å in diameter, in a Ag matrix. Larger GMR is likely to be obtained by the preparation of alloys containing uniformly small Co particles. Moreover, any dissolution of the Co in the Ag matrix is likely to lead to reduced GMR.[15]

A surprising result of these studies is the similarity of the GMR exhibited by crystalline and polycrystalline Fe-Ag alloys grown on NaCl substrates. The microstructure of these films is quite distinct. Moreover, the GMR of these films is also similar to ⟨111⟩ oriented Fe-Ag films of the same composition grown on a Pt buffer layer on (0001) sapphire. This suggests that crystalline orientation is not a very significant factor in influencing the GMR of Fe-Ag granular films. Note that the magnitude of the GMR exhibited by magnetic multilayers is often very sensitive to small variations in growth conditions. However, for magnetic multilayers the magnitude of GMR is directly connected to the degree of antiferromagnetic alignment of the magnetic layers. This can be very sensitive to structural defects, especially for multilayers containing thin spacer layers. This means that the GMR exhibited by multilayers is often more sensitive to structural defects than that found in granular alloys.

Giant magnetoresistance and its dependence on processing conditions in magnetic granular alloys

Jian-Qing Wang, Edward Price, and Gang Xiao
Department of Physics, Brown University, Providence, Rhode Island 02912

We have studied giant magnetoresistance (GMR) effect and its dependence on processing conditions in Fe-Ag and Co-Ag alloys made by magnetron sputtering. The effect of elevated substrate temperature on GMR has been investigated and compared with the results of post-deposition annealing. As a unique feature, *in situ* annealing yields a second GMR peak at high deposition temperatures, which is associated with a substantially reduced saturation field for GMR. Deposition rate was found to be another crucial parameter in affecting GMR, whereas little effect was observed in varying the sputtering gas pressure.

Since its discovery in magnetic multilayers[1-3] and granular materials,[4,5] the giant magnetoresistance (GMR) effect has been found to depend sensitively on material parameters and processing conditions. Studying the correlation between GMR and processing conditions is crucial not only in the application aspect, but also in the understanding of the underlying mechanism of GMR. It has been commonly agreed that GMR arises from spin-dependent scattering due to exchange interaction between conduction electrons and magnetic scattering centers. The magnitude of GMR directly depends on the strength of exchange interaction which in turn depends on the choice of constituents. The dimensional constraints and interface roughness of the magnetic component are also determining factors in the behavior of GMR. These factors are influenced by material growth processes, conditions, and post-deposition thermal annealing.

In this work we studied how the processing conditions affect the magnetotransport properties in two metallic granular systems, Fe-Ag and Co-Ag. The processing conditions include such factors as deposition rate, sputtering gas pressure, substrate temperature, and post-deposition annealing. We found that GMR is very sensitive to some fabrication parameters, in particular, to the deposition rate and annealing temperature. We investigated the effect of *in situ* annealing and compared it to post-deposition annealing results.

The Co-Ag samples were deposited on Si substrates by a single magnetron sputtering gun loaded with a composite target. The Fe-Ag samples were made by codeposition using cluster guns loaded with pure targets (>99.9%) of Fe and Ag. Typical samples were 5000 Å (Co-Ag) and 2500 Å (Fe-Ag) in thickness. For *in situ* annealing, the duration of heating and sputtering was about 15 min, about the same as the time of post-deposition annealing. Samples were deposited at ambient temperature (~50 °C), 200, 250, 300, 350, and 400 °C, with the same sputtering rate and gas pressure. For rate-dependence study sample depositions were done at ambient temperature (RT). All sample processing was carried out under a base vacuum of better than 1.0×10^{-7} Torr.

The standard photolithography and wet-etching technique was used to pattern the samples into a Hall bar configuration. This allowed us to simultaneously measure the resistivity and Hall resistivity. The Hall-effect measurement provides us with information of carrier density and type, as well as effective mean-free path.[6] In the transport measurements, the magnetic field was swept in a full circle (−8 T↔+8 T) to account for magnetic hysteresis effects. The hysteresis measured agrees with that determined by magnetic measurements, which were carried out in a superconducting quantum interference device (SQUID) magnetometer. Structural information was obtained by x-ray diffraction, transmission electron microscopy (TEM), and magnetic measurement. Detailed results are presented elsewhere.[7]

Figure 1 shows a typical measurement of magnetoresistance (MR) $\rho_{xx}(H)$ for a RT sample of $Co_{20}Ag_{80}$. Hysteresis is clearly observable with the MR maxima located at the coercive field H_c, where the magnetization of the sample reaches zero. There exist different definitions of GMR. In this work the GMR is defined as

$$\mathrm{GMR}=\Delta\rho/\rho=[\rho_{xx}(0\ \mathrm{T})-\rho_{xx}(8\ \mathrm{T})]/\rho_{xx}(8\ \mathrm{T}), \quad (1)$$

since at $H=8$T the MR is almost saturated.

Let us first pay attention to the effects of annealing. Under equilibrium Co or Fe is immiscible with Ag.[8] For the as-sputtered samples deposited at a moderate rate (~4.0 Å/s), the size of the magnetic particles is about ~20 Å as determined by TEM and magnetic measurements. Annealing

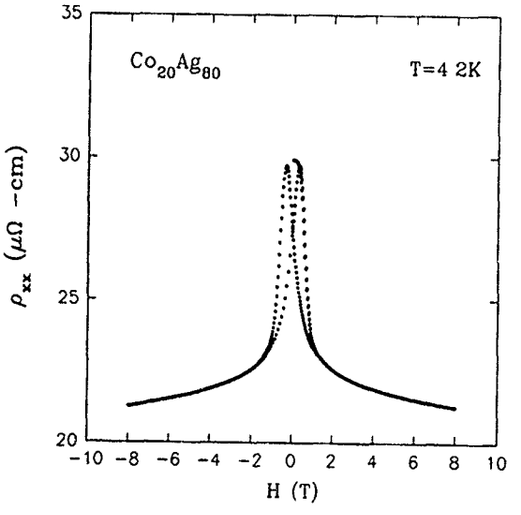

FIG. 1. Magnetoresistivity $\rho_{xx}(H)$ for $Co_{20}Ag_{80}$ deposited at ambient temperature with a rate of $R=4.0$ Å/s and $P_{Ar}=4.0$mTorr. $T=4.2$ K.

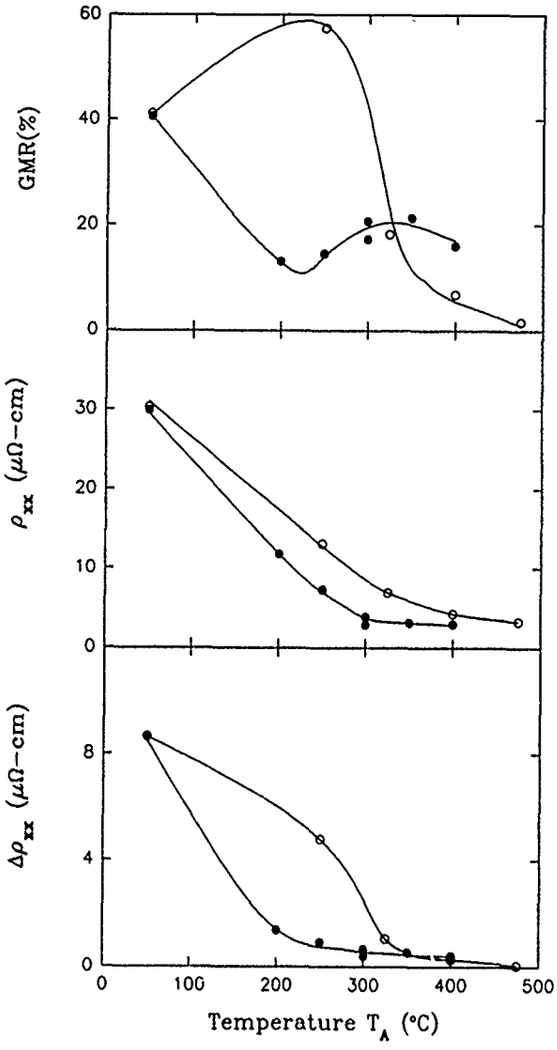

FIG. 2. GMR (upper), ρ_{xx} (middle), and $\Delta\rho_{xx}$ (lower) for $Co_{20}Ag_{80}$ samples (filled circles) deposited at various substrate temperatures, and for $Fe_{13}Ag_{87}$ samples (open circles) after post-deposition annealing at different T_A. Solid lines are guides to the eye. $T=4.2$ K.

increases the magnetic particle size and reduces disorder. For example, after post-deposition annealing for 15 min at 400 °C, the magnetic particle size increased to ~70 Å, whereas the zero-field resistivity ρ_{xx} decreased by one order of magnitude. ρ_{xx} contains contributions from magnetic and nonmagnetic scattering. Both are reduced by annealing. In granular materials, the magnetic spin-dependent scattering occurs primarily at the interface.[9] Thus if the magnetic scattering were dominant in ρ_{xx}, the decrease in ρ_{xx} would be much smaller (by about a factor of ~3) as a result of the reduced surface-to-volume ratio.

The effects of post-deposition annealing are demonstrated in Fig. 2. The measured GMR (upper panel), zero-field resistivity ρ_{xx} (middle), and the net change in resistivity $\Delta\rho_{xx}$ (lower) versus post-deposition annealing temperature T_A are presented for $Fe_{13}Ag_{87}$ samples as open circles. The results for $Co_{20}Ag_{80}$ and other granular systems are very similar.[6,10] GMR initially increases with annealing temperature T_A and subsequently decreases at higher T_A. But if ρ_{xx} and $\Delta\rho_{xx}$ are examined separately, both are found to monotonically decrease as T_A increases. The variation of GMR with T_A results from the difference in the rates of change of $\Delta\rho_{xx}$ and ρ_{xx}. In the low T_A region ($T_A<250$ °C), $\Delta\rho_{xx}$ decreases slowly, whereas ρ_{xx} decreases relatively quickly. This results in an initial increase in GMR. In the high T_A region, $\Delta\rho_{xx}$ drops very quickly over a narrow T_A range, and then monotonically approaches zero at 500 °C. The decrease in ρ_{xx} is, on the other hand, slow over the same T_A range. Hence the GMR shows the subsequent decrease in the high T_A region.

The observed variation in MR can be qualitatively explained as follows. $\Delta\rho_{xx}$ reflects the strength of the magnetic scattering. The structural characterization shows that the magnetic particle size increases slowly with T_A in the low T_A region. This results in a slow variation in magnetic scattering, and therefore in $\Delta\rho_{xx}$. The initial fast decrease in ρ_{xx} is mainly due to a decrease in the contribution of disorder and, to a lesser extent, magnetic scattering. In the high T_A region, magnetic particle size increases more rapidly with T_A. Other changes, e.g., interface roughness and particle shape, may also occur. The partial resistivity due to magnetic scattering is affected more strongly, resulting in a steeper decrease in $\Delta\rho_{xx}$ in the high T_A region. Disorder, being much reduced, becomes less sensitive to annealing.

Most studies so far have focused on the influence of post-deposition annealing on GMR. Little attention has been paid to the effects of growth temperature during thin-film deposition, i.e., *in situ* annealing, which affects the microstructure differently from post-deposition annealing. In Fig. 2, the filled circles represent the data of GMR, ρ_{xx}, and $\Delta\rho_{xx}$ for $Co_{20}Ag_{80}$ samples deposited at different substrate temperatures. It is seen that GMR suffers a large drop even at low T_A. At about $T_A\approx200$ °C, GMR reaches a minimum and then starts to develop a peak at $T_A\approx320$ °C. This behavior is substantially different from that of post-deposition annealing.

The cause for the above GMR behavior is again due to the rate of change of $\Delta\rho_{xx}$ and ρ_{xx}. Under *in situ* annealing, $\Delta\rho_{xx}$ decreases much faster with T_A than ρ_{xx} does below $T_A\sim200$ °C, resulting in the initial drop of GMR. However, between 200–300 °C, the rate of change of $\Delta\rho_{xx}$ slows down substantially, while the rate of change of ρ_{xx} remains about the same. This causes a temporary increase in GMR. Figure 2 shows that at low T_A, *in situ* annealing suppresses $\Delta\rho_{xx}$ much more efficiently than post-deposition annealing. This reveals the susceptibility of microstructural changes to *in situ* thermal annealing.

The appearance of a GMR peak at high T_A is very desirable from an application point of view. Samples made at higher T_A have substantially lower saturation field for GMR. The GMR value at the second peak is about a factor of 2 smaller than that of the as-sputtered sample. But the saturation field H_s has decreased by a factor of 5. We define H_s as the field at which 90% saturation has been achieved. We found that $H_s\approx3.1$ T for the RT sample, and $H_s\approx0.59$ T for samples annealed at 300–400 °C. Our study opens a new route in the search for the optimal condition for GMR effect.

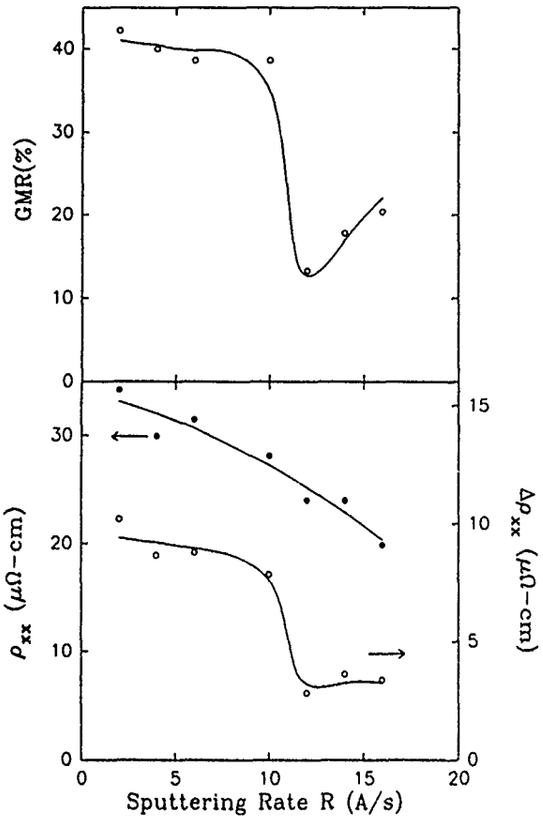

FIG. 3. GMR (top), ρ_{xx} and $\Delta\rho_{xx}$ (bottom) for $Co_{20}Ag_{80}$ samples obtained at different sputtering rates. Solid lines are guides to the eye. $T=4.2$ K.

In situ annealing could be more advantageous than post-deposition annealing.

Next we turn our attention to another processing parameter, i.e., deposition rate R. Different energies are carried by the deposited materials at various rates R. Thus different kinetics are involved in different rate regions. The measured GMR, ρ_{xx}, and $\Delta\rho_{xx}$ for $Co_{20}Ag_{80}$ as a function of R are presented in Fig. 3. GMR has its highest values (~40%) in the low R region ($0<R<10$ Å/s) and is only weakly dependent on R. But there is a sudden transition in GMR to a much lower value (~15%–20%) at $R\sim10$ Å/s. This transition marks the onset of microstructural change occurring in the high rate region.

Examining the variations of ρ_{xx} and $\Delta\rho_{xx}$ with R independently, we observe that the transition in GMR at $R\approx10$ Å is due to a large drop in $\Delta\rho_{xx}$. On the other hand, ρ_{xx} varies with R gradually, slightly decreasing as R increases. Thus the transition observed here is due to changes in magnetic arrangement in the samples deposited at high rates. This is presumably due to the higher kinetic energy carried by the deposited materials. Structural characterization showed that the Co particle sizes increased only slightly in the high R region, indicating that the particle size effect is unlikely to be the cause for the transition in GMR at $R\approx10$ Å/s. It is most likely due to changes occurred at the interface between the magnetic particles and Ag matrix.

It has been found that sputtering gas pressure induces changes in interface roughness and hence changes the size of GMR in multilayers.[11] We have investigated this possibility in our granular systems by varying the Ar gas pressure P_{Ar} from 2 to 8 mTorr. We found that the gas pressure has little effect on GMR and other magnetotransport properties in this pressure range.

In summary, processing conditions are very important in controlling the magnetotransport properties and GMR effect of metallic granular materials. A second peak in GMR at high annealing temperature is a unique feature to the *in situ* annealing. A substantially reduced saturation field coincides with this peak in GMR. We have also found a threshold in deposition rate, beyond which the strength of magnetic scattering, and hence GMR, suffers a precipitous drop. The different GMR behaviors between high substrate temperature and high sputtering rates are due to different microstructural changes in the systems. The former is mainly caused by an increase in particle size, whereas the latter is mainly due to changes in the magnetic structure at the granular interface. Among many processing parameters, only the sputtering gas pressure hardly affects GMR, ρ_{xx}, and $\Delta\rho_{xx}$.

Theory of magnetotransport in inhomogeneous magnetic structures

Horacio E. Camblong,[a] Shufeng Zhang, and Peter M. Levy
Department of Physics, New York University, New York, New York 10003

The origin of the giant magnetoresistance of magnetic multilayers and magnetic granular solids is investigated through a unified spin-dependent linear transport theory, in which the primary source of electrical resistivity is short-range scattering by impurities in the different magnetic or nonmagnetic regions and at the interfaces. Our theory predicts that magnetotransport in granular solids is similar to that for currents perpendicular to the plane of the layers in multilayers in that their magnetoresistance is independent of the average distance between adjacent magnetic regions.

Magnetotransport in inhomogeneous magnetic structures has been experimentally studied in both multilayers[1] and granular solids.[2] The main focus of these investigations has been the phenomenon of giant magnetoresistance, which holds promise for technological breakthroughs.

The theory of magnetotransport in multilayers with collinear magnetizations has been discussed in Refs. 3–8. Instead, magnetotransport through noncollinear magnetizations is not so well understood, either for multilayers or for granular solids.

In this paper we consider the problem of magnetotransport in inhomogeneous magnetic structures with arbitrary magnetization configurations via the introduction of a linear transport theory in the presence of effective spin-dependent fields, and we apply the formalism to three cases of experimental relevance: multilayers with currents in the plane of the layers (CIP), multilayers with currents perpendicular to the plane of the layers (CPP), and granular solids. Our model is based on scattering by impurities in the different regions of the system (layers for multilayers and granules or matrix for granular solids) as well as at the interfaces, rather than on scattering by entire regions of the inhomogeneous structure (multilayer or granular solid). We find that the characteristic exponential dependence of the magnetoresistance of CIP with respect to the thickness of the nonmagnetic spacer layer has no counterpart in either CPP or granular solids, a behavior that places them in a new class of magnetically self-averaging systems.

Our theory generalizes the real space Kubo approach of Ref. 4 and it starts from the model Hamiltonian[3]

$$H=H_0+\sum_a (v_a+j_a\hat{\mathbf{M}}_a\cdot\hat{\sigma})\delta(\mathbf{r}-\mathbf{r}_a), \tag{1}$$

where H_0 describes free electrons, $\hat{\sigma}$ is the one-electron spin vector operator, $\mathbf{r}_a$ is the position vector of a particular impurity, $\hat{\mathbf{M}}_a$ represents the direction of magnetization of a magnetic region, and v_a and j_a are phenomenological constants. As in Ref. 4, when the reduced Fermi wavelength $\lambda_F=k_F^{-1}\approx 1$ Å is much smaller than the other length scales (mean-free paths and inhomogeneity lengths), the one-particle propagator satisfies the Dyson's equation, which in real space reads

$$\left[\epsilon_F+\frac{\hbar^2}{2m}\nabla_r^2-\Sigma(\mathbf{r})\right]G^{\rm ret}(\mathbf{r},\mathbf{r}')=\delta(\mathbf{r}-\mathbf{r}'), \tag{2}$$

where $\Sigma(\mathbf{r})$ is the local self-energy due to scattering in the bulk and at the interfaces. In order to analyze transport properties we look at the imaginary part

$$\Delta(\mathbf{r})=-\mathrm{Im}[\Sigma(\mathbf{r})], \tag{3}$$

which we will refer to as the scattering strength.

The main difficulty posed by the existence of noncollinear magnetization is that the independence of physical properties with respect to arbitrary choices of the quantization axis requires a theory that is covariant under changes of that axis. The ensuing implication is that if the current is to be viewed as arising from different channels (two-current model), the only possible description is one in terms of the spin-dependent current densities, $\mathbf{j}_{\alpha\beta}(\mathbf{r})=\langle\hat{\mathbf{j}}_{\alpha\beta}(\mathbf{r})\rangle$, defined as the expectation values of the spinor current operators

$$\hat{\mathbf{j}}_{\alpha\beta}(\mathbf{r})=\frac{e\hbar}{mi}\Psi_\alpha^\dagger(r)\vec{\nabla}_\beta(\mathbf{r}), \tag{4}$$

where $\vec{\nabla}_r=(\vec{\nabla}_r-\overleftarrow{\nabla}_r)/2$ is the antisymmetric gradient operator, $\Psi_\alpha(\mathbf{r})$ is the real space one-electron field operator, and greek indicates label the two spin channels. Similarly, the spin-dependent constitutive relation

$$\mathbf{j}_{\alpha\beta}(\mathbf{r})=\sum_{\gamma,\delta}\int d^3r'\,\boldsymbol{\sigma}_{\alpha\beta,\gamma\delta}(\mathbf{r},\mathbf{r}')\cdot\mathbf{E}_{\gamma\delta}(\mathbf{r}'), \tag{5}$$

follows by absorbing the vertex corrections via a redefinition of the internal fields $\mathbf{E}_{\gamma\delta}(\mathbf{r}')$. As a result, the fourth-rank spinor two-point conductivity $\boldsymbol{\sigma}_{\alpha\beta,\gamma\delta}(\mathbf{r},\mathbf{r}')$, which contains only the contribution from the bubble diagram in the real space Kubo formula,

$$\boldsymbol{\sigma}_{\alpha\beta,\gamma\delta}(\mathbf{r},\mathbf{r}')=-\frac{2}{\pi}\frac{e^2}{\hbar}\left(\frac{\hbar^2}{2m}\right)^2 \times A_{\beta\gamma}(\mathbf{r},\mathbf{r}')\vec{\nabla}_{\mathbf{r}}\vec{\nabla}_{\mathbf{r}'}A_{\delta\alpha}(\mathbf{r}',\mathbf{r}), \tag{6}$$

[where $A_{\alpha\beta}(\mathbf{r},\mathbf{r}')=(G^{\rm ret}_{\alpha\beta}(\mathbf{r},\mathbf{r}')-G^{\rm adv}_{\alpha\beta}(\mathbf{r},\mathbf{r}')/2$ is the density of states function] is proportional to the bubble part of the current-current correlation of the spinor currents, i.e., $\boldsymbol{\sigma}_{\alpha\beta,\gamma\delta}(\mathbf{r},\mathbf{r}')\propto\langle[\hat{\mathbf{j}}_{\alpha\beta}(\mathbf{r})\hat{\mathbf{j}}_{\gamma\delta}(\mathbf{r}')]\rangle$.

In the quasiclassical regime, Eq. (2) can be solved via a global WKB integration. The corresponding reduced Green's function, $\mathcal{G}(\mathbf{r},\mathbf{r}')=(\hbar^2/2m)G(\mathbf{r},\mathbf{r}')$, is

[a]Present address. Department of Physics, University of San Francisco, San Francisco, CA 94117.

$$g(\mathbf{r},\mathbf{r}') \approx -\frac{1}{4\pi|\mathbf{r}-\mathbf{r}'|}\exp[ik_F|\mathbf{r}-\mathbf{r}'|]\times P_{\mathbf{r}'\to\mathbf{r}}\exp$$
$$[-\tfrac{1}{2}\xi(\mathbf{r},\mathbf{r}')|\mathbf{r}-\mathbf{r}'|]. \tag{7}$$

Equation (7) has a very simple physical interpretation: it represents a propagating electron with a complex wave number $k(\mathbf{r})=[k_F^2+i2m\Delta(\mathbf{r}/\hbar^2]^{1/2}$. In Eq. (7) the two-point exponent $\xi(\mathbf{r},\mathbf{r}')$

$$\xi(\mathbf{r},\mathbf{r}')=\left(\frac{2m}{\hbar^2 k_F}\right)\frac{1}{|\mathbf{r}-\mathbf{r}'|}\int_{\Gamma[\mathbf{r},\mathbf{r}']} ds''\Delta(\mathbf{r}''), \tag{8}$$

describes the damping of the electron's wave function (loss of momentum) as it propagates along the straight path $\Gamma[\mathbf{r},\mathbf{r}']$ connecting the points $\mathbf{r}$ and $\mathbf{r}'$, and it is essentially the average scattering encountered by the electron between $\mathbf{r}$ and $\mathbf{r}'$. In the presence of spin-dependent scattering, the one-particle propagator $G^{\rm ret}(\mathbf{r},\mathbf{r}')$, the self-energy $\Sigma(\mathbf{r})$, the scattering matrix $\Delta(\mathbf{r})$, and the two-point exponent $\xi(\mathbf{r},\mathbf{r}')$ are 2×2 spin matrices; thus, a path-ordering operator is required in Eq. (7), to reorder the noncommuting 2×2 scattering matrices in the exponential series from the point $\mathbf{r}'$ to the point $\mathbf{r}$ (from right to left). The corresponding WKB results for the two-point conductivity are [from Eq. (6)]

$$\sigma_{\alpha\beta,\gamma\delta}(\mathbf{r},\mathbf{r}')=\frac{3C_D}{4\pi}\frac{\mathbf{nn}}{|\mathbf{r}-\mathbf{r}'|^2}\{P_{\mathbf{r}'\to\mathbf{r}}\exp[-\tfrac{1}{2}\xi(\mathbf{r},\mathbf{r}')|\mathbf{r}$$
$$-\mathbf{r}'|]\}_{\beta\gamma}\{P_{\mathbf{r}\to\mathbf{r}'}\exp[\tfrac{1}{2}\xi(\mathbf{r},\mathbf{r}')|\mathbf{r}-\mathbf{r}'|]\}_{\delta\alpha}, \tag{9}$$

where $C_D=e^2k_F^2/(6\pi^2\hbar)$ and $\mathbf{n}$ is a unit vector from $\mathbf{r}$ to $\mathbf{r}'$.

The computation of global or measurable transport properties requires further work, as they do not follow straightforwardly from Eq. (9). In view of this complication we will start by analyzing global properties in multilayers, and only at a later stage we will consider transport in granular solids.

For the particular case of multilayers, which are characterized by in-plane translational invariance, a Fourier transform with respect to the in-plane relative positions yields two-point conductivities $\sigma(z,z')=\sigma(k_\parallel=0;z,z')$, given by

$$\sigma(z,z')=\frac{3C_D}{2}\int_1^\infty dt\frac{1}{t}\left[\frac{1}{2}\left(1-\frac{1}{t^2}\right)1_\parallel+\frac{1}{t^2}\mathbf{e}_z\mathbf{e}_z\right]$$
$$\times\exp\left[-t\int_{z<}^{z>}\frac{dz''}{l(z'')}\right], \tag{10}$$

where $1_\parallel$ is the unit tensor in the plane of the layers, the substitution $t=R/|z|$ has been made, and integration with respect to the in-plane azimuthal angle has rendered the tensor diagonal. Equation (10) describes electrical conduction in multilayers.[4] For the CIP case, the internal electric field induced by an external uniform field is uniform, due to the in-plane *symmetry* of the multilayers; then the global CIP conductivity can be found by integrating the two-point conductivity of Eq. (10) twice, with respect to both arguments, z and z', as has been explicitly derived in Ref. 4; the ensuing CIP conductivity and magnetoresistance exhibit a characteristic exponential dependence with respect to the thicknesses of the different layers[3,4] and the magnetoresistance vanishes exponentially in the local limit. On the other hand, for CPP the current for each spin channel is a constant[7] as seen from Eq. (14); then, we find from Eqs. (5) and (9) that the internal field $\mathbf{E}(z)$ is proportional to the local scattering rate $\Delta(z)$. Then, for the CPP geometry, the corresponding global resistivity is proportional to the average scattering encountered in each spin channel; thus, the CPP geometry for multilayers exhibits a self-averaging behavior (all transport properties are determined by the average scattering) not only in the homogeneous limit, but for all length scales, and the magnetoresistance is scale independent and does not vanish in the local limit, a result that had been predicted in Ref. 6 and was later experimentally confirmed.[9] This result leads to a current line picture, according to which transport properties are determined by the scattering sampled by current lines in the whole system, provided that all current lines be essentially equivalent.

Our analysis for multilayers suggests that there exist two categories of inhomogeneous magnetic structures (according to the behavior exhibited by their magnetoresistance): (i) magnetically self-averaging, when their magnetoresistance does not vanish exponentially and is independent of the average distance between magnetic regions (like for the CPP geometry of multilayers); (ii) magnetically non-self-averaging, when their magnetoresistance vanishes exponentially with respect to the average distance between magnetic regions (like for the CIP geometry of multilayers).

The case of granular solids requires considering limiting cases. We will first analyze the homogeneous limit, which is characterized by all mean-free paths being much larger than all inhomogeneity lengths.

In the homogeneous limit the two-point function $\xi(\mathbf{r},\mathbf{r}')$ [Eq. (8)] has a *unique limit*, as when $R=|\mathbf{r}-\mathbf{r}'|\to\infty$; in particular, this is independent of $\mathbf{r}$ and $\mathbf{r}'$, and applies to both granular solids and multilayers. For multilayers the caveat is that such a unique limit holds for almost all paths, and the exception are those paths in the plane of the layers for multilayers. For magnetic systems, the function $\xi(\mathbf{r},\mathbf{r}')$ is a spin matrix and its self-averaging limit is of the form $\bar{\xi}=\bar{\xi}_0+\bar{\boldsymbol{\xi}}\cdot\hat{\sigma}$. Thus, for both granular solids and multilayers, the "average scattering in the medium"

$$\bar{\Delta}=\frac{1}{V[\mathscr{R}]}\int_{\mathscr{R}} d^3r\Delta(\mathbf{r}) \tag{11}$$

is well defined and coincides with the asymptotic form (large R) of $\xi(\mathbf{r},\mathbf{r}')$, provided that the size of the region $\mathscr{R}$ be sufficiently large. In Eq. (11) $V[\mathscr{R}]$ is the volume of the corresponding region. The size of $\mathscr{R}$ is essentially restricted by the condition that the function $\xi(\mathbf{r},\mathbf{r}')$ become asymptotically a constant, i.e., R has is restricted by the linear dimensions L of the sample; whence, these systems have a length scale D_{sa}, such that for $D_{sa}\lesssim R\ll L$, and the volume integral in Eq. (11) is independent of $\mathscr{R}$. We will naturally refer to D_{sa} as the self-averaging length scale. Therefore, the homogeneous limit yields a two-point conductivity, Eq. (9) that is effectively a function of only $R=|\mathbf{r}-\mathbf{r}'|$. Then, choosing a quantization axis that diagonalizes $\bar{\Delta}$ Eq. (5) is simplified to

$$\mathbf{j}_{\alpha\beta}=\delta_{\alpha\beta}\sum_{\gamma}\left[\int d^3r'\,\boldsymbol{\sigma}_{\alpha\gamma,\gamma\alpha}(\mathbf{r},\mathbf{r}')\right]\cdot\bar{\mathbf{E}}=\delta_{\alpha\beta}(\bar{\rho}_\alpha)^{-1}\bar{\mathbf{E}}, \tag{12}$$

where $\bar{\mathbf{E}}$ stands for the average field, and it follows that the electrical resistance in each spin channel is essentially given by the average scattering $\bar{\Delta}$ sampled by the electron in the medium, i.e.,

$$\bar{\rho}_\alpha=\left(\frac{2m}{\hbar^2k_F}\right)([\bar{\Delta}^{-1}]_{\alpha\alpha})^{-1}. \tag{13}$$

This conclusion is achieved if it is assumed that the spin diffusion length is much larger than both the elastic mean-free paths and the inhomogeneity length scales, in which case the continuity equation for each spin component of the current density,

$$\nabla\cdot\mathbf{j}_{\alpha\beta}(\mathbf{r})=0, \tag{14}$$

is satisfied.

On the other hand, in the local limit, defined as the limiting scenario when all local mean-free paths are much smaller than the inhomogeneity lengths, the constitutive relation (5) becomes local; more precisely, the local conductivity becomes the produce of a one point conductivity function and the delta function $\delta(\mathbf{r}-\mathbf{r}')$. The electric field is then the product of the local resistivity and the current density, where the global resistivity is also $\bar{\rho}_\alpha$ along a typical current line, with the current constrained via Eq. (14).

From our analysis of limiting cases we conclude that our theory predicts that granular solids are magnetically self-averaging, due to *randomness* in the distribution of granules. In effect, the current line picture suggests that the global resistivity is proportional to the average scattering $\bar{\Delta}_\alpha$ in each spin channel, for all length scales, like for the CPP case. On the other hand, in the local limit for granular solids, current lines do *not* necessarily sample all the scattering in the medium but they only partially sample the scattering in the granules. Of course, the interfaces are probed regardless of the relative values of the local resistivities. This shows that the local resistivity and the current cannot be completely disentangled. In conclusion, we see that the only difference between the two limiting cases is at most the contribution from the granules. Thus, the scale dependence of the magnetoresistance will show up exponentially with respect to the size of the granules but not with respect to the average distance between adjacent granules. In this sense, granular solids are magnetically self-averaging. It should be noticed that these conclusions are based on our choice of a model in which the electrical resistivity arises from short-range impurity scattering within each region of the system rather from scattering by entire regions.

In summary, we have derived the two-point conductivity of inhomogeneous magnetic structures, as well as the global resistance and magnetoresistance of magnetically self-averaging systems, for which we have shown that they are independent of the average distance between adjacent magnetic regions.

Giant magnetoresistance of dilute Cu(Co) granular films

R. J. Gambino,[a] T. R. McGuire, J. M. E. Harper, and Cyril Cabral, Jr.
IBM Research Division, T. J. Watson Research Center, Yorktown Heights, New York 10598

Granular films of Cu (Co) with Co concentrations from 5.4% to 12% in the as-deposited form had magnetization showing about 60% of the Co as ferromagnetic particles and exhibited giant magnetoresistance (MR) of about 20% at 4.2 K. Annealing at ~310 °C increased the MR to 40% and also increased the saturation magnetization indicating additional Co precipitation. At higher annealing temperatures MR decreased to 1%. The Zhang theoretical model involving polarized conduction electron scattering at particle interfaces seems to give a reasonable description of our results including the quadratic behavior of MR vs $[M(H)]^2$ and MR vs $[M_s(T)]^2$.

I. INTRODUCTION

Giant magnetoresistance discovered by Xiao *et al.*[1] and Berkowitz *et al.*[2] in granular Cu(Co) alloys represents a new approach to the large magnetoresistance (MR) found originally in multilayer films.[3,4] The granular films consisting of a copper matrix with precipitated Co particles which have random position, random size, and random easy axis have magnetoresistive changes of up to 60% at 4.2 K. Both the magnitude and actual shape of the MR as a function of applied magnetic field are similar for both the granular and multilayer systems. Granular films, however, have substantial changes in MR when they are annealed.[1,2] The magnetic and transport properties are found to be sensitive to both fabrication conditions and annealing procedures because cobalt particle concentration and particle size are changed.[5,6]

Recently Zhang and Levy[7,8] have considered the origin of MR in granular films. The giant MR is attributed mainly to the conduction electron spin-dependent scattering at the interface of the Co particle with the Cu matrix. Expressions are given for MR in terms of particle concentration (c), average particle radius (r_m), and normalized magnetization (M/M_s). It is the objective of the present work to examine a series of films where c, r_m, and M_s are varied to compare with theory and to increase our understanding of these complex systems.

II. EXPERIMENTAL PROCEDURES AND RESULTS

Film samples are prepared by coevaporation onto 12-cm-diam oxidized silicon substrates at ambient temperatures of about 50 °C. The films varied in thickness from ~0.6 to 1.5 μm and Co concentrations from 5.4 to 12 at %. The as-deposited films are listed in Table I. Part of each film disc is annealed and these samples are listed in Table II.

Magnetization measurements are made using a Quantum Design superconducting quantum interference device (SQUID) magnetometer with applied fields (H) up to 50 kOe. In most cases films are peeled off the silicon substrate and weighted thus the saturation magnetization M_s is given in emu/g. Resistivity (ρ) is determined by the van der Pauw method and is given in $\mu\Omega$ cm. The values ρ_{max} and ρ_{min} refer to resistivities at $H \approx 0$ and H at 40 kOe as illustrated in Fig. 1, where $\Delta\rho = \rho_{max} - \rho_{min}$ and MR is $\Delta\rho/\rho_{min}$. Vacuum oven annealing temperatures are given in the last column of Table II. Data on M and ρ in the tables are for $T = 4.2$ K.

Figure 1 shows details of both MR and M data as a function of H for our film with the largest MR which is Co 12% (No. 13 in Table II). In this film the M_s at 124 emu/g is based on 12 at. % cobalt in particle form. If the Co is completely precipitated from the Cu matrix, the value should be ≈160 emu/g meaning that this film has about 78% precipitation of ferromagnetic Co particles and represents a value about 25% higher than the as-deposited 12% (No. 5). We note that all the 12% Co listed in the tables have low values of M_s compared to the 8% film. A second consideration is that the resistivity drops from values of ~20 $\mu\Omega$ cm and higher for as-deposited films to ~4 $\mu\Omega$ cm or less for annealed films for all Co concentrations. This decrease in ρ is evidently caused by the increased purity of the Cu matrix as the Co precipitates into particles. In the as-deposited state the matrix is a Co-Cu alloy with a high resistivity due to impurity scattering.

The MR at 4.2 K for the as-deposited films listed in Table I is around 20%. When the film is annealed two things occur. At a high annealing temperature, the MR drops to ~1%, while at $T = 311$ °C, MR can increase up to 40%. Evidently a delicate balance of particle size and Cu purity is needed to obtain the highest value of MR. The Co particle size can be determined by analyzing the superparamagnetic properties of the films. The blocking temperature was found from the temperature dependence of the coercivity. The particle diameter ($2r_m$) was calculated using the relation for the particle volume (V_p): $V_p = 25kT_B/K$. Using the anisotropy energy K of Co ($K = 4.5 \times 10^6$ erg/cm^3) and assuming spherical particles we find that the Co particles are about 50 Å in diameter in all the as-deposited films. The same analysis

gives a particle diameter of 90 Å in the fully annealed samples.

III. DISCUSSION

Zhang gives the following equation for the MR in granular films with single-domain particles:

$$\frac{\Delta\rho}{\rho}=\frac{\rho_2^2}{\rho_1^2-\rho_2^2}\left[1-\left(\frac{M(H)}{M_s}\right)^2\right], \tag{1}$$

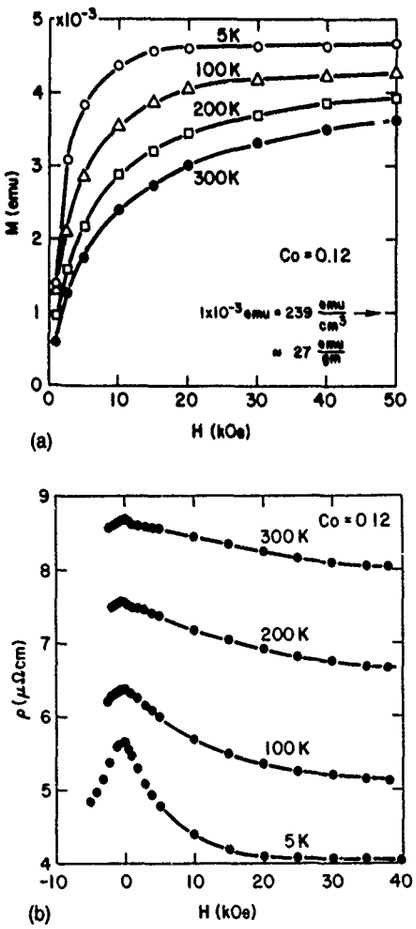

FIG. 1. (a) Magnetization and (b) resistivity as a function of applied field for various temperatures. This is the annealed 12% sample No. 13 Table II.

where ρ_1 and ρ_2 are functions of c, r_m and includes also a ratio p_s (p_b), of the electron spin-dependent to spin-independent scattering potential at the particle surface (bulk), as well as the conduction electron mean-free path at the surface λ_s and in the bulk λ_m of the particles and the mean-free path λ_{nm} in the nonmagnetic matrix. If we accept the simplification that the bulk and the interface-surface scattering of small magnetic particles are the same so that $p_b=p_s$ and $\lambda_m=\lambda_s$, Eq. (1) then reduces to

$$\frac{\Delta\rho}{\rho_s}=\frac{[2p_s(r_m+3)]^2}{\left((1+p_s^2)(r_m+3)+\dfrac{1-c}{c}\dfrac{r_m\lambda_s}{\lambda_{nm}}\right)^2-[2p_s(r_m+3)]^2}\times\left[1-\left(\frac{M(H)}{M_s}\right)^2\right]. \tag{2}$$

Large $\Delta\rho/\rho_s$ (MR) is thus predicted for long mean-free path λ_{nm} and small λ_s. The MR also increases with particle concentration c. In addition MR is quadratic in magnetization as a function of field and is largest for small M. At zero field where $M/M_s\approx 0$, the point of maximum MR with respect to saturation, Eq. (2) can be written

$$\left(1+\frac{1}{\Delta\rho/\rho_s}\right)^{1/2}=\frac{1}{2p_s}\frac{\lambda_s}{\lambda_{nm}}\frac{r_m(1-c)}{(r_m+3)c}+\frac{1+p_s^2}{2p_s}. \tag{3}$$

We wish to know how well our data fit the Zhang model as given by Eqs. (2) and (3). From Table I for as-deposited films MR seems to be large in the film having the highest Co concentrations No. 5. The large value of MR for No. 2 (5.4% Co) does not follow this trend. In addition, this film (No. 2) has the lowest value of resistivity meaning λ_{nm} is large and the largest M_s of all the as-deposited samples indicating a larger fraction of the Co is precipitated.

The quadratic behavior given by the proportionality $\Delta\rho/\rho_s\alpha\{1-[M(H)/M_s]^2\}$ fits quite well for M vs H dependence as shown in Fig. 2 for films No. 3, 8.3% Co. The quadratic proportionality holds best for the as-deposited samples and when M is close to saturation at high applied fields. At low fields in the annealed samples the magnetization may increase primarily by wall motion within large particles with only a small change in magnetic interface scattering. Consider also the affect of annealing at high temperatures which causes low MR. If the annealing causes a pre-

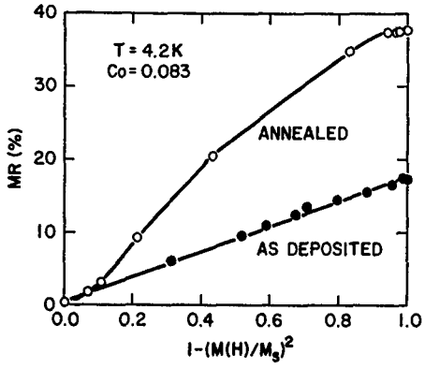

FIG. 2. Field dependence of MR at 4.2 K as a function of $1-[M(H)/M_s]^2$ for No. 3, 8.3% Co. Note the linearity of the as-deposited sample. Similar behavior is observed in the 5.4% and 12% samples.

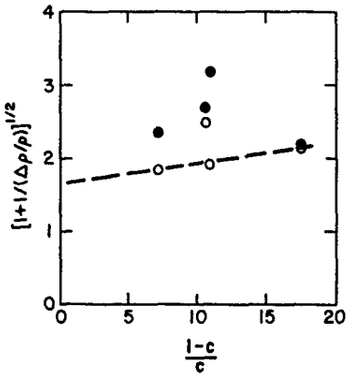

FIG. 4. Plot of $[1+(1/MR)]^{1/2}$ and $(1-c)/c$ parameters associated with Eq. (3) in text.

ponderance of large Co particles without smaller particles which take large fields to saturate, then, MR is low as observed.

The quadratic dependence is also observed for M as a function of T as shown in the plots of Fig. 3. However, Eq. (2) has a positive linear slope; this slope may be from the temperature dependence of the mean-free paths.

A final consideration is to use Eq. (3) to determine the value of p_s or the ratio λ_s/λ_{nm} by plotting $\{1+[1/(\Delta\rho/\rho)]\}^{1/2}$ vs $(1-c)/c$, where c is the starting Co concentration. The particle size is assumed constant for each group of samples in the respective tables. Data points plotted on Fig. 4 for the as-deposited samples are scattered sufficiently so that a quantitative fit is not possible. We assume the annealed samples with the highest values of MR are the most like the Zhang model, i.e., isolated single-domain particles in a pure copper matrix. These data give a small positive slope with an intercept of 1.65. From the intercept value we find p_s, the ratio of the spin-dependent to spin-independent scattering potential is about 3. From the slope and assuming r_m is 50 Å we find $\lambda_s/\lambda_{nm}=0.16$. In other words, the mean-free path in the nonmagnetic matrix λ_{nm} is about six times the mean-free path in and near the surface of the magnetic particles, a reasonable number.

The origin of the MR in the granular alloys fits a model that polarized conduction electrons from random easy axis single-domain Co particles are scattered by particles that have not fully rotated in the direction of the applied field. Application of a large field fully magnetizes most of the Co particles and the resistivity decreases. If the particles are of sufficient size, they all rotate together during magnetization and no differential spin-dependent scattering is found and MR is small.

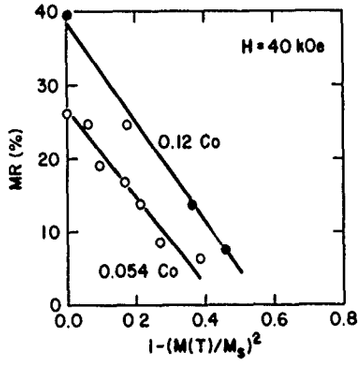

FIG. 3. Temperature dependence of MR as a function of $1-[M(T)/M_s]^2$ for film No. 2, 5.4% Co as deposited, as No. 13, 12% Co annealed.

Dependence of giant magnetoresistance on film thickness in heterogeneous Co-Ag alloys

J. R. Mitchell and A. E. Berkowitz
Physics Department and Center for Magnetic Recording Research, University of California, San Diego, California 92093

The dependence of magnetic properties on film thickness in as-deposited Co-Ag alloys is discussed. Films ranging in Co concentration from 0 to 100 vol % Co and thicknesses between 100 Å and 1 μm were deposited by sputtering onto Si(100) substrates. It was found that both magnetoresistance (MR, $\Delta\rho$) and MR ratio ($\Delta\rho/\rho$) increase with thickness. Resistivity (ρ) decreases with increasing thickness. The dependence of MR ratio on concentration of Co is not markedly different for 200 and 2000-Å-thick samples. Saturation magnetization is roughly constant for thicknesses greater than ~200 Å, decreasing rapidly below this cutoff. However, most of both the thin (200 Å) and thick (2000 Å) films begin showing magnetic hysteresis between 10 and 100 K. The differences in transport and magnetization properties may be ascribed to differences in film growth for thin versus thick films.

I. INTRODUCTION

Much interest is evident in the giant magnetoresistance (MR) of alloy films.[1–5] Most of the work in this field, however, uses samples at least 2000 Å thick. The properties of thinner alloy films are technologically and scientifically interesting. We report the effects of varying layer thickness for Co-Ag alloy films.

II. EXPERIMENT

Two series of Co-Ag films were produced by co-sputtering. The first series consists of films varying from 0 to 100 vol % Co. In one set, at each concentration, films 200 Å (thin) and 2000 Å (thick) were grown. The second set was comprised of films 27 vol % Co, with thicknesses ranging from 120 Å to 1 μm. All films were sputtered onto Si(100) substrates at room temperature as previously described.[3] Data are reported for as-deposited samples only. Magnetoresistance data were taken using a four-point probe. Magnetization measurements were made on a superconducting quantum interference device (SQUID) magnetometer. Volume concentrations are deduced from atomic absorption spectroscopy measurements of Co concentration, assuming all Co appears as precipitates.

III. RESULTS

The x-ray data are for films whose thicknesses are nominally 2000 Å or greater. In general, the films were fcc and (111) oriented. However, the pure Ag film was fcc but not oriented. The pure Co film was hcp. For Co concentrations greater than 14 vol %, separate Co and Ag lines are clearly visible. A typical diffraction pattern is shown in Fig. 1. As expected, the Co(111) line is shifted from the bulk value towards the Ag(111) line, and vice versa. Figure 2 summarizes the variation in lattice parameter with vol % Co. As the Co concentration increases, the difference between the calculated and the bulk lattice parameter increases for Ag and decreases for Co. In addition, the intensity of the Co(111) line increases with the concentration of Co.

Initial analysis of finite size broadening of the Co line indicates that the Co crystallite size varies as the volume fraction of Co is increased. Assuming that the Co grains are close-packed throughout the film, one can also calculate an

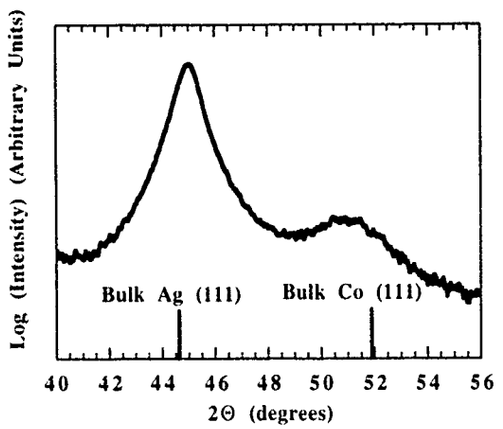

FIG. 1. X-ray diffraction spectrum using Co radiation ($\lambda = 1.79$ Å) for a 26.5 vol % Co alloy, as-deposited.

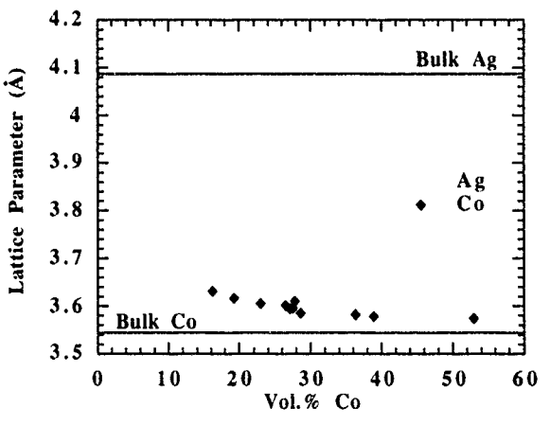

FIG. 2. Variation of Co and Ag lattice parameters with Co concentration.

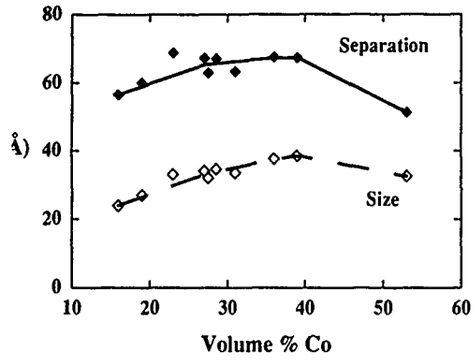

FIG. 3. Variation of Co grain size and separation for 2000-Å-thick films with Co concentration (vol %), assuming a close-packed array of particles.

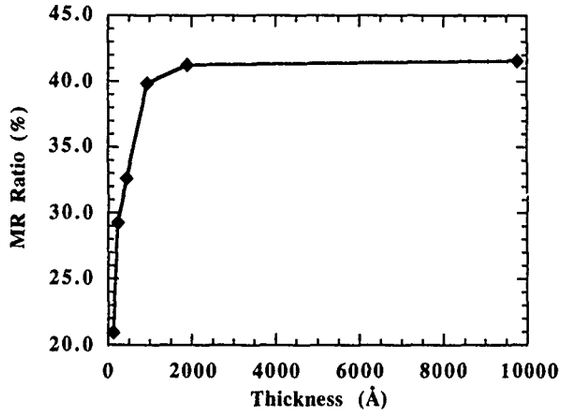

FIG. 5. Dependence of MR ratio at $T=10$ K on thickness. All samples have 27 vol % Co.

average intergranular separation, i.e., the spacing between the centers of neighboring particles. Figure 3 summarizes these results. The lines in Fig. 3 are drawn to guide the eye. The grain size increases until a concentration of 39 vol % Co is reached. The Co line broadening indicates that the 53 vol % film has smaller Co grains. However, magnetic hysteresis data indicates that there may be a bimodal distribution of Co grain sizes. The smaller set of grains is responsible for the broadening that gives the 32 Å grain size. The size and separation of the grains for the sample with the maximum magnetoresistance are 33 and 40 Å, respectively. Similar analysis on the Ag line gives a grain size of roughly 150 Å for all samples. This is supported by results of dark-field transmission electron microscopy (TEM). Analysis of the x-ray data for thinner films is ongoing. Initial results indicate that, at the same concentration of Co, the Co grains are smaller and more densely packed for thinner films.

The variation of MR ratio ($\Delta\rho/\rho_{min}$), where $\Delta\rho=\rho_{max}-\rho_{min}$ and $\rho_{min}=\rho(H=20$ kOe), with Co concentration is shown in Fig. 4. All MR data reported herein were taken at 10 K. The MR ($\Delta\rho$) displays a similar dependence on volume fraction of Co. The MR ratios of the thin (200 Å) and thick (2000 Å) films peak at similar volume fractions of Co. In the thin films, however, the MR ratio peaks at a slightly higher concentration and does not fall off quite as rapidly with increasing volume fraction Co. Since one expects both the size and packing of Co particles to affect the MR ratio, the differences in the MR ratio between thick and thin films indicates variations in the microstructure with thickness. Figure 5 displays the dependence of MR ratio at 10 K at 10 K on layer thickness for 27 vol % Co. At thicknesses <2000 Å, the MR ratio falls off quite rapidly. The MR displays a similar variation.

For both thick (2000 Å) and thin (200 Å) films, the high-field (20 kOe) resistivity peaks at 53 vol % Co. This is shown (for $T=10$ K) in Fig. 6. The peak in resistivity is probably due to impurity scattering. In other words, the electrons traveling through an Ag-rich matrix are more strongly scattered by the "impurity" (dissolved Co) than by defects in the matrix. The difference in resistivity between the thick films and the thin films also varies with Co concentration. The percent difference in high-field resistivity for the thick and thin films is smallest at the peak in the resistivity. In addition, at a fixed concentration, the relative resistivity increases with decreasing thickness as shown in Fig. 7. The data shown are for a 27 vol % Co alloy and pure Ag. The small variation in resistivity for the alloy cannot be ac-

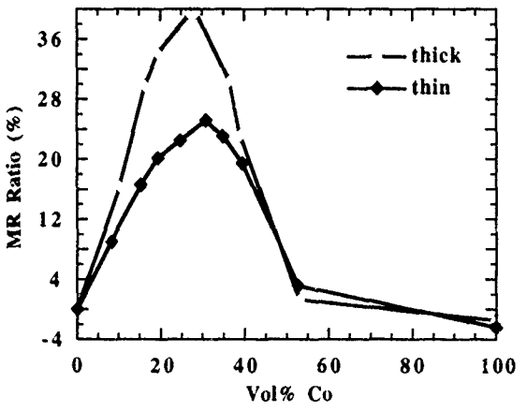

FIG 4 Variation of magnetoresistance ratio with volume concentration of Co at $T=10$ K for both thick (2000 Å) and thin (200 Å) films.

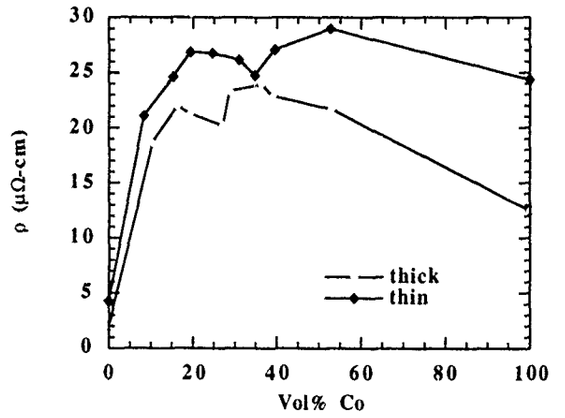

FIG. 6 Variation of high-field (20 kOe) resistivity at $T=10$ K with Co concentration for both thick (2000 Å) and thin (200 Å) films.

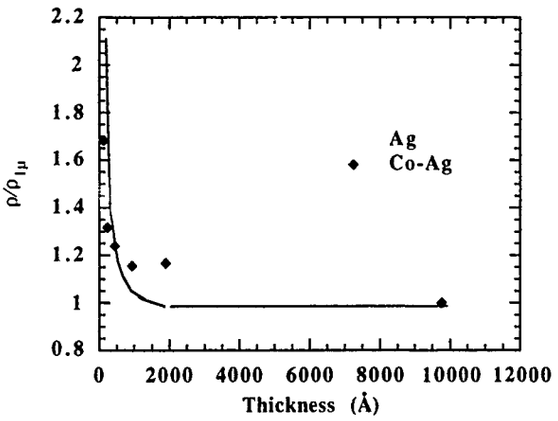

FIG. 7. Normalized resistivity (normalized to 1-μm-thick film) vs thickness for both pure Ag and a nominally 27 vol % Co-Ag alloy. The line for the pure Ag data is drawn to guide the eye.

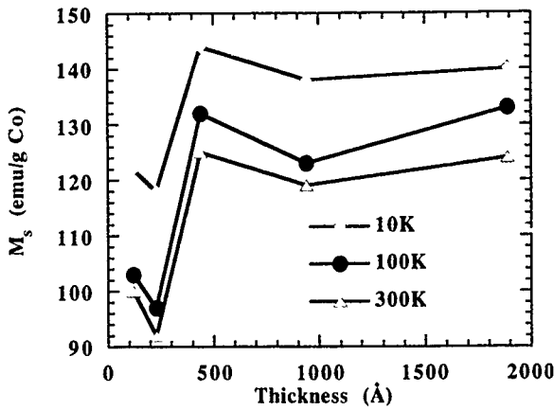

FIG. 8. Variation of saturation magnetization with thickness for 27 vol % Co.

counted for by considering the contribution of scattering at the air-film and substrate-film interfaces.[6,7] It is probable that the difference in microstructure between the thick and thin films mentioned earlier plays a role in the variation of resistivity with thickness seen here.

For Co concentrations greater than 10 vol %, the saturation magnetization is not highly dependent on fraction of Co present. It does, however, depend on layer thickness. At a thickness of ~200 Å, the saturation magnetization falls off, as shown in Fig. 8. Thick samples with concentrations less than 35 vol % Co do not exhibit hysteresis until the temperature is less than 100 K. Thin samples with less than 50 vol % Co show no hysteresis at temperatures above 100 K. Again, these data indicate differences in the films' microstructure, i.e., the size and separation of the Co grains.

IV. DISCUSSION AND SUMMARY

Although a decrease in resistivity with increasing thickness is expected, the large variation in the magnetoresistance is not. The variation of magnetoresistance cannot be accounted for simply by the increased importance of scattering at the film surfaces. In addition, the dependence of the magnetization on thickness indicates that the microstructure of the thin films differ from that of the thick films. In particular, the size of the Co particles and degree of percolation in the thin films is less than that of the thick films. In other words, for the same Co concentration, the Co particles are smaller and, therefore, closer together in the thin films than in the thick films. However, transport and magnetic measurements alone are insufficient to determine this. Other methods of structural characterization are, therefore, being used to determine the films' microstructure.

In summary, Co-Ag alloys have been produced over a range of concentrations and thicknesses. The variation of MR and magnetization with concentration is similar in both the thin and thick films. However, there are differences between the properties of thick and thin films. These variations indicate differences in microstructure between the films. Work is ongoing to determine the exact nature of the microstructure of the thin and thick films.

Giant magnetoresistance in a spinodally decomposed, bulk 60 Cu-20 Ni-20 Fe alloy is reported. An annealed, quenched, and heat-treated sample with a compositional modulation of ≲50 Å size exhibits a $\Delta R/R$ value as high as 9% at 4.2 K. Optimization of the ferromagnetic phase particle geometry through a combination of spinodal decomposition and uniaxial deformation led to a locally multilayered, superlattice-like structure and a dramatic increase in room-temperature magnetoresistance from ~0.6 to ~5%. This improvement in magnetoresistance is accompanied by a decrease in coercivity from ~620 Oe in the fully decomposed material to ~45 Oe in the optimized structure. Interestingly, this structure no longer exhibits the commonly observed temperature-dependent behavior of $\Delta R/R$ increasing at low temperatures, but rather shows a decrease at 4.2 K.

I. INTRODUCTION

The giant magnetoresistance (GMR) phenomenon has been discovered in recent years in Fe/Cr, Co/Cu, and various other multilayer superlattice films[1-7] as well as in heterogeneous (granular) Co-Cu thin films[8,9] These multilayer films exhibit electrical resistivity which decreases with magnetic field (negative magnetoresistance). The resistivity change is typically in the range of 5%–50%. The GMR effect offers a possibility of convenient magnetic sensing, e.g., as a high-resolution transducer (read head) for magnetic information storage systems.

In the present paper, we demonstrate that the GMR effect is not restricted to thin-film structures but can easily be obtained in bulk materials if a proper microstructure is introduced, for example, by spinodal decomposition and deformation in a Cu-Ni-Fe alloy.

II. EXPERIMENTAL

A 60 Cu-20 Ni-20 Fe (wt %) alloy (Cunife I, commonly used as a permanent magnet), in the form of ~5.0-mm-diam rod, was procured from UGIMAG Inc., Valparaiso, Indiana. The as-received material has the coercivity (H_c) of ~620 Oe and the remanent induction (Br) of ~2400 G at room temperature. A typical aging heat treatment to obtain these properties is an isothermal decomposition at 650–700 °C for several hours. The decomposed alloy was then either annealed (950 °C/30 min), water cooled, and heat treated to obtain fine spinodally decomposed precipitates or uniaxially deformed by swaging, wire drawing, and cold rolling to various diameters and thicknesses. The evaluation of magnetoresistance was carried out by four-point measurements (typical sample length ~2 cm) in the presence of an in-plane magnetic field up to 6 T. M-H hysteresis loops were obtained by using a vibrating sample magnetometer and a hysteresigraph machine. The microstructures of the alloys were obtained by high-resolution transmission electron microscopy using a JEOL 4000 microscope operated at 400 kV.

III. RESULTS AND DISCUSSION

Shown in Fig. 1 are the magnetoresistance (MR) ratio versus H curves at 4.2 K for the annealed and quenched sample as well as post-heat-treated samples. The MR ratio $\Delta\rho_M/\rho_S$ is defined here as $(\rho-\rho_S)/\rho_S$, where ρ_S is the resistivity at the near-saturation field and ρ is the resistivity at a magnetic field H. The electrical resistivity of the alloy samples at $H=0$ is about 20–25 $\mu\Omega$ cm at 4.2 K, which decreases when the field is applied. The as-quench sample shows a high magnetoresistance value of ~7.2%. This is further increased to ~9% after a brief heat treatment at 450 °C/3 min as the compositional amplitude of the modulation is increased without much particle coarsening. More ex-

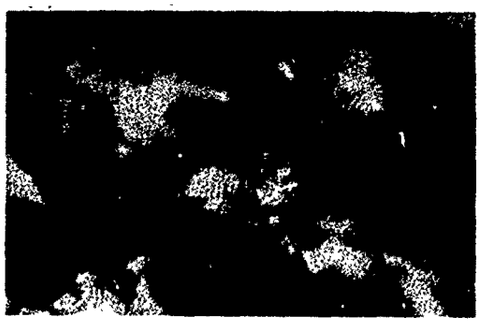

FIG. 2. TEM micrograph for the annealed and quenched alloy showing a ~30 Å sized modulated structure of the Ni, Fe-rich phase.

tensive heat treatment only reduces the MR effect presumably due to the coarsening of the particles and reduced surface scattering.

The Cu-Ni-Fe alloy is known to decompose spinodally into a uniformly distributed, modulated two-phase structure consisting of Ni, Fe-rich ferromagnetic phase, and Cu-rich nonmagnetic or weakly magnetic phase.[10–12] The observed giant magnetoresistance in the alloy is attributed to the formation of extremely fine-scale spinodally decomposed structure (Fig. 2), which shows the Ni, Fe-rich phase, ~30 Å in size and marked by circles (Moire fringes), dispersed in the Cu-rich matrix. The size scale of the particles is comparable to the thickness or diameter of ferromagnetic phase in other GMR materials.[1–9] The spin-dependent scattering of electrons at the two-phase interfaces and in the strongly ferromagnetic phase is expected to influence the magnetoresistance behavior, similarly as in the multilayer films[1–7] and granular materials.[8,9]

The samples in Fig. 1, however, exhibit much smaller values of MR ratio at room temperature, less than about one eighth of those at 4.2 K. The exact reason for this severe temperature dependence of MR ratio is not clearly understood. In order to achieve improved MR effect at room temperature, an alternative route of microstructural control was employed as described below.

The initial, as-received (as-decomposed) structure containing the oversized (~500 Å diameter) ferromagnetic phase particles, Fig. 3(a), was subjected to a uniaxial deformation to produce a locally multilayer-like structure with a very small layer thickness. (Wire drawing from 5.0 to 0.25 mm in diameter followed by cold rolling to about 0.052 and 0.015 mm thickness to produce three different thicknesses of the ferromagnetic phase measured or estimated to be about 60, 15, and 5 Å, respectively) Shown in Fig. 3(b) is the deformation-induced, superlattice-like structure with a 15-Å-thick ferromagnetic layers separated by nonmagnetic layers.

Shown in Fig. 4 are the room-temperature magnetoresistance (MR) ratio (given in %) versus H curve for the alloy samples with different particle thicknesses. As shown in the figure, the MR ratio increased from ~0.6% to ~3.8% after the diameter of the alloy rod was reduced by wire drawing from ~5.0 mm in the as-received condition to ~0.25 mm (99.75% reduction in cross-sectional area). The particle thickness of the ferromagnetic phase was reduced from

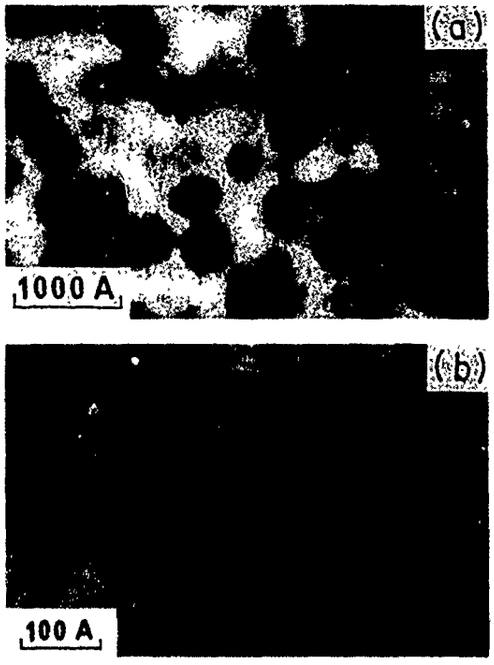

FIG. 3. Sectional TEM micrographs of the Cu-20Ni-20Fe alloy, (a) as-received, (b) after 99.94% deformation. The darker phase is the Fe, Ni-rich ferromagnetic phase.

~500 Å to an approximate size of ~60 Å (roughly estimated using the particle thickness in the similarly but more extensively deformed sample of Fig. 3(b), which was given ~99.94% reduction in area). The reason why the particle diameter was not reduced in exact proportional to the change in the alloy sample diameter is probably because of the difference in the mechanical properties of the two phases involved. The observed improvement in MR ratio is attributed to the much enhanced spin-dependent scattering in the ultrafine structure, similarly as in the multilayer films. Cold rolling process was subsequently applied to further reduce the dimension of the ferromagnetic phase in the Cu-Ni-Fe alloy. At the ribbon thickness of 0.052 mm [99.94% reduction in area with the measured particle thickness of ~15 Å, Fig. 3(b)], the MR ratio was measured to be as high as 5% as

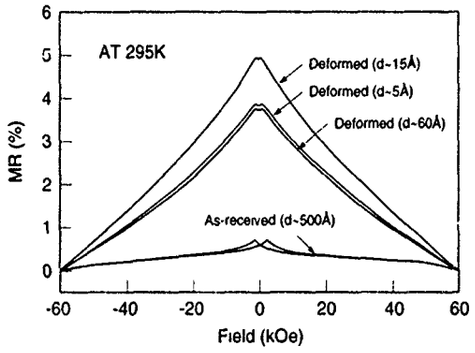

FIG. 4. MR ratio vs H at room temperature of the deformed Cu-Ni-Fe samples. The measured or estimated particle thicknesses of the ferromagnetic phase are indicated

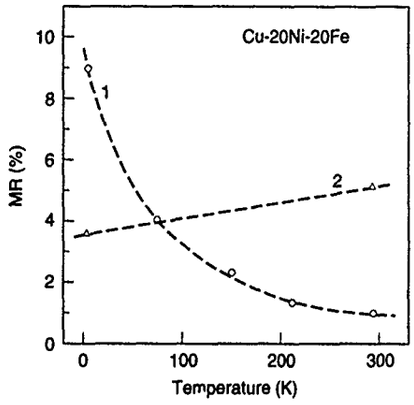

FIG. 5. Temperature dependence of the MR ratio for the sample of Fig. 2 (curve 1) and that of Fig. 3(b) (curve 2).

shown in Fig. 4. After additional rolling to a 0.015-mm-thick ribbon (99.984% reduction in area with an estimated particle thickness of ~5 Å), however, the MR ratio decreased to ~3.9%. There appears to be an optimal particle thickness of the ferromagnetic phase for the largest MR ratio in the Cu-Ni-Fe alloy.

Shown in Fig. 5 are the MR ratio versus temperature curves for both the modulated sample of Fig. 2 and the deformed sample of Fig. 3(b). It is interesting to note that the MR ratio for the deformed Cu-Ni-Fe alloy sample (curve 2) at 4.2 K is not significantly different from that at room temperature and in fact smaller than the room-temperature value for the 0.052-mm-thick sample. This is a rather unusual behavior when compared to the annealed, quenched, and heat-treated (450 °C/3 min) Cu-Ni-Fe alloy (curve 1) in which the MR ratio increases significantly (by a factor of ~8) when cooled from room temperature to 4.2K. Many multilayer thin films with GMR effect also exhibit a two to three times increase in the MR ratio upon cooling to 4.2 K, which is generally interpreted in terms of relatively strong temperature-dependent decrease in resistivity combined with a rather weak temperature variation of $\Delta\rho_M$.

The M-H hysteresis behavior of the Cu-Ni-Fe alloy samples is significantly affected by the material processing employed in this study. As the deformation reduced the particle thickness of the ferromagnetic phases from ~500 to ~15 Å, almost close to the superparamagnetic regime, much of the original permanent magnet properties were lost. The coercivity is reduced from ~620 to ~45 Oe, and the remanence ratio (M_r/M_s) from 0.87 to 0.21. The near-saturation magnetization at $H=3$ T of the deformed sample is ~175 emu/cc but the observed 10% increase in magnetization from 1 to 3 T field indicates that the ribbon sample is not fully saturated at $H=3$ T (and even at 6 T from the MR ratio versus H curves). This is different from the as-received sample, the magnetization of which appears to saturate at a field well below 5 kOe. Essentially a similar M-H behavior is observed at 4.2 K except that the remanence ratio is even further reduced to ~0.05.

IV. SUMMARY

The giant magnetoresistance effect has been created in a bulk, spinodally decomposed or deformed Cu-20Ni-20Fe alloy containing an ultrafine ferromagnetic phase, either as dispersed particles or as a locally layered superlattice-like structure. The optimization of particle geometry through a combination of heat treatment and uniaxial plastic deformation led to a drastic increase in the room-temperature MR ratio from ~0.6 to ~5%. The material exhibits a rather unusual temperature dependence of magnetoresistance, with the MR ratio being actually higher at room temperature than at 4.2 K.

We have prepared granular films of Fe (36 at. %)–Mg (64 at. %) and measured the magnetization, resistance, and thermopower as a function of the applied magnetic field at temperatures between 300 and 6 K. The as-prepared sample has a magnetoresistance ratio ($\Delta R/R_{max}$) of −6.3% in a field of 5.5 T at 6 K. The samples were annealed at temperatures between 150 °C and 228 °C for one hour. The MR does not vary as the square of the magnetization, as predicted by theory. We attribute this to a particle size distribution effect.

INTRODUCTION

In recent years, considerable interest has developed in the magnetoresistance (MR) of bimetallic magnetic/nonmagnetic multilayers and granular systems. The systems that have been studied most thoroughly are Co/Cu, Co/Ag, and Fe/Cr.[1–5] Most of the early theoretical work attributed the MR to the spin-dependent scattering at the magnetic/nonmagnetic interfaces.[6–9] More recently, the role of the spin-dependent density of states (DOS) in the magnetic medium has been investigated.[10–12] Measurements of the MR and magnetothermopower (MTP) in Co/Cu multilayers[11] and Co/Ag granular systems[13] suggest that the spin dependent DOS must be accounted for in any theoretical explanation of so-called giant magnetoresistance. We were interested in measuring the magnetization, MR, and MTP in a new system, and chose Fe–Mg because the constituents are immiscible and because we wanted to test the DOS argument in a system with a positive thermoelectric power.

EXPERIMENT

The 5800 Å thick Fe–Mg films were grown by coevaporation under ultrahigh vacuum onto Si and thin glass substrates. The concentrations were measured using inductively coupled plasma photoemission spectroscopy. The samples contained Fe (36 at. %) and Mg (64 at. %). The volume ratio is roughly 20%. A more complete description of the growth process, as well as an analysis of the as-prepared sample, can be found in an article by Araga, Kita, and Tasaki.[14]

Four samples were sealed in small evacuated quartz tubes and annealed at temperatures of 150 °C, 204 °C, 210 °C, and 228 °C for one hour. The temperature of the quartz tube containing the sample was monitored *in situ* and fluctuated less than 2 °C. We measured the magnetization of the samples using a SQUID magnetometer in fields of up to 5.5 T and at temperatures from 6 to 300 K. The resistance was determined using a conventional four-lead DC measurement in fields of up to 7 T. The temperature of the samples could be varied from 4.2 to 300 K. At around 6 K, the lowest temperature at which measurements were taken, the fluctuation in the sample temperature was relatively large, about ±2 K; however, the measured temperature dependence of the resistance was small. The uncertainty associated with the resistance measurements is ±0.05%. We measured the thermoelectric power of the as-prepared sample in fields of up to 8 T at 100, 200, and 300 K. This was done by varnishing one end of the sample to the copper sample holder and a chip-resistor heater to the other end. The voltage leads were made of thin (0.002 in.) lead wires that were attached to the sample with silver paint. The contribution of the lead leads to the measured thermoelectric power was subtracted out using the recommended values for the absolute thermoelectric power of lead.[15] The temperature gradient was monitored with a type-*E* differential thermocouple that was varnished to the sample. A temperature difference of 0.5 K was used in the measurements. The applied field was in the plane of the sample, parallel to the thermal gradient.

RESULTS

The as-prepared sample was studied by Araga, Kita, and Tasaki.[14] Their work is summarized here. High angle x-ray diffraction scans showed no Fe peaks, indicating that the Fe is amorphous. Magnetization curves for the as-prepared sample did not fit to a single Langevin function, which indicates that the Fe particles vary in size. The curves couid not be represented by a single function of H/T. This suggests that the Fe particles are weakly coupled. Using a mean field model with a discrete distribution of particle sizes, they have determined that the average Fe-particle moment is $220\mu_B$.

Magnetization curves taken at 6 K are shown in Fig. 1(a) for all the samples. Clearly, the initial susceptibility increases rapidly as the annealing temperature is increased. At this temperature the samples are hysteretic, but with coercive fields too small to be observable at this scale. The samples annealed at higher temperatures (210 °C and 228 °C) have a ferromagnetic contribution that can be readily observed in the 300 K magnetization curves shown in Fig. 1(b).

In order to quantify the magnetization curves, we make the simplifying assumption that the system consists of three components: a ferromagnetic cluster, smaller, and larger particles. Implicit here is the assumption that the annealing process ripens the system, producing a connected region that remains ferromagnetic at 300 K. We approximate the distri-

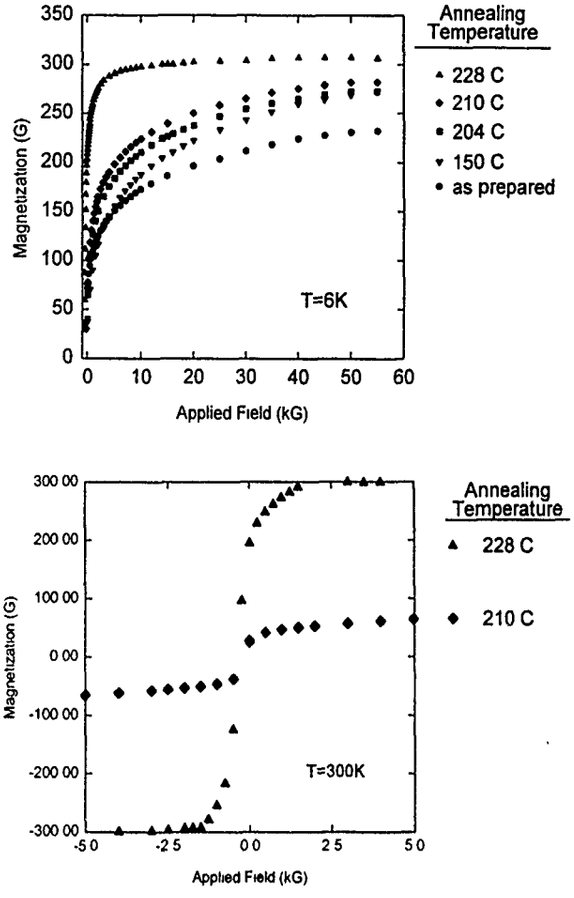

FIG. 1. (a) The 6 K magnetization curves for the Fe–Mg as-prepared sample and the samples annealed at the temperatures indicated. (b) The 300 K magnetization curves for the Fe–Mg samples annealed at 210 °C and 228 °C

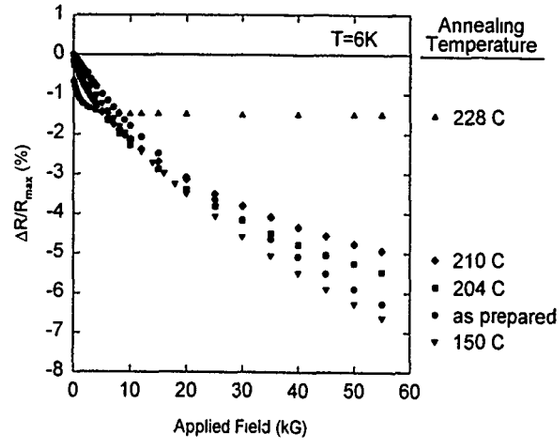

FIG. 2. The magnetoresistance ratio $\Delta R/R_{max}$ at 6 K for the Fe–Mg granular samples annealed at the indicated temperatures.

bution of smaller clusters as bimodal. We can fit the data to the sum of a ferromagnetic and two Langevin contributions, for which the smaller particles have a magnetic moment of approximately $10\mu_B$, independent of annealing temperature, and the larger particles have a moment that depends on the annealing temperature. In the as-prepared sample, there is no ferromagnetic contribution, and the smaller and larger particles (whose moment is about $150\mu_B$) contribute equally to the total magnetization. As the annealing temperature is increased, the larger particles grow in size to about $250\mu_B$, their contribution to the magnetization increases, and a ferromagnetic component appears, all at the expense of the smaller-particle contribution. After annealing at 228 °C, the ripening process is apparently complete, and essentially all the Fe atoms are part of the ferromagnetic cluster.

The MR ratio, $\Delta R(H)/R_{max}=[R(H)-R_{max}]/R_{max}$, at 6 K is plotted in Fig. 2 for all the samples. (Since the resistance does not saturate, we divide by the maximum resistance, which, like the magnetization, shows a slight hysteresis and occurs at fields very close to zero.) The MR and resistivity data are summarized in Table I. In all samples annealed at 210 °C or less, the resistance shows no sign of saturation in fields of less than 7 T, and the resistivities are quite high, 80–130 $\mu\Omega$ cm. In contrast, the sample annealed at 228 °C saturates in a field of less than 1 T, and its resistivity is much lower, ~18 $\mu\Omega$ cm.

The magnetization, MR, and resistivity measurements suggest that the system ripens. In the as-prepared state, the amorphous Fe granules have a broad size distribution. Upon annealing, the small Fe particles migrate into the larger clusters, and, since the Fe concentration is above the percolation threshold, the Fe clusters may form a ferromagnetic infinite percolating cluster. The resistivity and MR drop because the infinite cluster provides a channel through which the electrons may flow, uninterrupted by strong interfacial or spin-dependent scattering.

In Fig. 3 we plot the MR ratio versus the square of the magnetization for all samples at 6 K. The MR does not depend upon the square of the magnetization, as predicted.[12] We argue that this is due to the particle size distribution.

If the electrons scatter primarily from defects in the bulk of the granules, the granules will contribute to the resistance according to their volume. In this case the MR will vary as M^2. If, however, the electrons scatter primarily at the surface of the granules, the granules will contribute to the resistance, according to their surface area. Because the magnetization depends on the volume, the MR will not vary as M^2 in this case if the granules vary in size. This is because at low fields the larger particles magnetize easily but reduce the resistance rather feebly. As the field is increased, the smaller particles

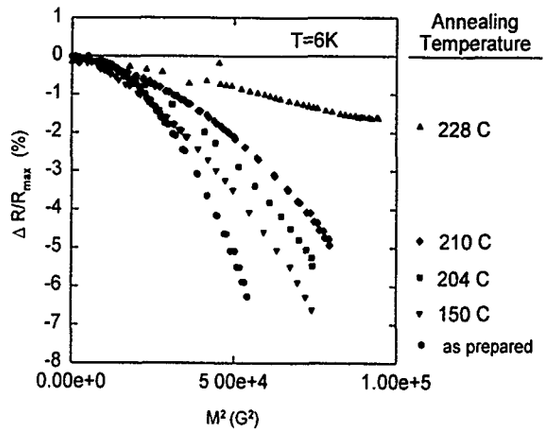

FIG. 3. The magnetoresistance ratio $\Delta R/R_{max}$ plotted against the square of the magnetization for the Fe–Mg granular samples annealed at the indicated temperatures.

begin to align, and, because of their larger surface to volume ratio, reduce the resistance more strongly.

The zero field thermoelectric power at 300 K of the as-prepared sample was $-9.7\ \mu$V/K$\pm 0.3\mu$V/K. This value is below the values of both Mg ($-0.97\ \mu$V/K) and Fe ($+15\ \mu$V/K). We measured the MTP of the sample to determine if the TEP varied as the inverse of the resistance as has been reported in other systems.[11,13] It has been shown that such a scaling relationship holds only when the electrons are strongly scattered into the spin-split d bands of the magnetic granules.[13] Spin-dependent scattering alone will not produce such behavior. We measured a change in the TEP from $-9.7\ \mu$V/K in the zero field to $-10.5\ \mu$V/K in a field of 8 T, and, as predicted, the TEP varied as $1/R$. This suggests that the spin-dependent density of states of the d bands plays an important role in the magnetotransport in this system. A more complete description of the TEP measurements will be presented elsewhere.

SUMMARY

We have measured the magnetization, MR, and TEP of Fe–Mg granular samples annealed at 228 °C and below. The magnetization data suggest that as the annealing temperature is increased, the Fe particles grow larger, and a ferromagnetic contribution emerges. The $\Delta R(H)/R_{max}$ data does not have an M^2 dependence, as predicted by theory. We attribute this to a particle size distribution coupled with strong interfacial scattering. The as-prepared sample has a zero field thermopower of $-9.7\ \mu$V/K at 300 K. A relatively large MTP effect was measured in fields of up to 8 T, and the TEP varied as the inverse of the resistance as predicted by the spin split density of states model.

Giant magnetoresistance of 7.7% at 5 K is observed in bulk mechanically alloyed $Co_{30}Ag_{70}$. Our recently defined $\delta(\Delta\rho/\rho)$ technique used to determine the predominant interactions within the system indicated that negative interactions dominate between the particles. Exchange anisotropy and metastable magnetization processes characterized by large Barkhausen jumps are observed at low temperatures on a small volume of the sample.

I. INTRODUCTION

The giant magnetoresistive properties exhibited by antiferromagnetically coupled multilayered films[1,2] has led to extensive interest in their electrical transport and spin-dependent scattering properties—stimulated by their potential applications as magnetoresistive sensors. The different scattering probabilities of spin-up and spin-down electrons are exploited in multilayered films, in which the mean-free path of the electrons is greater than the thickness of the layers, with the result that there is no low resistance channel when the alternate magnetic layers are antiparallel. These same requirements are satisfied in granular magnetic materials,[3] in which small volumes of single domain magnetic material are dispersed in a nonmagnetic matrix. Spin-dependent scattering now originates from the randomly aligned single domain regions, and is a maximum when there is the greatest degree of magnetic misalignment—usually close to the zero magnetization points on the hysteresis curve. In the as-prepared state, the material may tend to a single phase metastable alloy, however, annealing increases local fluctuations in the concentration of the magnetic species, eventually leading to phase segregation and magnetically rich clusters. The two metals used in this study are Co and Ag, in which most of the spin-dependent scattering is thought to arise from the interfacial regions between the Co and Ag, leading to a particle size dependence of magnetoresistance.[4] The discovery that multilayered materials are not a prerequisite for giant magnetoresistance has encouraged the exploitation of different, relatively inexpensive, preparation techniques capable of producing metastable alloys of immiscible materials such as cosputtering[3,5] and melt spinning.[6] In this study, mechanical alloying[7,8] has been used to produce bulk material as opposed to a thin film.

II. SAMPLE DETAILS

The starting material for the mechanical alloying consisted of a 10 g fine powder mixture of Co (99.8%, <2 μm) and Ag (99.9%, 2–3 μm) in a 3:7 atomic ratio. This mixture was ball milled in a Fritsch PM5 ball mill for 42 h with 170 g of 10 mm stainless steel balls. The grain size of the resulting free coarse powder was approximately 100 μm. Chemical analysis of energy-dispersive x rays in a scanning electron microscope indicated that the $Co_{30}Ag_{70}$ atomic composition was consistent on a micron scale, and that iron impurities were less than 1%. Structural analysis using x-ray diffraction showed broad diffraction peaks corresponding to those expected for small FCC cobalt particles (a_0=0.358 nm) embedded in a FCC silver matrix (a_0=0.408 nm), with the width of the peaks indicating particle size and strain broadening. All measurements were made on the as-prepared material without any heat treatment.

Magnetization measurements as a function of temperature were made on just a few grains of the powder in a SQUID magnetometer, on a larger volume pellet in a vibrating sample magnetometer and at room temperature using an alternating gradient force magnetometer. For magnetoresistance measurements, a pellet of 2-mm diam, 5 mm final length was made by compressing the powder under an isostatic force of two tonnes at room temperature. Magnetoresistance measurements were made in fields up to $\pm$1.4 T, with the current both parallel and perpendicular to the applied field by ball bonding aluminium wires onto the ends of the cylinder.

III. EXPERIMENTAL RESULTS

The magnetization loop of the pellet containing a relatively large volume of material was at all temperatures smooth, symmetric, and hysteretic, as shown at 6 K in Fig. 1. This corresponded well with the magnetoresistance, whose peak positions coincided with the coercive field. As the measurement temperature was reduced, the hysteresis in both the magnetization and magnetoresistance curves increased, with the maximum value of the latter increasing from 2.2% at room temperature to 7.7% at 5 K (Fig. 2). In complementary

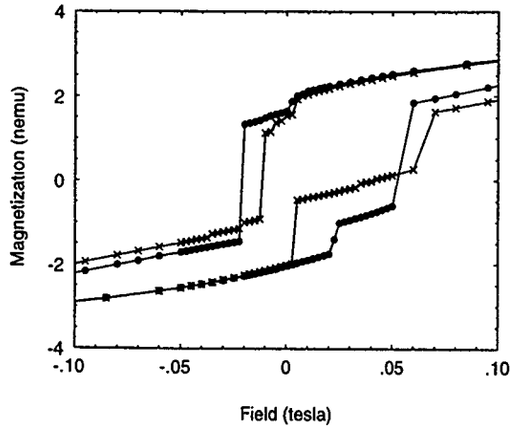

FIG. 3. Magnetization curves for a few grains of $Co_{30}Ag_{70}$ after cooling in an applied field of -8 T to $T=2$ K. The two curves were measured in nominally identical conditions.

experiments[8] on a compressed single grain, in which the effects of compacting the powder are removed; the magnetoresistance at 5 K was found to be 9.5% compared to 7.7% in the pellet, thus indicating that the increased spin-independent scattering due to the compaction process was insignificant compared to the change in magnetoresistance. The resistance measured at 5 K immediately after cooling in the zero applied field was 0.85% higher than at any time during subsequent field sweeping. This difference is defined as $\delta(\Delta\rho/\rho)$[5] and can be correlated with the magnetic interactions within the sample.

Magnetic measurements on the SQUID magnetometer, however, gave evidence of metastable magnetization characterized by large Barkhausen jumps corresponding in some cases to nearly half the magnetization reversing in one movement. Further, the actual magnitudes and positions of the jumps were not reproducible. This is illustrated in Fig. 3, in which two magnetization curves measured in nominally identical conditions are plotted. In both cases, the sample was cooled from room temperature to 2 K in an applied field of -8 T, and then field cycled to ± 8 T. The saturation value of magnetization was 4.0 nemu, as indicated in the figure. In addition to the metastability, when cooled in an applied field, the hysteresis loop was consistently asymmetric, with the loop shifted toward the direction of the field applied during cooling. This is illustrated in the sequence of Figs. 3, 4, and 5 in which the sample was cooled in -8 T, $+8$ T, and the zero field respectively. Both effects of exchange anisotropy and metastability increased as the temperature was lowered, a much reduced effect was observed at 175 K, as shown in Fig. 6, where the zero field cooled and field cooled in -8 T graphs are plotted together.

IV. DISCUSSION

The large hysteresis present in the magnetization curves of the pellet, even at room temperature, indicates that many of the particles are large enough to be blocked at room temperature. However, the remanence at 5 K is still only 30%, less than the 50% expected for a fully blocked system, indicating that there is a broad particle size distribution. The presence of giant magnetoresistance in the sample shows that in this temperature region there are active single domain

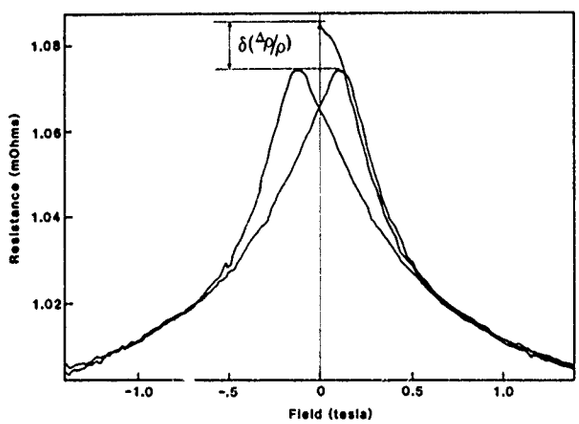

FIG. 2. Magnetoresistance of a pellet of $Co_{30}Ag_{70}$ after cooling in the zero field to $T=5$ K.

magnetic regions of a size conductive to efficient spin-dependent scattering. The positive value of $\delta(\Delta\rho/\rho)$ indicates that negative interactions dominate within this sample.

As neither the size or position of the Barkhausen jumps is repeatable, they cannot correspond to the reversal of whole particles of Co. The situation can be compared to that of an asperomagnet, such as has been observed at extremely low temperatures in DyCu.[9] The system experiences interactions between the particles—these may be both exchange and dipolar, leading to coupling of both signs. The particles are, however, constrained by the strong anisotropy axes of the individual particles. As the temperature is lowered, reducing their thermal energy, the effect of the anisotropy is increased. Magnetization reversal then occurs by cooperative inversion of a group of interacting particles, conserving both the anisotropy axes and the relative orientations of the coupled particles.

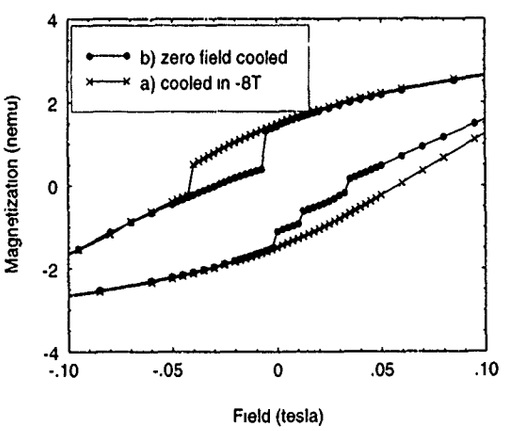

FIG. 6. Magnetization curves for a few grains of $Co_{30}Ag_{70}$ after cooling to $T=175$ K in (a) an applied field of -8 T and (b) the zero applied field.

The observation of exchange anisotropy suggests the presence of antiferromagnetic regions within the sample.[10] It is possible that some antiferromagnetic CoO has formed at the interfacial regions between the Co and Ag x-ray photoelectron spectroscopy has indicated the presence of a small amount of oxygen in the sample. There might also be Co particles experiencing very strong antiferromagnetic coupling—consistent with the positive value of $\delta(\Delta\rho/\rho)$ observed in the large pellet.

V. CONCLUSION

This study has provided the first observation of giant magnetoresistance (7.7% at 5 K) in a bulk material prepared by mechanical alloying. Measurements on a pellet of the material indicated a broad particle size distribution and net negative interactions between the active magnetic regions. The ability to measure just a few grains of the material enabled us to observe the micromagnetic behavior of this material, which is normally averaged out in a larger sample. Both metastable magnetization processes and exchange anisotropy were observed at low temperature. The hysteresis curve was characterized by large Barkhausen jumps corresponding to cooperative reversal of a number of interacting particles, whose direction of magnetization is increasingly constrained by their anisotropy axes as the temperature was lowered.

Correlation of x-ray diffraction and Mössbauer effect measurements with magnetic properties of heat-treated $Cu_{80}Co_{15}Fe_5$ ribbons

V. G. Harris, M. Rubinstein, B. N. Das, and N. C. Koon
U.S. Naval Research Laboratory, Washington, DC 20375

X-ray diffraction (XRD) and Mössbauer Effect (ME) measurements were performed on heat-treated $Cu_{80}Co_{15}Fe_5$ melt-spun ribbons in an attempt to understand the trends in magnetic properties with heat treatment. ME measurements indicate that the majority of Fe atoms (86%) occupy sites in ferromagnetic FCC CoFe clusters after the initial quench. A heat treatment at 900 °C acts to complete the chemical separation of Fe from the Cu matrix. The presence of Co in the Cu matrix, even after high temperature anneals, provides a paramagnetic component that prohibits saturation even at high fields.

Spurned by the recent discovery of a giant magnetoresistance (GMR) effect in granular vapor-quenched films of Cu–Co alloys,[1,2] melt-spun ribbons of similar compositions have been investigated to determine if a GMR effect is attainable in bulk materials.[3,4] The ribbon samples are found to display a GMR effect very near the magnitude of the vapor-quenched films. Like the films, a maximum in MR is attained after a heat treatment near 500 °C, presumably due to precipitate coarsening to a critical size and spacing. However, both bulk and film samples require high fields to saturate, a characteristic that limits their technological usefulness. In order to explore the role of structure and chemistry in the magnetic behavior of these samples, we have substituted Fe for 25% of the Co in $Cu_{80}Co_{20}$ (creating the ternary alloy: $Cu_{80}Co_{15}Fe_5$) to allow Mössbauer Effect (ME) measurements. ME investigations of dilute Fe and Co in Cu were performed by Gonser[5] and Nasu *et al.*[6] in the mid-1960s in pursuit of alternative Mössbauer source matrices. The results of those previous studies will be used here as a guide in understanding the ME results of this ternary alloy.

In an earlier paper[3] we established the structural response and magnetoresistance properties of this alloy to heat treatment procedures. In this paper, we present new results from a more extensive x-ray diffraction analysis, including line profile modeling. These results are correlated with the Mössbauer effect measurements to explain trends in magnetic properties with heat treatments. ME measurements indicate that most (≈86%) of the Fe atoms separate in the form of FCC CoFe particles from the Cu matrix upon the alloys initial quench. A heat treatment at 900 °C acts to complete the chemical separation of Fe from Cu, while a significant amount of the Co remains in the Cu matrix. This dilute Co provides a paramagnetic component to the alloy's magnetization, which increases the field required to saturate the sample.

Ribbon samples having a composition of $Cu_{80}Co_{15}Fe_5$ were fabricated via a traditional melt-spinning technique, where the molten alloy is ejected through a small orifice onto a rotating Cu wheel. Additional details of the melt-spinning operation are presented in Ref. 3. The as-spun ribbons are approximately 2 mm in width, 20 μm thick, and up to several meters long. They are reflective on both the free standing side and the Cu wheel side, with small pinholes visible to the unassisted eye. Several lengths of the melt-spun ribbon were annealed at temperatures ranging from 200 °C–900 °C for 15 min under flowing H_2 gas.

X-ray diffraction measurements were performed on all samples using a θ–2θ diffractometer equipped with a $Cu_{k\alpha}$ rotating anode source operating at 10 kW. Preliminary XRD results have been presented in Ref. 3. Here we present a more detailed analysis of the diffraction patterns, where all diffraction features are identified and indexed, and lattice parameters for each phase are calculated by plotting against the Nelson–Riley function.[7] The area under the (111) FCC diffraction peaks and the (110) BCC diffraction peak (when available) were calculated by least-squares fitting of Lorentzian curves. These areas were converted to volume fractions by applying the appropriate corrections for a structure factor and diffraction geometry.[8]

^{57}Fe Mössbauer Effect (ME) measurements were made on all samples at room temperature in the transmission mode. Because these samples were not enriched in ^{57}Fe, multiple lengths of ribbon were overlaid to enhance the signal. The resulting ME spectra were analyzed by least-squares fitting of multiple Lorentzian curves. For most samples the ME profile consists of a well-defined sextet and a central broad line. The sextet is associated with a high-spin magnetic site common to ferromagnetic α-Fe and the central resonance line was established by Gonser[5] to arise from paramagnetic Fe; that is, from dilute Fe atoms having 12 Cu near neighbors. Quadrapole splitting of the central resonance line from the presence of Fe–Fe dimers, trimers, and clusters are not resolved in our data, which are limited by the signal to noise ratio. The ratio of the area under the sextet to the central line provides a measure of the fraction of Fe atoms occupying magnetic sites to those occupying paramagnetic sites.

Figure 1 is a plot of the (111) diffraction peak for the as-spun $Cu_{80}Co_{15}Fe_5$ ribbon sample and those heat treated at 400 °C, 500 °C, 650 °C, and 800 °C. The solid curves in this figure represent fits to the data using four Lorentzian curves: two curves for each phases' α_1 and α_2 peaks. To simplify the modeling procedure the parameters used to fit the α_2 peaks were defined in terms of the α_1 position and amplitude using theoretical relationships. A summary of the fitting analysis is presented in Table I. X-ray diffraction measurements of the as-spun sample illustrate a family of FCC diffraction lines having a lattice parameter of 3.6104 Å. The smaller diffraction feature, appearing near 2θ=43.7°, corresponding with the (111) diffraction peak of a precipitate FCC phase having a lattice parameter of 3.5848 Å. Approximately 11.6 vol % of the as-spun sample exists in this precipitate phase. The ME

spectrum for this sample and samples annealed at 200 °C, 500 °C, and 900 °C are presented in Fig. 2. The spectrum for the as-spun sample illustrates a well-resolved sextet with a broad central resonance line. Modeling measurements indicate that 86% of the Fe atoms occupy magnetic sites, likely within the FCC CoFe precipitate phase. The phase separation in the alloy may have occurred either during the quenching process or prior to quenching when the alloy existed in the liquid phase. This is not unexpected, because the solubility of both Fe and Co in Cu is well below a percent under equilibrium conditions and a few percent at 500 °C.[9]

Heat treatments at temperatures ranging from 200 °C–400 °C serve to (i) increase the amount of the secondary FCC phase from 11.8% to 14.5%; (ii) increase the lattice parameter of the Cu-rich phase toward the FCC Cu value; (iii) decrease the lattice parameter of the CoFe-rich FCC phase; and (iv) increase the size of the CoFe particles, as evidenced from the sharpening of the (111) diffraction peak at $2\theta = 43.7°$ in Fig. 1. A BCC phase forms in the alloy after an anneal at 500 °C. Dark field TEM analysis of this sample illustrates uniformly dispersed spherical particles, ranging in size from less than 100 Å up to 250 Å in diameter, with a mean size of ≈150 Å. The diffraction peaks from the precipitate FCC CoFe phase are significantly reduced as a result of this heat treatment, suggesting that the precipitate FCC phase has transformed to a BCC structure. Inspection of the CoFe equilibrium phase diagram indicates that a BCC CoFe phase is stable over a composition range of Fe_xCo_{1-x}, where $0 \leq x \leq 0.725$. ME measurements indicate that approximately 10% of the Fe atoms remain in the Cu matrix in this sample. An anneal at 650 °C completes the transition from CoFe FCC to CoFe BCC as the FCC peak at $2\theta = 43.7°$ is seen in Fig. 1 to completely disappear. In this sample the lattice parameter of the Cu-rich FCC phase is very nearly equal to FCC Cu and the lattice parameter of the CoFe BCC phase is equal to 2.841 Å, the value reported to correspond with the $Co_{72.5}Fe_{27.5}$ alloy.[9]

Heat treatments at temperatures ≥650 °C facilitate the formation of another FCC phase, having a lattice parameter of 3.574 Å. In Fig. 1, the (111) peak of this phase appears at $2\theta = 43.85°$. The BCC CoFe phase that formed in samples annealed at 500 °C and 650 °C has undergone a BCC→BCC +FCC phase transition. This transition is inconsistent with the CoFe binary phase diagram, which indicates that a binary alloy of $Co_{75}Fe_{25}$ quenched from 800 °C should consist of a

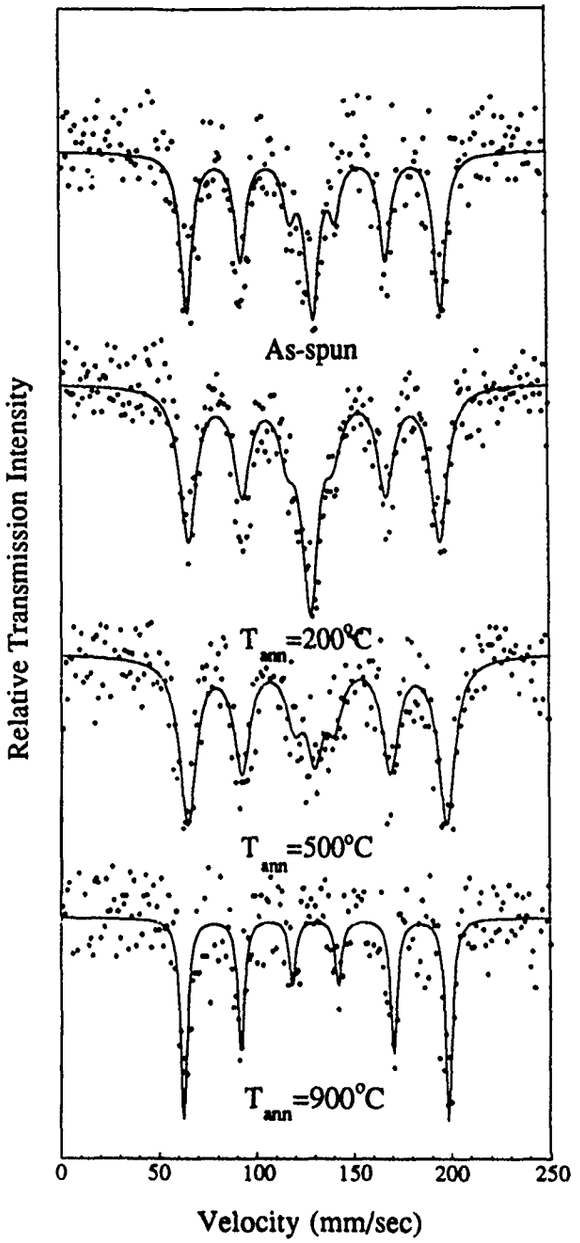

FIG 2. Mossbauer effect spectra for as-spun and heat-treated $Cu_{80}Co_{15}Fe_5$ ribbon samples. The solid curve represents the least-squares fits to the experimental data using Lorentzian curves.

mixed phase of 70% BCC $Co_{72.5}Fe_{27.5}$ (a_0=2.8410 Å) and 30% HCP $Co_{81}Fe_{19}$.[9] The presence of a small amount of Cu in the precipitate may have stabilized the FCC structure in favor of the HCP structure. Because the alloy experiences a slight preferential alignment of close-packed crystallites, we are unable to accurately measure the volume fraction of these phases in samples annealed at temperatures ≥650 °C. The ME spectrum of a sample annealed at 900 °C show that the central line has been eliminated, indicating that 100% of the Fe atoms occupy magnetic sites, signaling the complete chemical segregation of Fe atoms to high spin magnetic sites.

These $Cu_{80}Co_{15}Fe_5$ ribbons, similar to the vapor-quenched Cu–Co films, experience a maximum MR effect after a 15 min anneal near 500 °C, presumably due to precipitate coarsening to a critical size and spacing. The magnitude of the MR for these samples[3] is comparable to values reported for Cu–Co films.[1,2] Measured values decrease rapidly in samples annealed at higher temperatures.

The decrease in MR after heat treatments at temperatures ≥650 °C can be attributed to two mechanisms. The first involves particle clustering which we have observed directly via dark field TEM analysis of annealed samples.[3] The clustering of magnetic particles will act to reduce the spin-dependent scattering by reducing the interfaces between magnetic and nonmagnetic regions. The second mechanism is associated with the structural transition of the magnetic precipitate from FCC to BCC over the annealing range of 500 °C–650 °C. The BCC particles, being incoherent in the FCC matrix, will act to increase the spin-independent scattering component of the MR, because of the large strain fields that exist at the particle/matrix interface. It remains unclear as to which mechanism is dominant in reducing the MR in these samples.

SQUID magnetometry measurements performed on samples at room temperature show them how to saturate at a field strength near 8–10 kOe. However, at 4.2 K the magnetization curves have a slight positive slope over the saturation region, and do not saturate at fields up to 6 T, the limit of the SQUID magnetometer used here. This high field positive slope is evidence of a paramagnetic component to the sample's magnetization, and is present in all samples, including the sample annealed at 900 °C. ME measurements indicate that 100% of Fe atoms segregate to high spin magnetic sites after a heat treatment at 900 °C. In order to account for the paramagnetic signal, some of the Co must either remain in the Cu matrix or rediffuse during high temperature anneals and subsequent quenching operations. Energy dispersive x-ray spectroscopy performed during scanning electron microscopy indicates that a significant amount of Co, with very little Fe, remains in the Cu grains after high-temperature anneals.[9] The Cu–Co equilibrium phase diagram indicates that ≈5 at. % of Co can be stabilized in the Cu matrix upon quenching from 800 °C.

Giant magnetoresistance in $Ag_{1-x}Ni_{x-y}Fe_y$ heterogeneous alloy films

M. L. Watson
Centre for Data Storage Materials, Coventry University, Priory Street, Coventry CV1 5FB, United Kingdom

V. G. Lewis and K. O'Grady
Magnetic Materials Research Group, SEECS, University of Wales, Bangor, Gwynedd LL57 1UT, United Kingdom

We have investigated the effects of phase segregation and compositional variation on the giant magnetoresistance (GMR) observed in heterogeneous AgNiFe alloy films. The films were sputtered from a mosaic Ag/NiFe/Fe target onto glass substrates at the system ambient temperature. They had a thickness of 200–300 nm, and were rapidly thermally annealed (RTA) under vacuum in order to promote phase segregation. By altering the amount of Fe in the target mosaic, the Ni:Fe ratio was systematically varied from 80:20 to 34:66 atomic percent. The Ag concentration for all films was fixed at 78±5 atomic percent. The GMR was maximized using a RTA temperature of 650 °C. Annealing at higher temperatures decreased the saturation field of the GMR, but also lowered its size. Changing the film composition had little effect on the saturation field of the GMR, but for both as-deposited and optimally annealed samples the magnetoresistance was found to decrease as the Ni concentration decreased.

INTRODUCTION

The recent discovery of giant magnetoresistance (GMR) effects in heterogeneous alloys has greatly stimulated interest in such materials. This is based in part on the possibility of their use in magnetoresistive heads, magnetometry, or as sensors. The effect has been observed in cosputtered thin films of Co–Cu,[1] Co–Ag,[2] Fe–Ag,[3] NiFe–Ag,[4] Co–Au,[5] Ag–Co–Ni,[6] and Co–Fe–Ag,[7] in melt spun ribbons of Co–Cu[8] and mechanically alloyed Co–Ag.[9] It is assumed to originate from the spin-dependent scattering of electrons, either within or at the interfaces of phase segregated magnetic particles embedded in a nonmagnetic matrix.[10] When the moments of the particles are randomly oriented, the resistivity is higher than when the moments are aligned by the application of an external magnetic field. Although potential use of these materials in magnetic recording may be possible, it has recently been shown to be greatly limited by both the size and anisotropy of the magnetic particles.[11]

In order to investigate the effect of varying both the size and anisotropy of the magnetic particles on the GMR, we have deposited Ag–Ni–Fe films, having a fixed Ag concentration and varying Fe and Ni concentrations. In bulk Ni–Fe alloys, such variations result in the K_1 value of the alloy changing sign,[12] and for Ni concentrations >31% and the magnetization increasing with Fe concentration.[13]

EXPERIMENTAL METHOD

Ag–Ni–Fe films of thickness 200–300 nm were RF sputtered onto glass microscope slides at the system ambient temperature using a Nordico 2000 sputtering system. The target consisted of a 4 in. Ag (99.999%) disk, onto which $Ni_{80}Fe_{20}$ and Fe 0.25 cm^2 squares were placed in a mosaic pattern. The base pressure was $<2\times10^{-7}$ Torr, the sputtering pressure was 8 mTorr of argon and the sputtering power was 300 W. At this power the deposition rate was found to be ≈3 nm/s, depending on the target mosaic composition, and the deposition times were fixed at 1 min. The film thicknesses were measured using a Tolansky multiple beam interferometer and the composition determined using EDAX on a Phillips electron microscope. As the sputtering rate from $Ni_{80}Fe_{20}$ and Fe are very similar the film composition could be controlled by adding or removing squares of either of the two magnetic materials. In all cases the Ag content of the films was fixed at 78±5 atomic percent.

To promote post deposition phase segregation and magnetic particle growth, strips ≈7 mm wide diced from the substrate were rapidly thermally annealed (RTA) under vacuum. The system uses two 6 in. 2 kW halogen bulbs which, produce a power density at the substrate of ≈80 W/cm^2. The bulb illumination is controlled by a signal generator and the temperature of the strips is measured using a thermocouple mounted directly onto the sample holder. Three maximum annealing temperatures were investigated: 600, 650, and 750 °C, and these were reached in ≈20 s, 2 min, and 3 min, respectively. Due to the walls of the annealing chamber being radiatively heated during the annealing process, the cooling times for the maximum annealing temperature varied for each of the temperatures used. Thus the sample temperature fell to <200 °C in 1.5 min and 6.5 min for the samples heated to a maximum temperature of 600 and 650 °C, respectively, and to <250 °C in 6 min for the sample heated to a maximum temperature of 750 °C.

The resistivity and magnetoresistance of the films were measured at room temperature using a computer controlled four point probe system based on a Keithley 196 digital voltmeter. The maximum field that could be applied was ≈9 kG, and thus the magnetoresistance is underestimated due to it not being fully saturated. Hysteresis loops of the films were measured at room temperature in fields up to 40 kG using an Oxford Instruments VSM and in fields up to 8 kG using a VSM constructed at the Centre for Data Storage Materials at Coventry University. The as-deposited samples were investigated by XRD using a Philips XRD system.

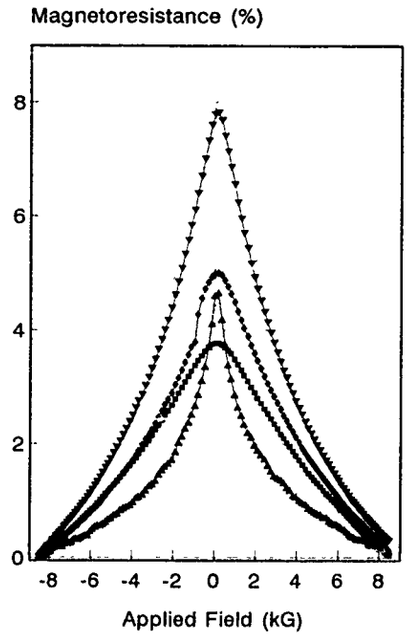

FIG. 1. Plot of the magnetoresistance of a film of composition $Ag_{72.8}Fe_{5.5}Ni_{21.7}$ for four different rapid thermal annealing temperatures. ■, as-deposited; ♦, annealed at 600 °C; ▲, annealed at 650 °C; and ▼, annealed at 750 °C.

RESULTS

It was found that for all film compositions the annealing temperature of 650 °C produced the largest GMR (calculated using $[R(H_0) - R(H_{max})/R(H_{max})]$. This is illustrated in Fig. 1, which shows the effect of annealing a film having the composition $Ag_{72.8}Fe_{5.5}Ni_{21.7}$ atomic percent. Such behavior has previously been attributed to the formation of ferromagnetic particles in the heterogeneous film. These grow to an optimum size, dependent on the electron mean-free path, after which any increase in size results in a decrease in the GMR due to the decrease in particle surface to volume ratio.[14] Although the largest GMR was found for an annealing temperature of 650 °C, a more extensive study of the effect of annealing this type of material would be required to identify the optimum annealing cycle.

Annealing at the lower temperature (600 °C) was found to increase the film resistivity by ≈5%–10%. However, the magnetoresistance of most films was unaffected by their being annealed at this temperature. It is postulated that the increase in resistivity observed is due to increased phase segregation of the alloy materials, leading to an increase in film disorder, but without well-defined ferromagnetic particles being formed. When the films were annealed at a higher temperature (650 °C) their resistivity decreased (from typically 30–40 μOhm cm to 10–15 μOhm cm), and magnetoresistance increased markedly. This is consistent with an increase in both grain and magnetic particle size. Annealing at a still higher temperature (750 °C) lowered the saturation field of the magnetoresistance, but also decreased its size.

The effect of annealing at the highest temperature investigated (750 °C) on the hysteresis of the films is shown in Figs. 2 and 3. These figures show hysteresis loops for

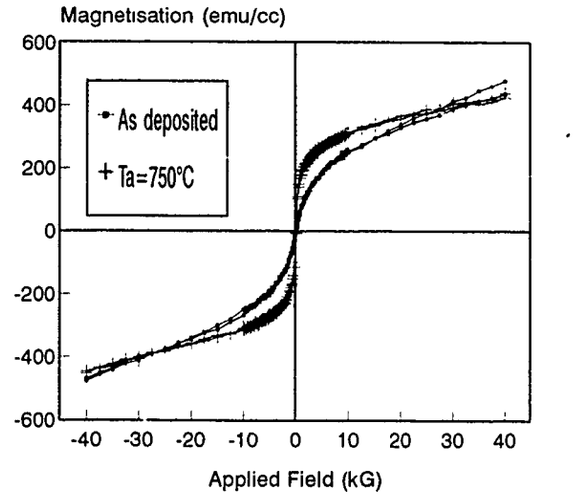

FIG. 2. Hysteresis loop of a film having the composition $Ag_{72.8}Fe_{5.5}Ni_{21.70}$ as-deposited and annealed at a maximum temperature of 750 °C.

samples having the composition $Ag_{72.8}Fe_{5.5}Ni_{21.7}$ atomic percent (Fig. 2) and $Ag_{75.98}Fe_{7.32}Ni_{16.40}$ atomic percent (Fig. 3). Note that no attempt has been made to correct this data for the diamagnetism of the Ag matrix or the substrate. As can be seen from these figures, the approach to saturation is much more rapid in the annealed samples. This is consistent with an increase in the size of the magnetic particles on annealing, rather than thermodynamically driven dilution.

Figure 4 shows the GMR of both the as-deposited and annealed at 650 °C samples in maximum applied fields of 6.4 kG. As can be seen from the figure, the GMR of the annealed samples is reduced as the Ni:Fe ratio in the film is decreased below 0.4. A similar decrease was also found for the samples annealed at a maximum temperature of 750 °C. Although the possibility exists that this decrease is related to the formation of Ni/Fe particles having the Invar composition and therefore greatly reduced magnetizations, it was not possible to obtain any corroborating structural information using the XRD sys-

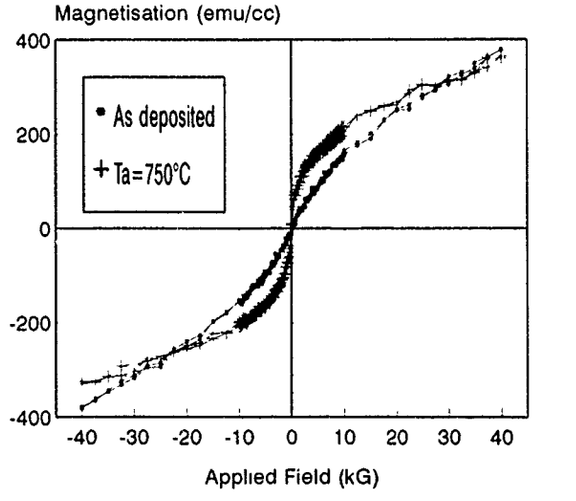

FIG. 3. Hysteresis loop of a film having the composition $Ag_{75.98}Fe_{7.32}Ni_{16.40}$ as-deposited and annealed at a maximum temperature of 750 °C.

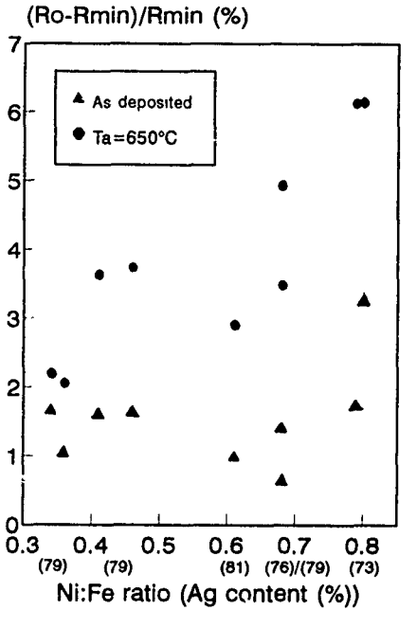

FIG. 4. Graph of the magnetoresistance of the as-deposited and annealed at 650 °C samples, plotted as a function of the Ni:Fe ratio. Note the magnetoresistance has been calculated using $[R(H_0)-R(H_{max})/R(H_{max})]$, and that the maximum applied field was 6 kG.

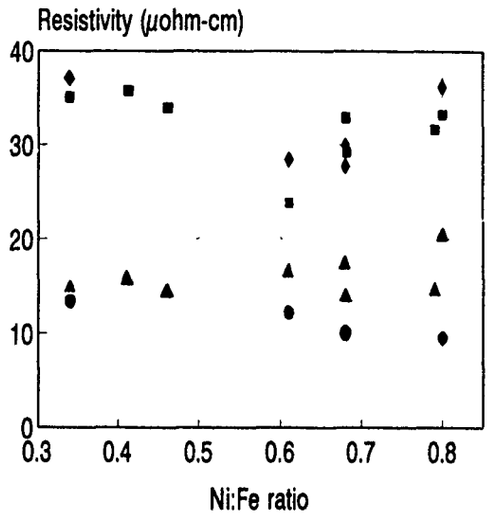

FIG. 5. Graph of the as-deposited and annealed samples resistivity plotted against their Ni:Fe ratio. ■, as-deposited: ♦, annealed at 600 °C; ▲, annealed at 650 °C; and ●, annealed at 750 °C.

tem available. However, the GMR of the as-deposited films (which were investigated using XRD and found to be metastable AgNiFe alloys) is little changed as the Ni concentration is reduced. Additionally, the decrease observed may be related to small changes in the Ag(Ni/Fe) ratio. Despite the change in the Ni:Fe ratio, the saturation field of the GMR was found to be broadly constant, for a given annealing temperature, for all film compositions.

The film resistivity as a function of composition is shown in Fig. 5 for each annealing temperature. As can be seen in this figure, the resistivity of the samples annealed at an elevated temperature (650 °C and 750 °C) is broadly constant as a function of the Ni:Fe ratio. However, the resistivities of the as-deposited and annealed at 650 °C samples exhibit a shallow minima for the Ni:Fe ratios of ≈0.60. It is possible that this difference in behavior reflects differences in the spin-independent electron scattering processes, occurring in the two groups of films. In the former case the ferromagnetic atoms have formed particles, while in the later case well-dispersed magnetic atoms are present.

CONCLUSIONS

Little effect of changing the composition of the ferromagnetic particles formed by phase segregation on the GMR saturation field was observed. It is postulated that this is due to shape and/or stress anisotropy dominating the magnetization process. The size of the GMR was found to depend on the film composition, decreasing with increased Fe concentration. It is postulated that this is related to changes in the magnetic particles' magnetization, resulting from the variation in their Ni:Fe concentration ratios, altering the spin-dependent scattering of electrons by these particles.

Giant and anisotropic magnetoresistance in single layer $Ni_{66}Fe_{16}Co_{18}$–Ag films

A. Waknis, J. A. Barnard, and M. R. Parker[a)]
The Center for Materials for Information Technology and Department of Metallurgical and Materials Engineering, The University of Alabama, Tuscaloosa, Alabama 35487-0202

Single layer $Ni_{66}Fe_{16}Co_{18}$–Ag thin films were made by cosputtering from a composite $Ni_{66}Fe_{16}Co_{18}$–Ag target. At the silver rich end of the composition range (≈57%–80 at. % Ag) we have found "giant" magnetoresistance (a maximum of ≈9% at room temperature at ≈72 at. % Ag after annealing at 300 °C for $\frac{1}{2}$ h), while in the midcomposition range (≈42–≈57 at. % Ag), we have observed anisotropic magnetoresistance.

I. INTRODUCTION

In the last two years, remarkably large room temperature GMR ratios have been observed in a variety of single layer film systems[1–4] prepared by codeposition of a ferromagnet and nonmagnet. which strongly phase separate at equilibrium. Single layer "granular" GMR appears to be restricted to alloy systems which exhibit extremely small mutual solubilities. Ni, Fe, and Co are all essentially immiscible in Ag. $Ni_{66}Fe_{16}Co_{18}$ is a zero magnetostriction and near zero magnetocrystalline anisotropy material.[5,6] In multilayer geometries this alloy has yielded promisingly field-sensitive GMR.[7]

In this study, $Ni_{66}Fe_{16}Co_{18}$–Ag single layer films were made over a broad composition range (≈42–80 at. % Ag). Ag-rich samples (≥57 at. % Ag) exhibit familiar granular GMR behavior. Samples in the midcomposition range (from ≈42–≈57 at. % Ag) exhibit classical AMR. A maximum GMR of ≈9% at room temperature at ≈72 at. % Ag has been found after annealing at 300 °C for $\frac{1}{2}$ h. The magnitude of AMR observed is of the order of 1%.

II. EXPERIMENTAL METHODS AND MATERIALS

A series of $(Ni_{66}Fe_{16}Co_{18})_{100-x}Ag_x$ (x varying between ≈42 at. % and 80 at. %) films were grown on 7059 Corning glass substrates (2 in.×1 in.) from a 4 in. split target using different sputtering conditions (p_{Ar}=5, 10, and 15 mTorr; power =100 W and 200 W). The background pressure was 5×10^{-7} Torr. A good combination of high GMR at the silver-rich end of the composition spectrum and sharp AMR peaks at the midcomposition range of the spectrum were found for p_{Ar}=15 mTorr and 100 W; that set of films is discussed in this paper. The films were characterized for their magnetic properties and structure. The characterization techniques used are explained elsewhere.[2] They were then subjected to a series of annealing treatments (first and second anneals were carried out each at 300 °C for $\frac{1}{2}$ h, while a third anneal was carried out for samples exhibiting AMR at 400 °C for $\frac{1}{2}$ h) in a high vacuum annealing chamber.

[a)]Department of Electrical Engineering.

III. EXPERIMENTAL RESULTS AND DISCUSSION

A. Results on films exhibiting GMR

Figure 1 shows the plot of magnetoresistance (MR) versus composition (at. % Ag) for both as-deposited and annealed films at the Ag-rich end of the composition spectrum. There is a gradual rise in MR values with increasing Ag, with a maximum of about 9% at approximately 72 at. % Ag (following the anneal), after which the MR value begins to decline. A broad maximum in GMR versus composition in the range 30–40 at. % ferromagnetic component has been observed in other granular systems.[2,8] There is not much difference in the MR values in the as-deposited and annealed states for the three low Ag samples (60, 64, and 68 at. % Ag), but a considerable improvement in the MR value is noted in the annealed state for the two most Ag-rich samples. A plot of MR as a function of applied field for the sample with 75.6 at. % Ag appears in Fig. 2. The MR magnitude increases from 4.5% to 7.5% on annealing. Annealing also sharpens the MR curve at low fields. This sharpening is related to ferromagnetic particle growth.

Figure 3 reveals the variation in the lattice spacing of Ag (111) as a function of at. % Ag at the Ag-rich end. In the as-deposited state there is a marked increase in the lattice spacing of Ag, as the composition of the films become more Ag rich. In the annealed state, the lattice spacing values are independent of the composition and close to (but slightly less than) the bulk Ag (111) value of 2.355 Å. This is an indication that, on annealing, the Ag more completely phase separates from the magnetic particles. Figure 4 shows the x-ray diffraction scans in the θ–2θ mode for a sample with ≈63 at. % Ag in the as-deposited and annealed states. The dashed lines in the figure are drawn at the pure, bulk positions of the Ag (111), Ni (111), and Ag (222) peaks. The observation of a sharp Ag (111) peak and the suppression of the Ag (200) peak is evidence for a (111) growth texture. The Ag (111) peak sharpens and moves to a slightly lower angle on annealing [toward bulk Ag (111)]. The positions of bulk Ni (111), Ag (200), and Co (111) are located at 2θ=44.49°, 2θ =44.27°, and 2θ=44.21°, respectively. The peak observed next to the Ag (111) can be due to the partial overlap of these three peaks.

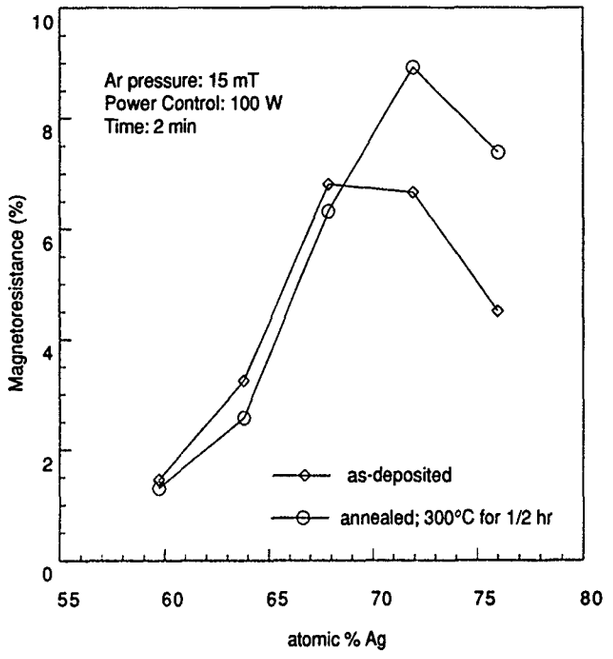

FIG. 1. Giant magnetoresistance (%) versus composition (at. % Ag) for films in the as-deposited state and after the first anneal.

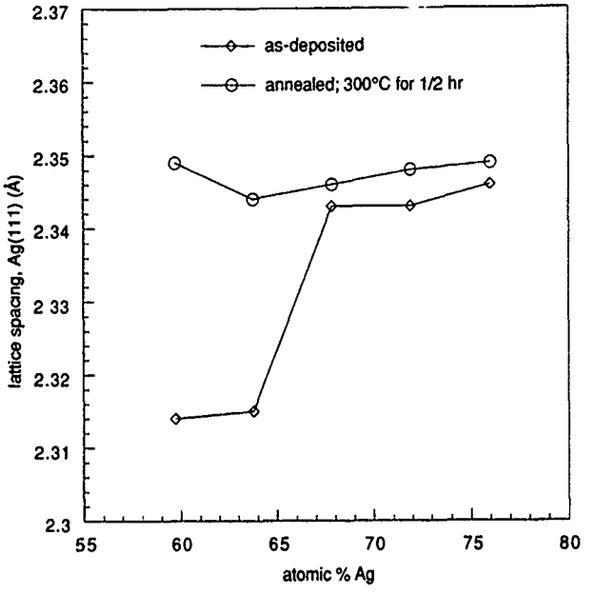

FIG. 3. Lattice spacing (Å) versus composition for samples showing GMR both in the as-deposited state and after the first anneal.

B. Results on films exhibiting transverse AMR

Samples richer in the magnetic phase exhibited anisotropic MR in both the as-deposited state as well as after annealing. However, these samples did not show any appreciable improvement in MR after annealing. Figure 5 shows the MR plot in the as-deposited state, as well as after annealing, for a sample with ≈46 at. % Ag. The MR curves in the as-deposited state and after the first anneal are weakly hysteretic over an applied field range of ±25 Oe, but become strongly hysteretic (over ±175 Oe) after the third anneal (at 400 °C for $\frac{1}{2}$ h). These hysteretic curves closely correlate with the coercivity of the samples, as observed from the VSM loops (not reproduced in this paper). The increase in coercivity on the third anneal may be associated with the growth of the single domain NiFeCo particles.

The variation of lattice spacing with at. % Ag in the Ag-poor samples appears in Fig. 6. There is a marked variation in the lattice spacing of Ag in the as-deposited state, as

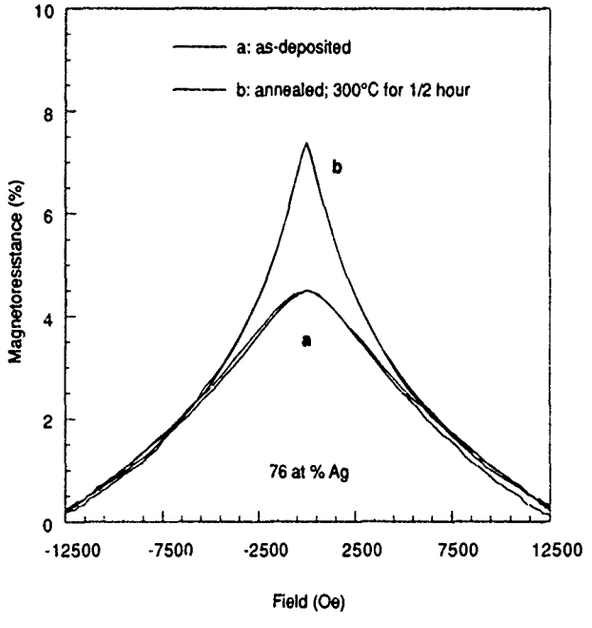

FIG. 2. Giant magnetoresistance (%) versus applied magnetic field (Oe) for films with 76 at. % Ag.

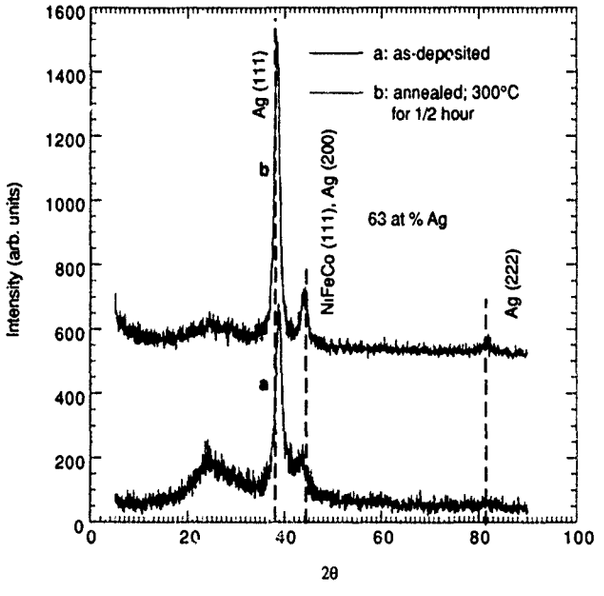

FIG. 4. Typical x-ray diffraction scans of samples showing GMR.

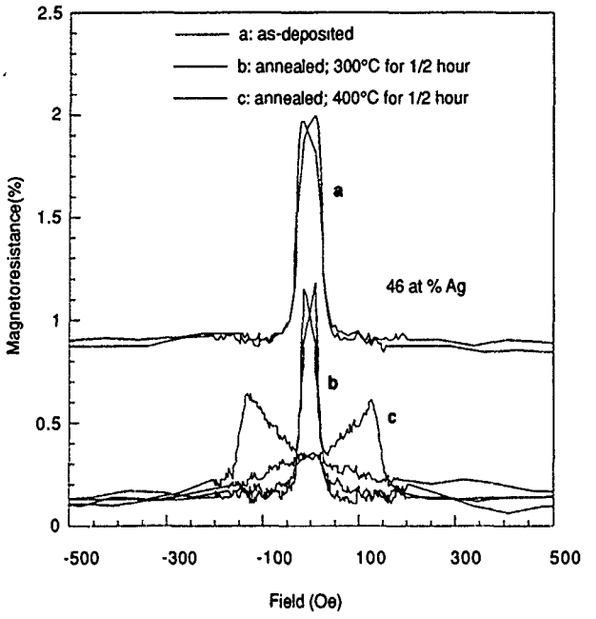

FIG. 5. Anisotropic magnetoresistance (%) versus applied magnetic field (Oe) for films with 46 at. % Ag.

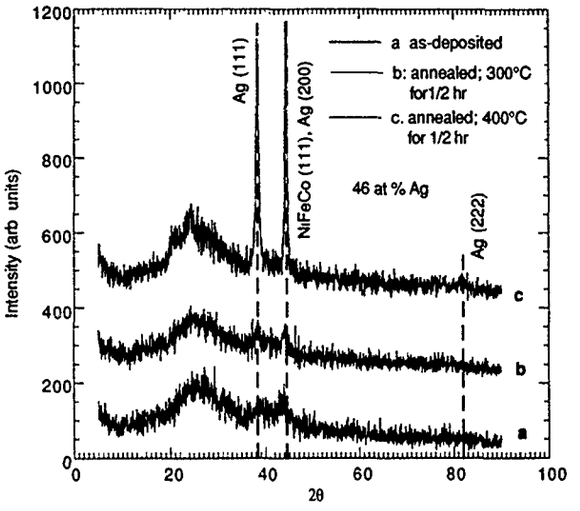

FIG. 7. X-ray diffraction scans of samples showing the evolution of Ag (111) and NiFeCo alloy (111) peaks on annealing

well as after the first annealing. But after the second annealing the lattice spacing does not vary much with the composition of Ag and is near (but again slightly less than) the bulk Ag (111) lattice spacing of 2.355 Å. Figure 7 illustrates the effect of annealing on the evolution of Ag (111) and NiFeCo alloy (111) peaks for the sample with 46 at. % Ag. The dashed lines represent the positions of pure, bulk Ag (111), Ni (111), and Ag (222) peaks. Ag (111) and NiFeCo alloy (111) peaks are seen as very weak peaks in the as-deposited state, and after the first anneal (at 300 °C for $\frac{1}{2}$ hour), but show a significant increase in magnitude and sharpness after the third anneal (at 400 °C for $\frac{1}{2}$ h). This is evidence for a sharp increase in particle size during the third annealing cycle. The lattice parameter of Ag (111) shifts toward its bulk value on annealing.

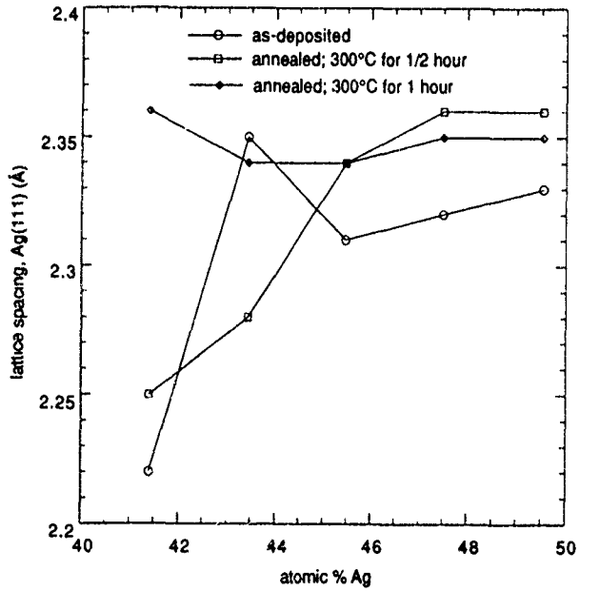

FIG. 6. Lattice spacing (Å) versus composition for samples showing AMR

Giant magnetoresistance in heterogeneous $(CoFe)_X Ag_{1-X}$ films (abstract)

R. S. Beach, D. Rao, M. J. Carey, F. T. Parker, and A. E. Berkowitz
Center for Magnetic Recording Research, Mail Code 0401, University of California, San Diego, La Jolla, California 92093-0401

The soft magnetic properties of CoFe prompted an investigation of magnetoresistance in Co-Fe-Ag alloys. A series of $(FeCo)_x Ag_{1-x}$ $(10<x<30)$ films were prepared by dc magnetron sputtering, followed by annealing in H_2 at a variety of temperatures $T_A \leq 400$ °C. The samples exhibit giant magnetoresistance (GMR) ratios which exceed 25% at a temperature of $T=10$ K, and 17% at $T=300$ K. The results of magnetization and x-ray scattering experiments indicate that FeCo alloy particles precipitate from the Ag matrix upon annealing. We note in particular that the full width at half maximum (FWHM) of the MR curves (approximately 2 kOe) is significantly less than that of Fe-Ag or Co-Ag sputtered films having comparable GMR ratios. We compare the sharp MR response of the $(FeCo)_x Ag_{1-x}$ system to that of heterogeneous $(Ni_{80}Fe_{20})_x Ag_{1-x}$ films.

The effects of film geometry on the properties of FeTaN films

Gan Qiu and J. A. Barnard
The Department of Metallurgical and Materials Engineering, The University of Alabama, Tuscaloosa, Alabama 35487-0202

FeTaN single layer and FeTaN/SiO_2 multilayer films were grown by high rate reactive dc magnetron sputtering. The film geometry (FeTaN layer thickness, SiO_2 spacer thickness, and number of bilayer units) dependence of the structure, magnetic properties and high-frequency permeability characteristics were investigated.

I. INTRODUCTION

High performance magnetic heads for high density and high data transfer rate recording require new thin film materials with high magnetizations, low coercivities, high permeability, and near zero magnetostriction. Additionally, high-frequency response of permeability is also needed for heads used at high relative speed. In this context, FeN-based single layer films with high magnetization have received considerable recent attention.[1-4] Lamination of high moment metal films can lead to good frequency characteristics of permeability if dielectric spacers are used to suppress the eddy current loss.[4-7] We have previously grown high moment FeTaN single layer films with soft magnetic properties and good thermal stability by high rate dc magnetron sputtering.[8]

II. EXPERIMENTAL METHODS

The FeTaN films were made by dc reactive magnetron sputtering at a fixed power of 300 W, fixed Ar pressure of 3 mTorr, and fixed N_2 flow rate of 5 sccm, where good film characteristics were obtained. These conditions produce growth rates of ~900 Å/min. A vacuum melted Fe-Ta target with nominal composition 10 w/o Ta was used. The SiO_2 spacer was deposited by rf magnetron sputtering from an SiO_2 target. Si(111) is used as the substrate with a base layer of ~92 Å of sputtered SiO_2. The films were grown in an aligning field of ~90 Oe. Three sets of films were prepared. In set A the properties of single layer FeTaN films as a function of layer thickness (from 0.19 to 1.8 μm) are studied. In set B the properties of bilayer films are studied as a function of the single spacer layer thickness. In set C the properties of multilayer films are studied as a function of number (from 1 to 5) of 0.9-μm-thick FeTaN layers for two different SiO_2 spacer thicknesses. The overall average M_s for these films is ~1570 emu/cm^3.

III. EXPERIMENTAL RESULTS AND DISCUSSION

A. Set A: Single layer films

Uniaxial anisotropy induced by the external field was obtained in all the films. Typical B-H curves of the films with ~4800 Å in both hard and easy directions are shown in Fig. 1. Figures 2(a) and 2(b) show the dependence of the coercivity (H_{ce},H_{ch}) and initial permeability (μ' at 10 MHz) on film thickness. Films with thickness greater than ~4800 Å have good soft magnetic properties (H_c<1 Oe and μ'>2000), which exhibit little thickness dependence. Initial permeability increases with film thickness which is consistent with the decrease of H_c. H_c of 0.6 Oe and μ' (at 10 MHz) of 2300 are obtained for the 1.8-μm-thick films. For films with thickness of 2500 and 3300 Å, μ' is independent of frequency up to 100 MHz and f_{50} (the frequency at which initial permeability drops to 50% of its low-frequency value) is higher than 250 MHz. A permeability spectrum for a single layer 1-μm film is shown in Fig. 3. μ' begins to roll off at 60 MHz and μ' decreases faster at high-frequency compared with thinner films due to the eddy current effect. The film thickness dependence of magnetostriction (λ_s) is shown in Fig. 4(a). λ_s systematically declines from $+9\times10^{-6}$ to $+6\times10^{-6}$ with an increase in film thickness. The lattice spacing derived from the expanded α-Fe (110) peak decreases with increasing film thickness, as shown in Fig. 4(b), which could be due to decreased incorporation of N_2 during the later stages of film growth.[4] The full width at half-maximum (FWHM) of the (110) peak [Fig. 4(b)] decreases with film thickness indicating a stronger (110) film texture. The increasing amount of {110} oriented grains in the films

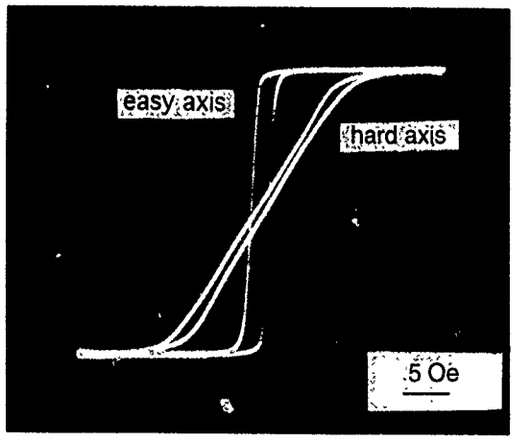

FIG. 1. B-H hysteresis loop of 4800-Å-thick single layer FeTaN film.

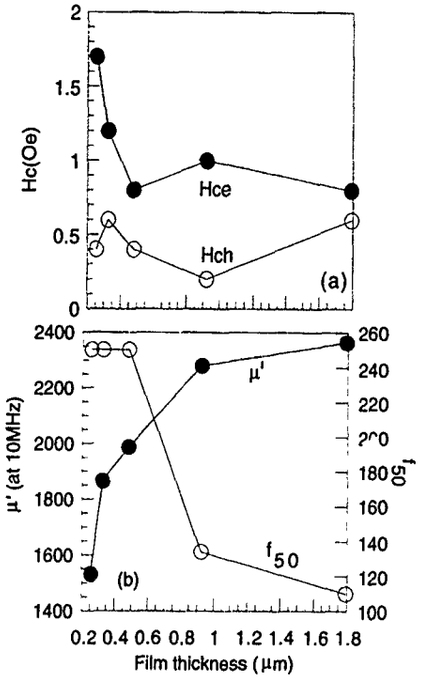

FIG. 2. Magnetic properties of FeTaN films as a function of film thickness; (a) H_c and (b) μ and f_{50}.

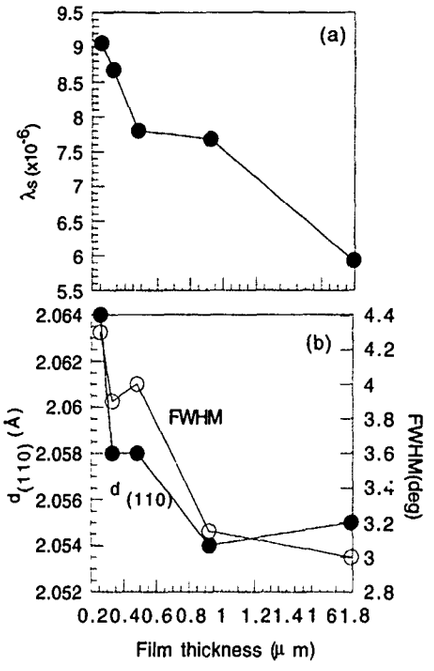

FIG. 4. Saturation magnetostriction (λ_s) (a) and d_{110} and FWHM (b) vs film thickness for single layer FeTaN films

may account for the decrease of λ_s with increasing thickness [λ_s values for pure α-Fe films with (110) plane preferred orientation are negative].

Set B: Bilayer films

In this set two 0.9-μm FeTaN layers are separated by a sputtered SiO_2 layer of variable thickness. The SiO_2 thickness dependence of coercivity is shown in Fig. 5(a). H_{ch} which reflects anisotropy dispersion decreases up to a spacer thickness of 200 Å, and then begins to increase at a spacer thickness of 400 Å. The increases of coercivity with an increase in SiO_2 spacer layer thickness may be caused by weaker magnetostatic coupling between magnetic layers. When the spacer thickness reached 400 Å, the two films switched independently giving rise to two values of H_c in a hysteresis loop shown in the inset of Fig. 5(a). The SiO_2 thickness dependence of initial permeability μ' (at 10 MHz) and frequency at 50% of initial permeability (f_{50}) appear in Fig. 5(b). Initial permeability shows a declining trend with increasing spacer thickness, which agrees with the increase

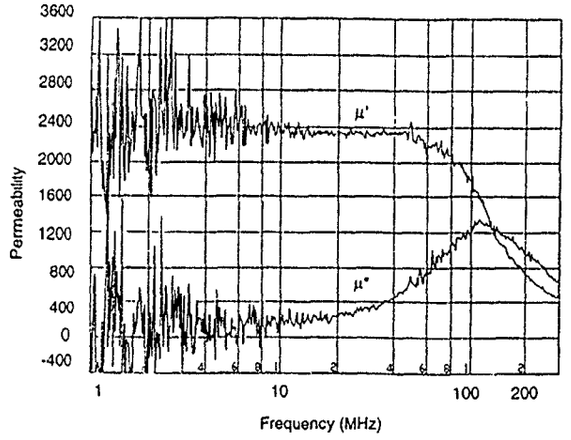

FIG. 3. Frequency dependence of permeability for 1-μm FeTaN films.

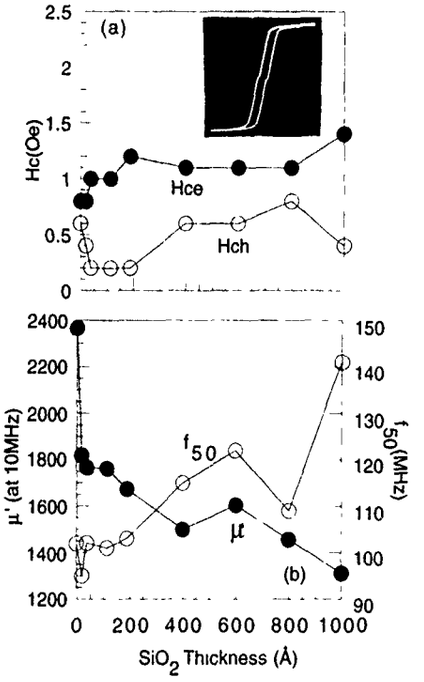

FIG. 5. Magnetic properties of 2×1-μm double layered FeTaN films as a function of SiO_2 spacer thickness, (a) H_c and (b) μ and f_{50}. Insert of (a) shows a two-valued H_c B-H loop.

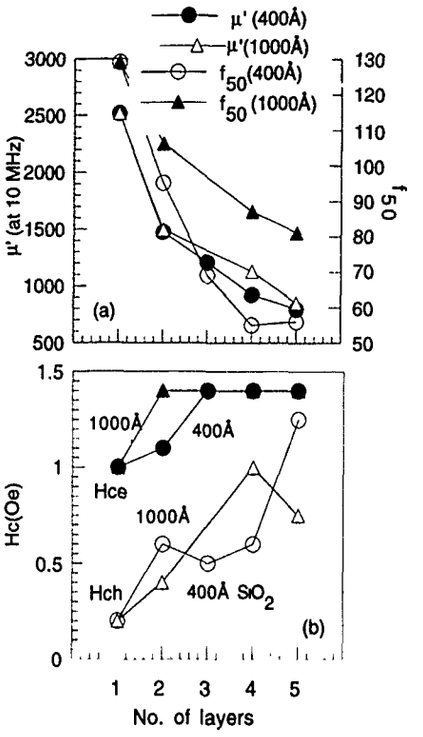

FIG. 6. Magnetic properties of multilayer FeTaN films as a function of number of layers for SiO_2 spacer thickness of 400 and 1000 Å; (a) μ and f_{50} and (b) H_c.

of H_c in the films. f_{50} appears to increase with increasing SiO_2 thickness due to more complete separation of the films resulting in increasing resistivity. Magnetostriction is essentially independent of spacer layer thickness in the bilayer films (λ_s is $\sim+6.25\times10^{-6}$).

C. Set C: Multilayer films

In set C the dependence of magnetic properties on number of layers, n, in a multilayer is studied for FeTaN layer thicknesses of 0.9 μm and two different SiO_2 spacer layer thicknesses, 40 and 100 nm. Hard axis coercivity increases with number of layers for both spacer layer thicknesses from ~0.2 to 1.25 Oe, which may again be caused by the reduced magnetostatic coupling between the magnetic layers for thicker spacers [Fig. 6(b)]. The initial permeability and f_{50} for set C is plotted in Fig. 6(a). The decrease of the initial permeability with the increase of the number of layers corresponds to the increase of the coercivity. Unexpectedly, f_{50} shows a systematic decrease with increasing number of layers, which could be caused by a poorly grown insulator, weaker coupling between the magnetic layers and film stress. Permeability spectra of two 4×1-μm four-layered films (SiO_2 spacer thicknesses=40, 100 nm) are shown in Fig. 7. The high-frequency response of the multilayer is improved by increasing SiO_2 spacer thickness. μ' is maintained till 60 MHz for the films with spacer thickness of 1000 Å whereas μ' started to roll off at 35 MHz for the films with 400-Å spacer. Interestingly, the magnetostriction exhibits a significant and systematic decrease with increasing number of layers, dropping from $\sim+7.7\times10^{-6}$ to $+3.8\times10^{-6}$.

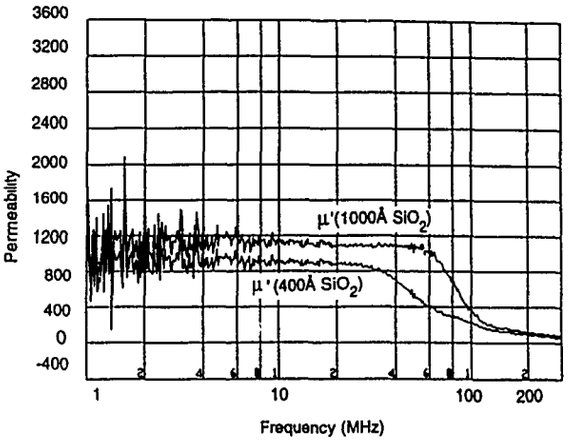

FIG. 7. Permeability as a function of frequency for 4×1-μm four-layered films with SiO_2 spacer thickness of 400 and 1000 Å.

How the ac effective permeability (μ_e) correlates with dc magnetic properties over a wide frequency range of 1 to 1000 kHz was studied, in an effort to understand the magnetization behavior of the Co-based amorphous alloy of Metglas 2714A subject to an ac magnetic field. In the low-frequency range up to 50 kHz, the correlations between μ_e and the dc initial permeability, and between μ_e and the coercivity are found to be good, the correlation coefficient being positive and negative, respectively. No definite correlation is observed with the dc maximum permeability. At high frequencies ranging from about 200 to 1000 kHz, the correlations between μ_e and the dc maximum permeability, and between μ_e and the coercivity are observed to be good, the correlation coefficient being negative and positive, respectively. The correlation of μ_e with the dc initial permeability is poor in this high-frequency range. The correlation with the remanence ratio is found to be rather different from the other three; the ac permeability exhibits a maximum at the value of remanence ratio of 0.5–0.6 at frequencies up to 200 kHz but, at frequencies higher than 500 kHz, it decreases linearly with the remanence ratio. From the correlation results it is considered that the dominant magnetization mechanism is the domain wall motion at frequencies up to 50 kHz and it is spin rotation at frequencies higher than 500 kHz.

Zero-magnetostrictive Co-based amorphous alloys exhibit excellent soft magnetic properties, and, hence, are of great commercial importance.[1] These alloys are mainly used in high-frequency electromagnetic devices. Therefore, it is necessary to clearly understand magnetization behavior at high frequencies, in order to use soft magnetic alloys more efficiently, and improve their magnetic properties. However, this does not appear to be easy, since magnetization behavior under an ac field is much more complex than under a dc field. Whilst dc magnetization behavior is mainly affected by domain wall motion, ac magnetization behavior is affected by numerous factors including eddy currents (both classical and anomalous) and spin rotation as well as domain wall motion.[2]

In an effort to understand magnetization behavior at high frequencies, we investigate how an ac magnetic property correlates with dc magnetic properties. The ac magnetic property considered in this study was the effective permeability (μ_e). Four dc magnetic properties were considered; the initial permeability (μ_i), the maximum permeability (μ_m), the coercivity (H_c), and the remanence ratio (B_r/B_{10}, where B_r is the remanent flux density and B_{10} the flux density at a field of 10 Oe). The alloy used in this investigation was the Co-based alloy of Metglas 2714 A which was supplied by Allied Signal Corp., U. S.

Two ribbons of different widths (4.5 and 6.0 mm), which were slit from wider ones, were used in the investigation. The ribbon thickness was 17 μm. The ribbons were wound onto a torodial core with inner diameter of 19 mm.

In order to examine the relationships between the magnetic properties more clearly, varying values of the magnetic properties were intentionally obtained by annealing over a wide temperature range and carrying out different cooling methods immediately after annealing; the annealing temperatures selected were 300, 350, 400, and 500 °C, and the cooling methods included water quenching, air cooling, and furnace cooling. The annealing time was 60 min; however, at the temperatures of 350 and 400 °C, four different annealing times of 15, 30, 60, and 120 min were also used.

The ac effective permeability of annealed samples was measured by using an impedance analyzer. The dc magnetic properties were measured with a hysteresis loop tracer. The ac permeability was measured at an applied field of 5 mOe and over a wide frequency range of 1 to 1000 kHz. Each datum point presented in this work was obtained by averaging about ten separate results.

In Figs. 1(a)–1(c) are shown the results for the relationship between μ_e and μ_i. Although the results were obtained at many frequencies ranging from 1 to 1000 kHz, only the results obtained at frequencies of 1, 100, and 1000 kHz are displayed in Figs. 1(a)–1(c), respectively. (Also in the figures to be shown later, only the results from these three frequencies will be presented due to space limitation.) The present results show that μ_e is correlated well with μ_i at low frequencies below 50 kHz. The correlation coefficient between the two properties is positive, viz., μ_e increases with increasing μ_i. Although results are not shown in the figures, the degree of correlation decreases progressively as the frequency (f) increases in this range. However, at frequencies above 100 kHz, no obvious correlation is observed. The present results for the correlation between μ_e and μ_i (good correlation at low frequencies and poor one at high frequencies) can be well understood; at low frequencies, dynamic magnetization behavior is expected to be similar to static

magnetization behavior, but is expected to deviate as f increases.

The dependences of μ_e on μ_m are shown in Figs. 2(a)–2(c). At frequencies up to 100 kHz, it is observed that the correlation between μ_e and μ_m is rather poor compared to the correlation between μ_e and μ_i. This poor correlation between μ_e and μ_m even in the low-frequency range is believed to result from the fact that large magnetization including Barkhausen jumps is usually involved with the measurement of μ_m; however, magnetization is small in the measurement of both μ_e and μ_i. It is noted that values of μ_i were measured at the (dc) magnetic field ranging from 1 to 2.6 mOe, whilst μ_m at the (dc) magnetic field ranging from 5 to 15 mOe. It is recalled that μ_e was measured at the (ac) field of 5 mOe. At high frequencies above 200 kHz, μ_e is rather well correlated with μ_m and the correlation coefficient between the two properties is negative.

The correlation results between μ_e and H_c are shown in Figs. 3(a)–3(c). In the low-frequency range, the well-known reciprocal relationship between μ_e and H_c is observed to exist. However, at intermediate frequencies of 100 and 200 kHz, there appears no definite correlation between the two properties. At high frequencies between 500 and 1000 kHz, there is a surprising good correlation between μ_e and H_c with positive correlation coefficient; this is the opposite of the low-frequency correlation behavior.

The plots of μ_e vs B_r/B_{10} are shown in Figs. 4(a)–4(c). At frequencies up to 200 kHz, μ_e increases with B_r/B_{10}, reaches a maximum value at B_r/B_{10}=0.5–0.6, and then decreases with a further increase of B_r/B_{10}. The remanence

ratio is known to be a measure of the distribution of the magnetization direction of domains; thus it is mainly determined by the magnitudes and directions of the anisotropies present in a given material. For a Co-based alloy where magnetization is governed by domain wall motion of 180°-type domains, the remanence ratio is estimated to be 0.5 if domain orientation is completely random.[3] If more domains are in the length (transverse) direction, the remanence ratio is greater (less) than 0.5. The present results for the variation of μ_e with B_r/B_{10} in the low-frequency range may indicate that high values of μ_e are achieved when domain orientation is random, or more domains are slightly in the length direction. A similar result was previously reported by Luborsky *et al.* for $Fe_{40}Ni_{40}P_{14}B_6$ amorphous alloy ribbons.[4]

The value of μ_e for a sample with a small remanence ratio decreases more slowly with increasing f than that for a sample with a high remanence ratio does, as can be understood from Figs. 4(a)–4(c). As a result, at very high frequencies between 500 and 1000 kHz, the correlation behavior changes; a clear correlation between the two properties emerges, the correlation coefficient being negative.

A feature to be noted from the present results is that correlation behavior begins to change rather sharply at frequencies of 50–100 kHz for the dc properties μ_i and H_c which are mainly determined by domain wall motion. This may indicate that the dominant magnetization mechanism below 50–100 kHz is the motion of domain walls. The dominant magnetization mechanism at high frequencies may be understood from the correlation results between μ_e and B_r/B_{10}. At frequencies higher than 500 kHz, μ_e increases with decreasing remanence ratio, indicating that the ac permeability is high when more domains are distributed in the transverse direction. It is noted here that, since the magnetic field is applied in the length direction during the measurement of all the magnetic properties, more domains are in the perpendicular direction with respect to the applied field when the remanence ratio is low. Since it is known that dynamic magnetization by spin rotation occurs easily, viz., ac permeability is high, when directions of applied field and domain are perpendicular to each other rather than parallel,[5] the present correlation results between μ_e and B_r/B_{10} may indicate that the dominant magnetization mechanism at frequencies higher than 500 kHz is spin rotation.

In summary, we have investigated how the ac effective permeability is correlated, over a wide frequency range of 1 to 1000 kHz, with the dc initial permeability, dc maximum permeability, coercivity, and remanence ratio for the Co-based amorphous alloy of Metglas 2714A. From the correlation results it is considered that the dominant magnetization mechanism is the domain wall motion at frequencies up to 50 kHz and it is spin rotation at frequencies higher than 500 kHz.

Amorphous samples of Vitrovac® 6025 metallic alloys were nanocrystallized by thermal annealing at temperatures in the range 576–716 K, well below the crystallization temperature (831 K, as obtained by differential scanning calorimetry at 20 K/min) and times in the range 10–90 min. Initial magnetic permeability exhibited a maximum of ~109 000 (from ~20 000 for the as-quenched state) for annealing times of ~15 min, and then a decrease toward a plateau value (30 000–40 000) for longer times. Domain wall relaxation frequency showed the opposite behavior, a minimum of ~9 kHz (from 40 kHz for the as-quenched value) for the permeability maximum, and then a stabilization at ~15 kHz. Transmission electron microscopy observations confirmed that for annealing times up to 60 min., crystallite size is smaller than 30 nm. Permeability and relaxation frequency results are interpreted in terms of the dependence of wall bulging on anisotropy and free-wall surface area between pinning sites.

Systems with particles in the nanometer range, which are also known as nanocrystals, show unusual magnetic properties.[1,2] Amorphous alloys provide an extremely convenient material to produce nanocrystals since the crystallization process from these phases can be controlled by thermal treatments to obtain crystals in a variety of dimensions.[3]

In this paper, we present an investigation of the initial magnetic permeability as a function of frequency of nanocrystallized Co-based amorphous alloys. The dynamic properties of domain walls[4,5] provide additional information about the effects of nanocrystals on the magnetization processes.

Samples of Vitrovac® 6025 amorphous ribbons with the nominal composition $Co_{66}Fe_4Mo_2Si_{16}B_{12}$, obtained by melt spinning were crystallized in an electric furnace (stability: ±3 K) at temperatures in the range 570–710 K, for times from 10 min up to 90 min. Since crystallization rates at these temperatures were considerably slow (the crystallization temperature is 831 K as determined by differential scanning calorimetry at a 20 K/min rate), a good control of the extent of crystallization was possible. The sample was mounted in a holder inside a silica glass with an inert (argon) atmosphere. A thermocouple close to the sample was used to monitor temperature. To avoid the effects of slow heating and cooling, the holder and sample were inserted into the silica glass tube in a preheated furnace at the beginning of the experiment, and removed from the furnace at the end of the annealing time without altering the furnace setting. Heating and cooling rates in excess of 80 K/min were achieved.

Magnetic permeability measurements were made on samples made of ~1-m ribbon wound as a toroid. To apply a magnetic field, a copper wire was wound around the toroid as a coil. Usually, the toroidal shape was conserved during several consecutive thermal treatments since after the first annealing, samples became brittle. Frequency measurements were performed at room temperature on a system that includes a HP 4192A Impedance Analyzer controlled by a HP 85 microcomputer with all the peripherals. Our software allows the measurement of 94 frequencies in the range 5 Hz–13 MHz.

The crystallization temperature was determined in a 2100 Thermal Analyst System with a differential scanning calorimetry (DSC) cell at a heating rate of 20 K/min. Transmission electron microscopy (TEM) observations were made in a JEOL JEM-1200 microscope under 200-kV accelerating voltage. Samples were thinned by electropolishing in a solution of nitric acid and alcohol.[6] Thinning of samples annealed for long times became difficult because of their brittleness; an alternative method was to electropolish them in the as-quenched state, and perform the same thermal treat-

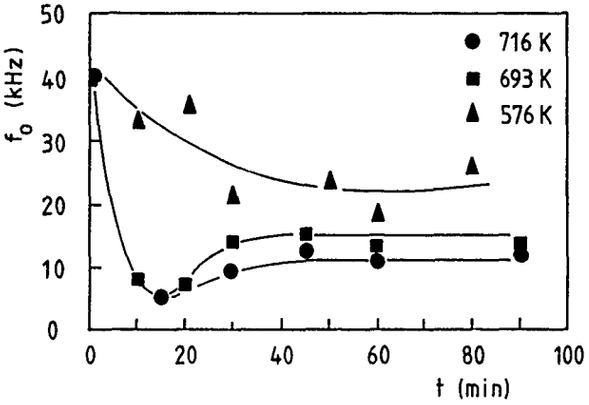

FIG. 2. Domain wall relaxation frequency as a function of time for three annealing temperatures.

ments in the DSC cell as in the toroidal sample. No substantial differences were observed between the two methods.

The resolution of initial permeability from hysteresis phenomena by impedance measurements as a function of frequency has been discussed elsewhere.[4,5] In this paper, initial permeability, μ_0, and domain wall relaxation frequency, ω_0 are investigated. The former corresponds therefore to the reversible magnetization variations at low fields [at a field lower than the pinning or propagation field (Ref. 5)], and the latter, to the frequency above which the domain walls are unable to follow the cyclic, driving field. Initial permeability as a function of time for three annealing temperatures is shown in Fig. 1, and for the same times and temperatures, domain wall relaxation frequency appears in Fig. 2. For 693 K, initial permeability goes through a maximum (~5 times the as-quenched value) for $t \sim 15$ min and then decreases toward a plateau for times larger than 30 min. Similar behavior is observed for $T=716$ K, with a decrease to the plateau occurring for longer times but practically the with the same maximum permeability value. The results for the 576-K annealing exhibit a difference, since the tendency toward a constant value occurs without the passage through a maximum.

The relaxation frequency shows the opposite behavior from permeability; for 716 and 693 K, ω_0 goes through a minimum; from ~40 kHz for the as-quenched state to ~9 kHz for the permeability maximum, and then stabilizing at about 15 kHz for times longer than 30 min.

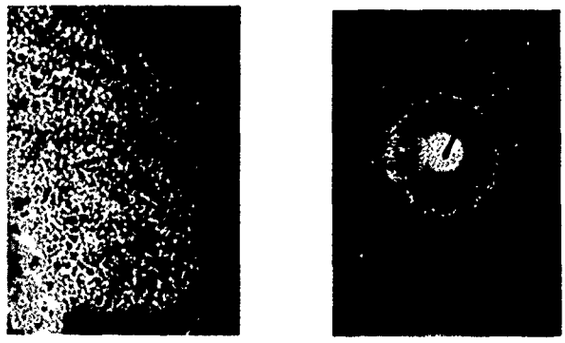

FIG. 4. TEM image and EDP for annealing 40 min at 693 K.

The microstructures and their corresponding electron diffraction patterns (EDP) appear in Figs. 3, 4, and 5 for 20, 40, and 60 min, respectively, at 693 K. The nucleation of crystallites takes place between 0 and 20 min; electron diffraction pattern changes from the characteristic, diffuse ring in the amorphous phase to diffraction rings formed by discrete spots. An increase in crystallite number is observed between 40 and 60 min, with a small growth in size (note the difference in magnification). Electron diffraction pattern show an increase in intensity of rings. In these annealings, however, crystallite size remains smaller than 30 nm.

The initial permeability mechanism is the result of a reversible bulging of pinned domain walls,[7] under the "pressure" of the external field. An increase in permeability can therefore be expected to be associated with an increase in the free-bulging area, which can occur essentially by two factors, a coarsening in the domain structure and a decrease in anisotropy. The latter results in a "softer" domain wall, easier to deform under the field. A coarsening in the domain structure can be produced by factors such as stress relief, or a decrease in the pinning site concentration.

The domain wall relaxation frequency depends on an inverse manner on the above factors. A "softer" domain wall relaxes at lower frequencies than a "stiff" wall: also, an increase in pinning sites leads to a smaller bulging area, and in a similar way to the string of a musical instrument, this results in a higher vibration frequency.

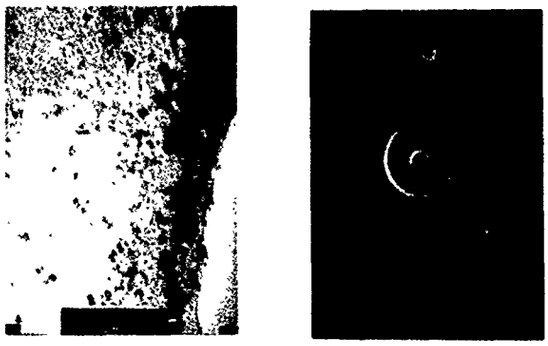

FIG. 3. Transmission electron microscopy image and electron diffraction pattern for annealing 20 min at 693 K.

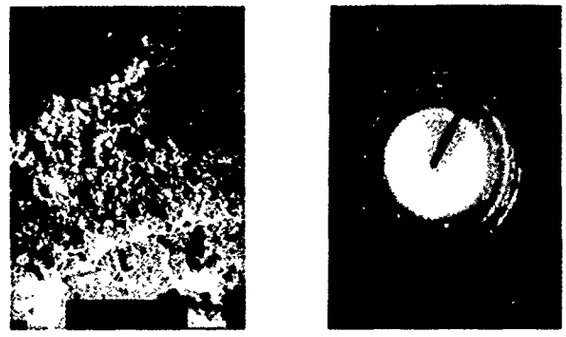

FIG. 5. TEM image and EDP for $t=60$ min and $T=693$ K.

Similar results, i.e., the tendency of the $\mu_0 f_0$ product to a constant value, have been reported in amorphous materials as a result of thermal annealings involving stress relief,[8] *in situ* diffusion to directional order[9] and "macrocrystallization."[10] It seems therefore a general phenomenon associated with initial permeability. In the present case, results can be interpreted on the basis of a decrease in anisotropy and/or a coarsening of the domain structure leading to longer, unpinned walls of the amorphous phase. The same maximum permeability value for the two high annealing temperatures suggests that pinning of the walls occurs only at the external surfaces of the sample.

It has been shown in many studies[11] that the presence of crystallites in ferromagnetic amorphous phase leads to wall pinning. In the case of magnetic nanometer-range crystallites, however, a preferential orientation of the magnetic axis of these crystallites can lead to a cooperative effect with the domain structure of the amorphous matrix, resulting[12] in an in-plane induced anisotropy. As annealing progresses, the growth in crystallite size seems to destroy the cooperative effect, leads to a decrease in free-bulging area and therefore to a decrease[10] in permeability. The fact that annealings at 576 K result in an increase in permeability with no maximum in this property seems to be due to a coarsening of the domain structure (by simple elimination of stress), but involving no decrease in anisotropy.

Finally, it has been shown that nanocrystallized structures can also be obtained in commercially available materials, by using annealing temperatures well below the conventionally measured crystallization temperature.

Authors thank Dr. H. R. Hilzinger for providing the amorphous samples. S. Jiménez-Cortés, J. Guzman, C. Vazquez, and A. Caballero for technical assistance, as well as partial funding from DGAPA-UNAM (Mexico), the CONACyT-British Council collaboration scheme and the European Commission.

Effects of cooling rate after annealing on the soft magnetic properties were investigated for an $Fe_{88}Zr_7B_4Cu_1$ alloy with nanoscale grain structure, which was prepared by melt quenching. As the cooling rate increased, the effective permeability improved and the remanence ratio, which indicates the orientation of magnetic anisotropy (degree of pair ordering), decreased. The increase of permeability and decrease of remanence ratio were considered to result from the suppression of the induced magnetic anisotropy. Furthermore, the variation of disaccommodation behaviors with cooling rate was investigated in the $Fe_{88}Zr_7B_4Cu_1$ nanocrystalline alloy. It was found that the value of D (intensity of disaccommodation) was a little higher for the samples obtained from the high cooling rate than that for the low cooling rate. This result can be explained by domain structure stabilization due to local induced magnetic anisotropy.

Nanocrystalline magnets are promising materials for future soft magnetic applications.[1,2] Among these materials, Fe-Zr-B-Cu based nanocrystalline alloys were reported to exhibit excellent soft magnetic properties with a high saturation magnetization and a high permeability.[3] The reason for the good soft magnetic properties is rather well understood to be the reduction of the effective magnetocrystalline anisotropy by forming ultrafine grains. Although the formation of nanocrystalline grains, which are obtained by annealing at temperatures above crystallization temperature, play a dominant role in soft magnetic properties, it is important from the application point of view to know how the cooling rate after annealing influences the soft magnetic properties of these alloys. Generally, it has been known that induced magnetic anisotropy can be effectively suppressed by controlling the quenching rate or annealing in a rotating magnetic field in the case of amorphous alloys.[4] However, not much work has been done on the effects of the cooling rate after annealing in nanocrystalline alloys. In this study the effect of the cooling rate was investigated for the $Fe_{88}Zr_7B_4Cu_1$ nanocrystalline alloy.

Ribbon samples of amorphous $Fe_{88}Zr_7B_4Cu_1$ alloy were prepared in an argon atmosphere by the single roll melt spinning technique. The ribbons were, typically, 1–2 mm wide and about 20 μm thick. They were confirmed to be amorphous by x-ray diffractometer using Cu K_α radiation. The as-quenched ribbons were wound onto a toroidal core with 21-mm inner diameter, and subsequently annealed in the temperature range of 500 to 650 °C for 1 h in a vacuum of about 10^{-3} Torr. The cooling rate was varied by carrying out two different cooling methods, the first is water quenching of the vacuum-sealed specimen (conventional method); and the second is water quenching with Ar gas introduction after vacuum annealing (our new method). It is considered that the latter gives a much higher cooling rate than the former, because Ar atmosphere is more thermally conductive than the vacuum. It is noted that direct water quenching without protection is very harmful due to surface oxidation. The effective permeability (μ_e) was measured at 1 kHz under 10 mOe with an impedance analyzer. The magnetic induction at 10 Oe (B_{10}) and coercive force (H_c) were measured with a dc hysteresis loop tracer.

Figure 1 shows the effective permeability (μ_e) of $Fe_{88}Zr_7B_4Cu_1$ alloy as a function of annealing temperature (T_a). The ranges of maximum and minimum values (the bars indicate data scattering range) are shown in Fig. 1. With

onset of crystallization the effective permeability of the alloys from the higher cooling rate after annealing increases to about 4×10^4. It is notable from Fig. 1 that this value is much higher than that of the alloys from the lower cooling rate (conventional method). The substantial improvement of μ_e can be explained by the decrease of induced magnetic anisotropy due to fast cooling rate. In the case of the higher cooling rate, the optimum annealing temperature is observed to be low compared to the lower cooling rate. μ_e begins to decrease with T_a above T_a=590 °C. This may be caused by generation of internal stress due to very fast cooling after annealing.

Figure 2 shows the results for H_c as a function of T_a for the two different cooling rates. The coercive force decreases continuously with T_a regardless of the cooling rate. This indicates that the reciprocal relation between coercive force and permeability does not hold well for fast cooling where thermal stress is reintroduced at high T_a. As shown in Fig. 2, lower coercive force is obtained at all annealing temperatures for the higher cooling rate.

Figure 3 shows the remanence ratio (B_r/B_{10}) as a function of annealing temperature. The remanence ratio is a measure of the distribution of domain orientation and is strongly correlated with induced magnetic anisotropy.[5] In ribbon-type amorphous and nanocrystalline soft magnets most of spontaneous magnetization is aligned to the direction of the ribbon axis. Therefore the self-induced magnetic anisotropy is considered to form along this direction. As shown in Fig. 3, the values of the remanence ratio in the higher cooling rate are low, indicating that the small induced magnetic anisotropy is formed during cooling. From this result, it is considered that induced magnetic anisotropy can be effectively suppressed by fast cooling after annealing. We examined the relationship between the effective permeability and the remanence ratio at all the temperatures investigated in this work and the result is shown in Fig. 4. Some kind of correlation between these two quantities seems to exist. The increase of the remanence ratio is associated with the decrease of μ_e. In the case of the lower cooling rate, the values of remanence ratio are higher in most cases. This indicates induced magnetic anisotropy can be formed easily in the case of slow cooling.

From the above results it is found that a higher cooling rate has an advantage in obtaining higher permeability within the limit of creating no internal stress. The present result is in accord with that of Co-based amorphous alloys.[6] As shown in Fig. 4, the remanence ratio which gives the maximum effective permeability is about 0.6. This value agrees well with the result of Yoshizawa *et al.*[7] and Lim *et al.*[8]

The disaccomodation is of significant practical importance and is known to be affected by cooling rate. Therefore, we also investigated the time dependence of permeability in

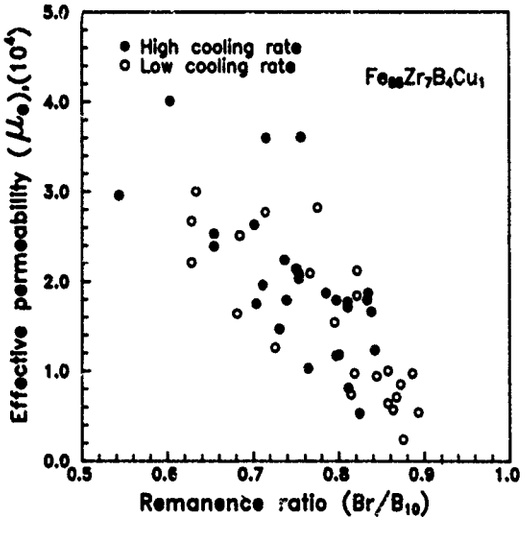

FIG. 4. The relationship between effective permeability at 1 kHz and the remanence ratio for $Fe_{88}Zr_7B_4Cu_1$ alloy annealed for 1 h.

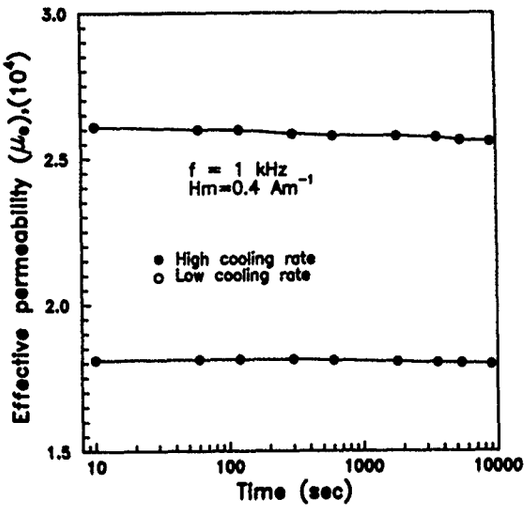

FIG. 5. The dependence of the permeability at 1 kHz on the time for $Fe_{88}Zr_7B_4Cu_1$ alloy annealed for 1 h.

the alloys obtained from different cooling rates. The result is given in Fig. 5. For the lower cooling rate little change in permeability is observed while for the higher cooling rate the permeability decreases slightly with time. Figure 6 shows the

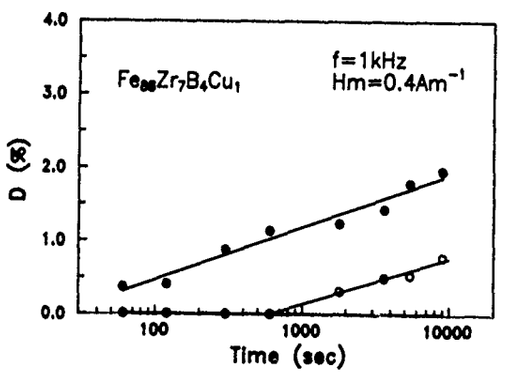

FIG. 6. Change in the intensity of disaccommodation as a function of time for $Fe_{88}Zr_7B_4Cu_1$ alloy annealed for 1 h.

intensity of disaccommodation (D) as a function of measured time. Here, D is defined by

$$D=\frac{\mu_e(10)-\mu_e(t_1)}{\mu_e(10)}\times 100(\%),$$

where $\mu_e(10)$ and $\mu_e(t_1)$ are the values of effective permeability measured at $t=10$ and $t=t_1$ s after demagnetization, respectively. In the case of $t=10$ and $t=9000$ s, the values of D are 1.9% and 0.8% for the alloys with higher and lower cooling rates, respectively. From this result, it can be seen that the higher μ_e which is obtained using a high cooling rate is related to the larger disaccommodation. This can be explained by the fast recovery rate of the frozen atoms, because free energy in the fast quenched state is high. In the case of slow cooling after annealing domain wall stabilization due to induced local magnetic anisotropy occurs during cooling, and lower permeability and lower disaccommodation are obtained.

We have investigated the effect of the cooling rate after annealing on the soft magnetic properties of an $Fe_{88}Zr_7B_4Cu_1$ alloy with nanoscale grain structure, which was prepared by melt quenching. Enhanced effective permeabilities are obtained for the alloys prepared by high cooling rates. The remanence ratio decreases with the cooling rate. The increase of permeability and decrease of remanence ratio are considered to result from the suppression of the induced magnetic anisotropy.

We have also investigated relationship between disaccommodation and cooling rate. In the higher cooling rate, the value of D is a little higher than that in the lower cooling rate. The low value of D in the slow cooling can be explained by domain structure stabilization due to local induced magnetic anisotropy.

The magnetic properties of amorphous FeSiB (2605-S2) and CoFeMoSiB (6025-Vac) tapes have been measured after conventional furnace annealing and dynamic current annealing, which takes place in air and during the winding process of tapes using Joule heating. The measurements showed a significant improvement of the magnetic properties when dynamic annealing temperatures are far below the crystallization temperatures but above the Curie temperature. Magnetic properties and domain patterns are presented and we find that our method of about 10 s of annealing gives a similar magnetic quality to that obtained by classical techniques.

The improvement of soft-magnetic properties of metallic glasses is attained after heat treatments destined to induce relaxation of both internal stresses to zones of quenched-in density fluctuation and excess due to imposed shapes, such as those imposed by a curved shape of a transformer toroid manufactured with magnetostrictive materials, as for example, FeSiB tapes. The relaxation of these stresses requires diffusive motion especially of structural defects, whose kinetics also control structural relaxation in general.[1-3]

Relaxation for improvement of magnetic properties of amorphous tapes is usually induced by ≈2 h of furnace annealing at temperatures lower than the Curie temperature under inert gas. Joule heating was also shown to have a strong effect on structure and magnetic properties of metallic glasses after current-annealing times of the order of milliseconds (flash annealing) to several minutes.[4-6] It had also been shown[7] that rapid Joule heating for about 20 s just below the crystallization temperature of FeSiB glassy tapes resulted in improvement of all measured magnetic properties which were then better than those of tapes classically relaxed by furnace annealing.

We have conceived and used a new dynamic relaxation process, hereafter referred to as dynamic current annealing (DCA), which can use continuous Joule heating during the winding process of tapes as they slide on a cylindrical surface of a chosen curvature at which the tape will be used. The setup, which also quenches the tapes down to room temperature before they leave the cylinder, allows dynamic current annealing times of amorphous tapes of the order of seconds, at temperatures near crystallization, $T \approx T_x$, in air. The winding speed of the tapes can be fixed. Application of this technique during winding of transformer toroids with FeSiB amorphous tapes was found to give very good magnetic properties.[8] The procedure, which also raises some interesting questions concerning stress and structural relaxation in amorphous alloys, is described in more detail in a previous paper.[9]

The aim of this work was to assess the effect on magnetic properties of amorphous tapes of different thermal relaxation techniques, namely, classical furnace annealing versus dynamic current annealing using Joule heating.

The amorphous $Fe_{78}Si_9B_{13}$ and $Co_{66}Fe_4Mo_2Si_{16}B_{12}$ samples used in this study were purchased batches from Allied Signal and Vacuumschmelze, respectively, in lengths of several hundred meters. Table I gives some characteristics of the samples used. FeSiB was chosen for its highly positive magnetostriction and the CoFeMoSiB for its almost zero magnetostriction.

We have carried out on these tapes three different thermal relaxation treatments:

(1) A furnace annealing (FA) under inert gas to 380 °C during 2 h for the FeSiB tape, and 430 and 240 °C for 1-h periods for the CoFeMoSiB tape.
(2) A furnace field annealing (FFA) on FeSiB sample, similar to the previous one but with an applied magnetic field (800 A/m) directed along the tape axis.
(3) Our dynamic current annealing process,[9] which had been used to relax FeSiB and CoFeMoSiB amorphous tapes at temperatures above T_c for times of the order of 2 s.

The temperature profiles and maximum temperatures were determined from thermocouples and pyrometric readings. A radius of curvature $r=4$ cm was chosen with tape rolling

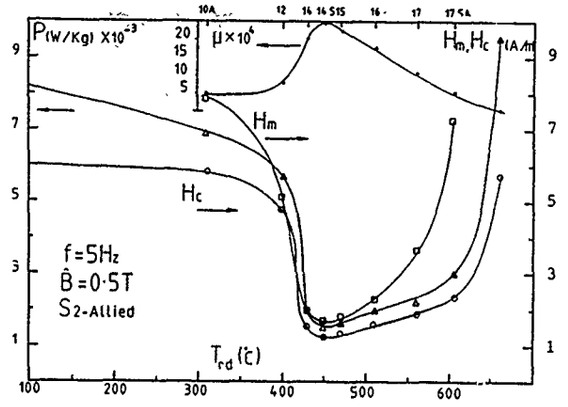

FIG. 1. Evolution of magnetic power losses P, coercive field H_c, relative permeability μ, and maximum field H_m at $B=0.5$ T and $f=5$ Hz, of the FeSiB alloy vs maximum dynamic current annealing temperature T_{rd} (°C) and dynamic annealing current $I(A)$.

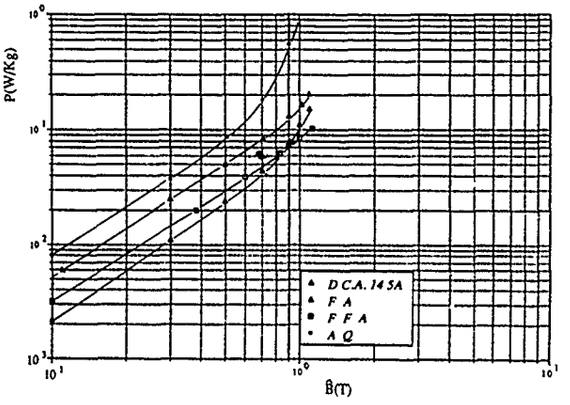

FIG. 2. Magnetic power losses P vs peak induction value B at $f=50$ Hz for FeSiB tapes annealed by different techniques.

speed of $v=1$ cm/s. To assure good contact between the tape and the current leads, the moving tape was maintained under a measured tensile stress of ≈50 MPa. The strength of electric currents used in our dynamic treatment of FeSiB and CoFe-based tapes were between 9 and 18 A.

Three techniques for magnetic characterization were used to assess the effect on magnetic properties of amorphous tapes annealed with the various treatments given previously. (1) Magnetic measurements under sinusoidal flux on transformer toroid. Magnetic properties data were obtained by numerical integration of digitized hysteresis loops. Magnetic power losses P (W/kg), relative permeability μ, coercive field H_c (A/m), and maximum field H_m (A/m) at peak induction value B (T), were measured as a function of frequency f and of temperature of dynamic current annealing T_{DCA} (or T_{rd}). (2) Observation of domain structures using the magneto-optic Kerr effect. (3) Determination of the saturation magnetostriction λ_s, using a linear capacitive high precision dilatometer.[10,11] At each stage the samples were usually checked for appearance of crystallinity by x-ray diffraction and differential scanning calorimetry (DSC).

Figure 1 shows the evolution of the magnetic properties (P, H_c, μ, and H_m), of the FeSiB alloy annealed by our dynamic process as a function of the current strength $I(A)$ and maximum temperature T_{rd} (±10 °C) reached during dynamic current annealing, at peak induction value $B=0.5$ T and $f=5$ Hz. The most remarkable result is that the magnetic properties improve very rapidly in the T range $410<T<450$ °C, close to the Curie temperature. The optimum magnetic properties, that is minimal P and H_c and maximum μ, were found at $T_{rd}\approx 450$ °C and $I=14.5$ A, respectively. The x-ray patterns and DSC experiments[9] show that the degradation of the magnetic properties for currents $I\geq 17$ A can indeed be attributed to the onset of crystallization and that for $I=16$ A no significant crystallization is occurring.

Figure 2 compares the magnetic power losses at 50 Hz, of FeSiB amorphous tapes annealed in different conditions. Results are presented for the as-quenched (AQ) sample before and after FA, FFA, and DCA for $I=14.5$ A. For all induction levels we observe that the magnetic losses of the DCA sample are less than the FA sample. They are also smaller than the FFA sample if the peak induction is smaller than 1 T. Figure 3 shows the peak induction B versus applied field H for the same samples at $f=50$ Hz. For all applied field levels, the magnetization curve $B(H)$ of the DCA sample is better than the FA sample one. It is also better than the FFA sample one if the peak induction is smaller than about 0.7 T. Figure 4 shows the magnetization curve $B(H)$ for the CoFe-base sample, after FA and DCA for $I=9$ A, at $f=5$ Hz and 50 kHz, respectively. The absence of any significant difference between the magnetization curves at 5 Hz and 50 kHz for the DCA sample indicates no significant dependence of the frequency in this range.

To obtain information on the magnetic moment distributions of our samples, we have performed observations of domain structures using the magneto-optic Kerr effect. Figure 5 shows the domain patterns of FeSiB samples in the middle of the tapes. In Fig. 5(a) we observe the complex pattern of domains in the AQ sample. In Fig. 5(b) we observe that the FA sample exhibits relatively large domains whose orientation is ill defined. The FFA and DCA samples present similar magnetic structures with domains oriented along the

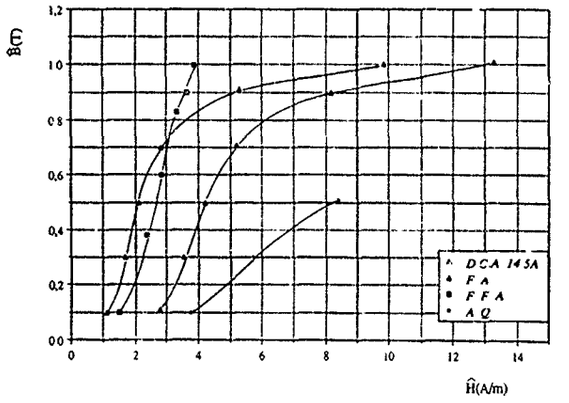

FIG. 3. Magnetization curves; peak induction value B vs applied field H at $f=50$ Hz for FeSiB tapes annealed by different techniques.

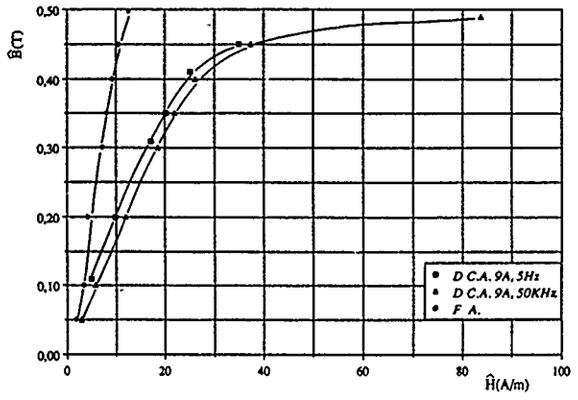

FIG. 4. Peak induction value B vs applied field H at 5 Hz and 50 kHz for CoFeMoSiB tapes annealed in different conditions.

ribbon axis [Figs. 5(c) and 5(d)]. Figure 6 shows the domains of the CoFe-base amorphous tapes for the AQ sample and the DCA sample to I=9 A. It was found that the DCA sample presents a narrow domain structure perpendicular to the ribbon axis.

We have measured and examined the evolution of the saturation magnetostriction λ_s of Fe- and CoFe-base amorphous tapes after FA and DCA. It was found that although very different in all respects, the two types of annealing can produce the same results, including the same optimum values of magnetostriction, indicating equivalent structural relaxation and chemical short range order states.[10]

The effects responsible for the improvement of the magnetic properties and in particular the magnetic anisotropy induced by our DCA, are probably due to plastic deformation and to the thin surface oxide layer that forms during the DCA in air and that puts the plane of the tapes under tension. These beneficial effects and the effect of T_c on the relaxation kinetics of amorphous tapes can only be speculative at this point and further experiments are needed and planned.

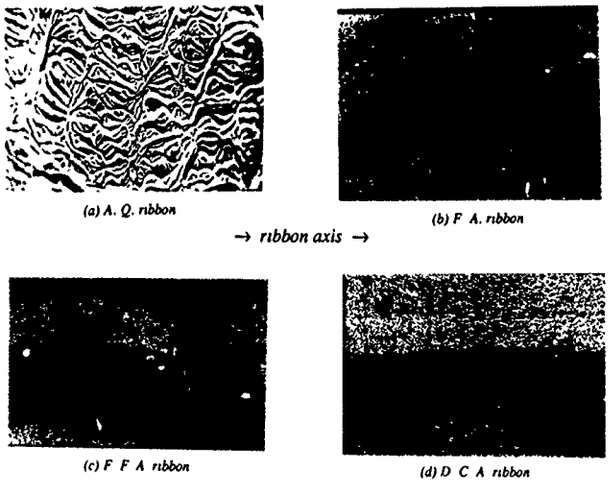

FIG. 5. Domain structure observed by Kerr effect for the FeSiB samples. We observe the magnetic anisotropy induced by our DCA at 14.5 A.

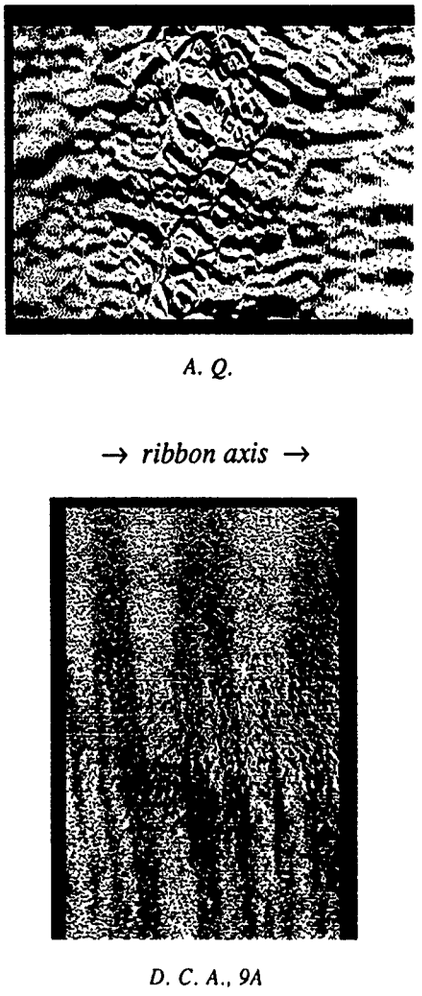

FIG. 6. Domain structure observed by Kerr effect for the CoFeMoSiB sample. We observe the magnetic anisotropy induced by our DCA at 9 A.

The dynamic current annealing process yields excellent magnetic properties of ferromagnetic amorphous tapes compared with those obtained by classical furnace annealing and close to those of furnace field annealed tapes. The best magnetic properties of commercial FeSiB and CoFeMoSiB tapes were attained after only about 10 s of annealing in air far below the crystallization temperatures but above the T_c. For industrial purposes it is possible to render this process continuous.

Magnetic properties are presented of amorphous wires covered by glass, with the compositions $Fe_{65}B_{15}Si_{15}C_5$, $Fe_{60}B_{15}Si_{15}Cr_{10}$, and $Fe_{40}Ni_{40}P_{14}B_6$, which were prepared by melting the alloy in glass tubes and drawing fibers from the softened glass. The magnetization, the remanence, and the coercive force of the samples covered by glass, and of those obtained after removing the glass cover, were measured at a field of 2054 A/m. These amorphous wires have a square-shaped hysteresis loop, a value of the coercive force ranging between 255 and 462 A/m and an axial magnetization of 0.21–0.32 T for different compositions. The glass removal leads to an increase in magnetization and a decrease in the coercive force. The influence of a passing dc current through the wire during measurements has also been studied, influence that is much pronounced in the case of the wires obtained after removing the glass cover. The observed different magnetic properties of the amorphous magnetostrictive wires are attributed to the difference in internal stress distribution produced during preparation of the samples.

I. INTRODUCTION

Amorphous ferromagnetic wires present a special interest due to their magnetic properties that make them useful in sensor devices. Usually they are studied as as-quenched amorphous wires of about 125 μm in diameter,[1] obtained by the "in-rotating-water spinning method" and cold drawn in several steps down to 50 μm or lower from the 125 μm one.[2] The aim of this article is the study of the behavior of the amorphous wires in glass cover, having the compositions FeBSiC, FeBSiCr, and FeNiPB, with diameters ranging from 10 to 26 μm. Based on our knowledge this is the first work on the magnetic properties of the amorphous wires covered by glass.

These wires were obtained by an improved variant of the Taylor method, which consists of sealing one end of the glass tube in which the master alloy was introduced, heating the end of the tube to a temperature at which the glass is soft and the alloy molten, and drawing a fiber from the heated end. In this way metallic amorphous wires were obtained in glass cover with diameters ranging between 5 and 30 μm. The amorphous state was checked by x-ray diffraction, differential thermal analysis and thermomagnetic measurements.

II. EXPERIMENTAL PROCEDURE

The magnetization value of the above-mentioned alloys was measured by the fluxmeter method[3] at 500 Hz in an alternating sinusoidal field having a maximum value of 2054 A/m, on samples 10 cm in length. The remanence and the coercive force were determined from the hysteresis loops plotted on an X-Y digital oscilloscope. We measured the saturation magnetization of these alloys using a vibrating sample magnetometer. We also studied the influence of a direct current passing through the wires during measurements. The magnetic field H_p created by this current corresponds to the maximum circular field at the surface of the wire, given by the following expression:

$$H_p = \frac{I}{2\pi R_w},$$

where I is the value of the direct current which passes through the wire and R_w is the radius of the metallic wire. In order to avoid a significant heating of the wires, the current passes through them just for a few seconds.

The magnetic measurements were made on as-quenched samples (wires covered by glass) and after the glass removal. The glass was removed by chemical etching. We used successively different concentration solutions based on hydrofluoric acid (38% and lower). Optical and electrical methods were used to have a careful control of the removing process, in order to avoid any reactions between the chemical solutions and the metallic wire.

III. RESULTS AND DISCUSSION

The values of the saturation magnetization for the studied alloys are: 1.50, 0.80, and 0.79 T for FeBSiC, FeBSiCr, and FeNiPB, respectively.

Table I illustrates the results of the measurements on the amorphous wires covered by glass with diameters ranging from 18 to 26 μm. All these samples present a square-shaped hysteresis loop, a high value of the coercive force (H_c=250–450 A/m) as compared with that of the amorphous ribbons or amorphous wires obtained by the in-

rotating-water spinning method having the same composition. When a dc current passes through the wire, a significant change in the squareness of the hysteresis loop cannot be observed, but a decrease in the coercive force is observed. A decrease in the axial magnetization of all samples can also be observed. After removing the glass from the amorphous wires, the measurements show an increase in magnetization and a pregnant decrease in the coercive force. These results are illustrated in Table II. For these samples, the most pronounced increase in the value of the magnetization is observed for the FeNiPB alloy, at the maximal value of the measuring field. The most pronounced decrease in the coercive force is observed for the FeBSiCr samples.

Covered wires have strong transverse anisotropy as supported by the small values of M_r/M_s. After removing the glass cover, transverse anisotropy partially relaxes (M_r/M_s increases). Because of bistability, the wires (covered and after removing the glass) have a domain structure with an inner core (axially magnetized) and an outer shell (with transverse anisotropy). The radius of the core R_c can be estimated as

$$R_c=\left(\frac{M_r}{M_s}\right)^2 R_w,$$

where R_w is the radius of the metallic wire. The ratio R_c/R_w increases after removing the glass cover because the transverse anisotropy, induced by the glass cover, relaxes.[4] Reduction of coercivity after glass removal is a consequence of removing the stresses induced by the cover.

When a direct current passes through these samples, a decrease in the magnetization and in the coercive force can be observed. Figure 1 shows the hysteresis loops for the samples covered by glass [Fig. 1(a)] and after removing the glass [Fig. 1(b)]. Figures 2(a) and 2(b) show the hysteresis loops for a FeBSiCr sample covered by glass and after removing the glass cover, respectively. At the same time, these figures illustrate the influence of a direct current that passes through the samples during measurements. Asymmetry of the hysteresis loop produced by the current through the wire is observed. It is much more pronounced when the current increases. The observed shift in the loop is found to follow the direction of the current. The bistable behavior of the amorphous wires has been explained by the fact that the macroscopic magnetization processes in these materials are especially determined by the magnetoelastic anisotropy, due to the coupling between the internal stresses induced by the fabrication process and the magnetostriction constant of the

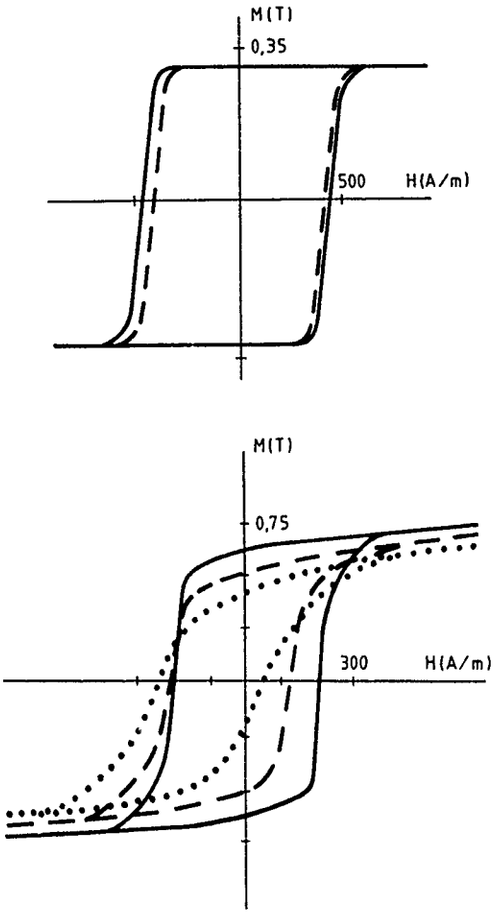

FIG. 1. M-H loops of $Fe_{65}B_{15}Si_{15}C_5$ amorphous wires: (a) in glass cover, H_p=0 A/m (solid line), H_p=318 A/m (dashed line), (b) after removing the glass cover, H_p=0 A/m (solid line), H_p=245 A/m (dashed line), H_p=490 A/m (dotted line).

material. This behavior is in accord with the model proposed by Humphrey *et al.*,[5] Kinoshita,[6] and Mitra and Vázquez.[7] These wires have high positive magnetostriction constants ($\lambda \approx 10^{-5}$) and they behave as if they were made of two distinct regions, an axially magnetized inner core and a radially magnetized outer shell. The differences in magnetic behavior of the amorphous wires covered by glass and that of the same wires after removing the glass indicate a transverse anisotropy induced by the glass cover, as mentioned before. For the samples covered by glass, at the maximal value of the measuring field, the square-shaped hysteresis loops and the small value of the axial magnetization show a high value of the induced transverse anisotropy and it stretches on a large region as compared with that occupied by the axially magnetized inner core.

The shape of the hysteresis loops after removing the glass cover, the magnitude of the measured magnetic parameters, and their changes produced by the dc current through the wires agree with the above-mentioned model. At the same measuring field the magnetization of these samples after removing the glass cover is, however, lower than that of the samples with the same compositions, obtained by the in-rotating-water spinning method[8] or by cold-drawing process; the FeNiPB alloy is an exception.[9] This behavior sug-

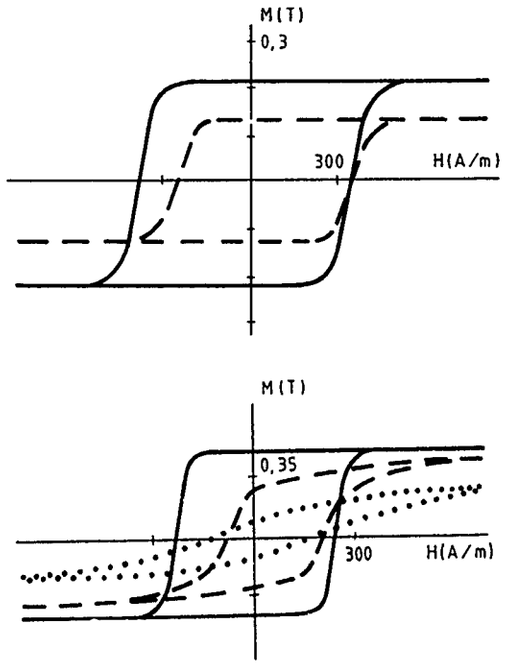

FIG. 2. M-H loops of $Fe_{60}B_{15}Si_{15}Cr_{10}$ amorphous wires: (a) in glass cover, H_p=0 A/m (solid line), H_p=350 A/m (dashed line); (b) after removing the glass cover, H_p=0 A/m (solid line), H_p=290 A/m (dashed line), H_p=579 A/m (dotted line).

gests the existence of another ratio between the dimensions of the axially and radially magnetized regions, namely, the increase of the radially magnetized outer shell due to the internal stresses induced by the presence of the glass cover during the fabrication process. The thickness of the radially magnetized outer shell is reduced after removing the glass cover.

IV. CONCLUSION

The metallic amorphous wires obtained by a variant of the Taylor method[10] exhibit a square-shaped hysteresis loop and a high value of the coercive force. This behavior makes them useful to generate sharp voltage pulses. Passing a dc current through these wires does not change the squareness of the hysteresis loops. It produces only a decrease of the coercive force with maximum 20%. The removal of the glass cover leads to a change in the shape of the hysteresis loop, a decrease in the value of the coercive force of about 50%, accompanied by an increase in the magnetization value, at the same value of the measuring field. It also leads to a higher variation of the magnetic parameters versus the value of the passing current through the sample. We also observed the influence of passing the dc current through the wires on these parameters, during measurements. Comparative measurements between the samples covered by glass and those obtained after glass removal were performed.

Four components of the susceptibility tensor of a high magnetostrictive amorphous $Fe_{77.5}Si_{7.5}B_{15}$ wire are investigated by means of ac hysteresis loop measurements. The samples have been carefully annealed in order to eliminate the internal stresses produced during the quenching. When tensile stress and/or torsion are applied bistable magnetic behavior with a large Barkhausen jump is observed. The effect of applied torque on the longitudinal and circular components of remanence magnetization and on the longitudinal and circular coercive fields is studied for different constant values of tensile stress. With increasing torque the axial and circular components of remanence decrease and increase, respectively, approaching the limit value of 0.71 M_s. The axial coercive fields for the axial and radial magnetization components coincide. They are nearly constant at low torsion and above same threshold value, depending on applied stress, follow approximately a square-root dependence on applied torque. When tensile stress is applied the circular coercive fields show a well pronounced minimum at the same threshold torque. The experimental results are interpreted by taking into account the axial and helical components of magnetic anisotropy induced by magnetoelastic coupling.

The most outstanding property of Fe-rich amorphous wires—magnetic bistability—is a consequence of the particular distribution of internal stresses introduced by the rapid quenching process.[1] The magnetic bistability can be excited by axial H_z or circular H_ϕ magnetic fields and can be observed for both the axial M_z and circular M_ϕ magnetization components. In general, the relation between the two components of magnetization and the two components of magnetic field are described by the susceptibility tensor χ

$$\begin{pmatrix} M_z \\ M_\phi \end{pmatrix} = \begin{pmatrix} \chi_{zz} & \chi_{z\phi} \\ \chi_{\phi z} & \chi_{\phi\phi} \end{pmatrix} \begin{pmatrix} H_z \\ H_\phi \end{pmatrix}. \tag{1}$$

The diagonal components of χ correspond to the axial (M_z-H_z) loop and so called magnetoinductive (M_ϕ-H_ϕ) effect,[2] respectively. The nondiagonal terms are related to inverse Wiedemann (M_z-H_ϕ) and Matteucci (M_ϕ-H_z) effects.[3,4] For the appearance of inverse Wiedemann and Matteucci effects the presence of helical magnetic anisotropy is required. This can be introduced by applied torque or by torsion annealing.

Most of the previous works deal with the conventional M_z-H_z magnetization process where the bistability is interpreted by magnetization reversal in the inner core of the wire. More complex interpretation is needed when studying the nondiagonal magnetization process or the circular magnetization process in the magnetoinductive effect. In some previous papers[2–4] also the other types of hysteresis loops have been separately studied.

The aim of the present work is to measure and analyze all four components of the susceptibility tensor. In this way, a deeper information about magnetization distribution and magnetizing process can be obtained. In order to start from a more homogeneous anisotropy distribution, the internal stresses were relieved by preannealing treatment. The effect of axial and helical anisotropies was then studied by applying tensile stress and torque.

Amorphous wire $Fe_{77.5}Si_{7.5}B_{15}$ (diameter 131 μm) was kindly supplied by Unitika Co., Japan. Alternating current hysteresis loops M_z-H_z, M_z-H_ϕ, M_ϕ-H_z, and M_ϕ-H_ϕ of a 31.2-cm-long sample were measured under various applied torque and/or tensile stress. Alternating current magnetic field of frequency 11 Hz to 5.5 kHz was provided by passing triangular-wave current through either the magnetizing solenoid (H_z) or the wire (H_ϕ). The output voltage taken either from a 4-cm-long pickup coil (at the center of the sample) or between the ends of the wire was electronically integrated and supplied to one channel of a digital oscilloscope. To the other channel a voltage proportional to the driving current was supplied. The ohmic component of the output voltage produced by the driving current through the wire (in case of M_ϕ-H_ϕ measurements) was subtracted by means of a resistance Wheatstone bridge. The wire was current annealed for 2 min with a dc current of 605 mA in order to eliminate the internal stresses produced by the quenching.

The influence of applied torque ξ on the hysteresis properties was investigated at the frequency of 110 Hz. The example of a set of four hysteresis loops is shown in Fig. 1. In the case of M_z-H_ϕ and M_ϕ-H_ϕ measurements the circular magnetic field h_ϕ produced by electric current through the wire is nonuniform so we use the "ballistic" average of the field $H_\phi = (1/R)\int h_\phi\, dr = jR/4$, where j is the current density and R the radius of the wire.

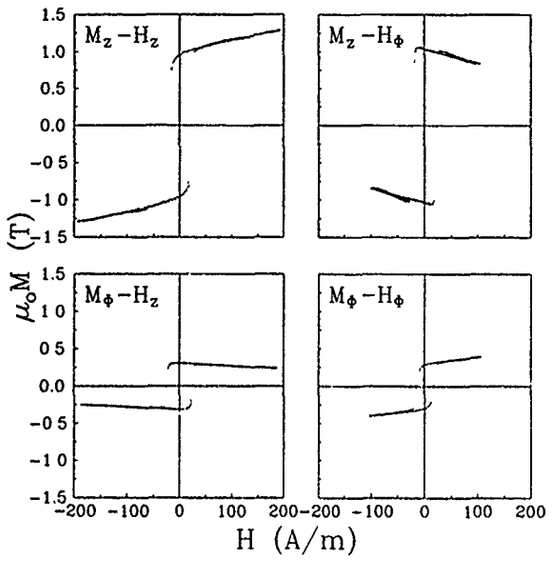

FIG. 1. Hysteresis loops of the stress-relieved amorphous $Fe_{77.5}Si_{7.5}B_{15}$ wire (frequency=110 Hz, torque ξ=1.67 rad/m, tensile stress σ=0).

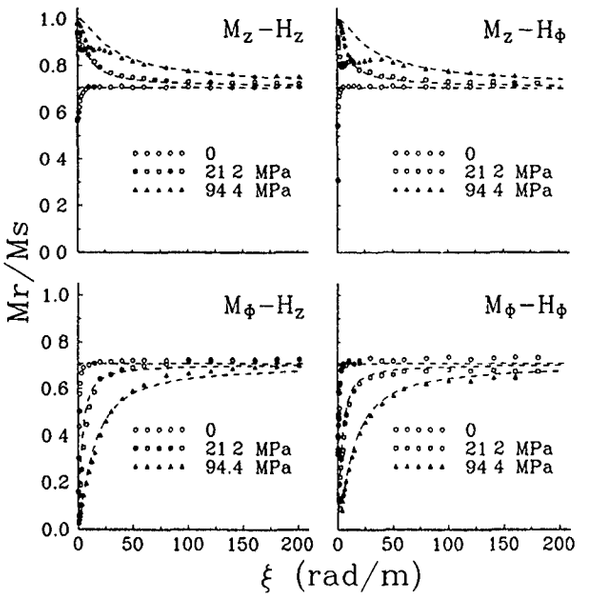

FIG. 2. Remanence-to-saturation ratio vs applied torque.

All four hysteresis loops are sensitive to applied stress and torque. For M_ϕ-H_z and M_z-H_ϕ no hysteresis is observed at zero torque which indicates that there is no spontaneous helical anisotropy in the stress-relieved wire. In the strain-free state (σ, ξ=0) the M_r/M_s ratios of the M_z-H_z and M_ϕ-H_ϕ loops are 0.56 and 0.40, respectively, which can be accounted for the presence of domain structure and the usual magnetization reversal by domain wall movement and rotational processes. With a small tensile stress and/or torque all the loops became rectangular and the magnetization reversal takes place by a large Barkhausen jump between two nearly saturated states.

The effect of applied strain on magnetic properties is related to magnetic anisotropy induced by magnetoelastic coupling. In an amorphous wire under simultaneous action of tensile stress σ and torsional strain ξ the magnetoelastic free energy is given by

$$E_a(r) = -(3/2)\lambda_s(\sigma\alpha_z^2 + 2\mu\xi r\alpha_\phi\alpha_z), \tag{2}$$

where μ is the shear modulus, r the distance from the axis of the wire, and α_ϕ, α_z are the circular and axial components of the vector M/M_s, respectively. Provided there is no intrinsic stress one obtains for λ_s>0 an orthorhombic anisotropy with the local easy direction along the helical path at the angle

$$\Theta = (1/2)\text{arc } tg(2\mu\xi r/\sigma) \tag{3}$$

with respect to the wire axis. For σ=0 one has Θ=45° in the whole volume. For σ>0 the angle Θ continuously increases from zero at the axis to Θ_0<45° at the surface of the wire. Using Eq. (3) most of the experimental results can be explained.

In Fig. 2 the dependencies of M_r/M_s vs applied torque ξ are shown for three different levels of tensile stress σ. The experimental data are compared with the theoretical curves calculated with the assumption that there are no magnetic domains and the local magnetization is parallel to the local easy direction. The axial and circular remanences are obtained by averaging $M_s \cos\Theta$ and $M_s \sin\Theta$, respectively, over the appropriate cross sections of the wire. (μ=6×10^{10} Pa and $\mu_0 M_s$=1.55 T were used for the calculations). It can be seen that except for low torsion the experimental data agree well with the theoretical curves. For σ=0 the remanence rapidly approaches the value 0.71 M_s, expected for helical saturation at 45°. The approach to this limit value is much slower when tensile stress is applied because of the competition between the axial and helical anisotropies induced by stress and torque, respectively. Discrepancies between experimental and calculated behavior for the range of small applied torques should be related to the presence of some closure domains at the surface of the wire. This explanation is supported by the shape of M_z-H_z and M_z-H_ϕ loops in this range of ξ. The loops are curved before the Barkhausen jumps occur. No such anomaly is observed for the circular remanence.

The coercive force is shown in Fig. 3 as a function of square root of torsion. For σ=0 all four coercive fields are nearly equal and follow quite well the linear dependence on $\xi^{1/2}$ in agreement with the previously reported data.[4] With applied axial stress the nature of these dependencies substantially changes. The axial coercive fields H_{czz} and $H_{c\phi z}$ are nearly constant at low applied torsion but above some critical value of ξ they also roughly follow the $\xi^{1/2}$ dependence with higher slope than in case σ=0. The circular coercive fields $H_{cz\phi}$ and $H_{c\phi\phi}$ are large at low ξ, then decrease and show minima at approximately the same critical values of torsion. With further increasing ξ they again roughly follow the dependence obtained for σ=0. The observed behavior of coercive fields can be explained by the model proposed for bistable behavior of as-quenched wires.[5] According to this model the magnetization reversal is caused by depinning of a residual oppositely polarized domain from the end of the wire. When the switching field is achieved the domain wall

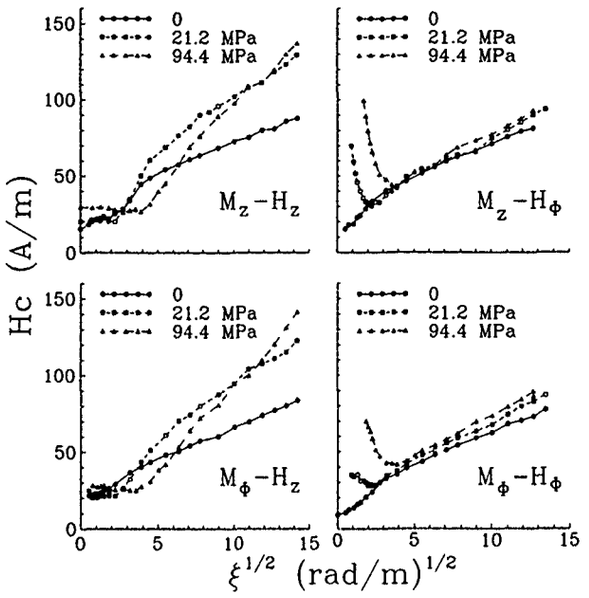

FIG. 3. Coercive fields vs square root of torque.

becomes free and rapidly moves to the opposite end of the wire. It has been shown that in wires with predominantly axial anisotropy the switching field is proportional to domain wall energy γ_w.[6] When the applied magnetic field is not parallel to the easy direction the pressure exerted by the wall is proportional to cos ω, where ω is the angle between magnetization and magnetic field. One can thus introduce a more general equation for the switching field

$$H^* = \alpha \gamma_w / \cos \omega, \tag{4}$$

where α is a parameter accounting for the depinning process. In case of orthorhombic anisotropy the domain wall energy $\gamma_w = 4(AK_{\text{eff}})^{1/2}$ depends on the orientation of the wall.[7] Using Eq. (2) one finds the minimum γ_w for the wall perpendicular to the surface of the wire with

$$K_{\text{eff}} = (3/4)\lambda_s\{\sigma + [\sigma^2 + (2\mu\xi r)^2]^{1/2}\}. \tag{5}$$

Using Eq. (4) for axial (H_z^*) and circular (H_ϕ^*) switching fields one obtains

$$H_z^* = \alpha \gamma_w / \cos \Theta, \quad H_\phi^* = \alpha \gamma_w / \sin \Theta. \tag{6}$$

These formulas cannot be directly applied to the measured coercive fields because at the frequency of 110 Hz, which we have used, there is a large contribution of anomalous eddy current losses to H_c. Some qualitative conclusions, however, can be made.

The local domain wall energy and consequently the local switching fields depend on the distance r from the axis of the wire. It is obvious from Eq. (5) that the depinning of the wall does not take place at $r=0$ because then the switching fields are independent of torque. For zero axial stress one has $\Theta=45°$ and $\gamma_w \propto \xi^{1/2}$ which explains well the linear dependence of H_c on $\xi^{1/2}$. For $\sigma>0$ and low applied torque the helical easy axis is close to the wire axis (Θ is small) and the domain wall energy is predominantly determined by the tensile stress σ. This can explain the nearly constant axial coercive fields at low ξ and the high values of circular coercivities. With increasing torque sin Θ increases and the circular coercive fields decreases. At high levels of torque, where the helical anisotropy dominates, similar behavior to $\sigma=0$ can be expected.

The observation of all four components of the "hysteresis-loop tensor" in the stress-relieved Fe-rich amorphous wire have shown that the bistable switching behavior observed with applied torque and/or tensile stress can be qualitatively explained by a simple model based on the superposition of helical and axial magnetic anisotropies. For the quantitative comparison of experimental data with the model the quasistatic measurements of the switching fields are needed. These experiments are now in progress.

A metastable ternary Nd-Fe-B compound

B. X. Gu, B. G. Shen,[a] and H. R. Zhai
Department of Physics, Nanjing University, Nanjing 210008, China, and CCAST (World Laboratory), P.O. Box 8730, Beijing 100080, China

The metastable compound $Nd_6Fe_{77}B_{17}$ has been obtained by the crystallization from the amorphous phase in the Nd-Fe-B system. Its crystal structure is similar to that of the compound $Nd_2Fe_{23}B_3$. At high temperature this metastable compound decomposes into α-Fe and $Nd_{1.1}Fe_4B_4$ phases. The room temperature magnetization and coercivity are 154 A m^2/kg and 12 kA/m, respectively.

I. INTRODUCTION

Metastable phases have an important influence on the hard magnetic properties of a permanent magnet. The study of the structure, magnetic properties, and stability of metastable phases has attracted attention. However the metastable compounds with a single phase cannot be obtained in the cast alloys. The advent of amorphous alloys offers the possibility of preparing metastable compounds which are not observed in the corresponding phase diagrams. Boschow *et al.*[1] have found the metastable compounds $Nd_2Fe_{23}B_3$, $NdFe_{12}B_6$, and $Y_3Fe_{62}B_{14}$. We reported the structure, magnetic properties, and the stability of metastable compound $Nd_2Fe_{81}B_{16}$.[2,3] These metastable intermetallic compounds are prepared by the crystallization of suitable amorphous alloys at lower temperatures. Recently during the investigation of the crystallization of amorphous $Nd_xFe_{83-x}B_{17}$ alloys we obtained a metastable compound $Nd_6Fe_{77}B_{17}$. Its structure is similar to that of the compound $Nd_2Fe_{23}B_3$. In this article the structure and magnetic properties of the metastable compound $Nd_6Fe_{77}B_{17}$ are reported.

II. EXPERIMENT

The alloys with composition $Nd_6Fe_{77}B_{17}$ were prepared by induction under argon atmosphere using raw material of 99.9% purity. The homogenized alloys were rapidly quenched by ejection from a quartz crucible on to a copper wheel rapidly rotating at a speed of about 37 m/s under argon atmosphere. The samples were annealed in the temperature range of 773 to 1200 K for 10 min in a quartz tube which was evacuated to 7.5×10^{-6} Torr and backfilled with flowing high purity helium evaporated from liquid He. X-ray microanalysis was used to determine the chemical composition of the samples. The structure of as-quenched samples and phase composition of annealed samples were identified by x-ray diffraction with Co $K\alpha$ radiation. Differential thermal analysis (DTA) measurement was performed under an argon atmosphere at a heating rate of 20 K/min. Magnetic properties were measured by vibrating sample magnetometer at a maximum applied magnetic field of 800 kA/m.

III. RESULTS AND DISCUSSION

A. Structure

X-ray diffraction spectra of the as-quenched and annealed $Nd_6Fe_{77}B_{17}$ alloys are shown in Fig. 1. It can be seen that the x-ray diagram of as-quenched samples exhibits a diffused broad maximum. No contribution from the crystalline phases is seen, suggesting the amorphous nature. The x-ray spectrum of the samples annealed at 900 K shows sharp peaks. The observed values of the diffraction angle θ and relative diffraction intensity I of the compound $Nd_6Fe_{77}B_{17}$ are shown in Table I. For comparison the values of θ and I of the compound $Nd_2Fe_{23}B_3$ (Ref. 4) are given in Table I too. It can be seen that the angles and intensities of all diffraction lines are almost in agreement with that of the compound $Nd_2Fe_{23}B_3$. This result shows that the compound $Nd_6Fe_{77}B_{17}$ annealed at 900 K is single phase. It has the same crystal structure as the compound $Nd_2Fe_{23}B_3$. Mooij *et al.*[4] have reported that the crystal structure of the compound $Nd_2Fe_{23}B_3$ is a body-centered cubic and belongs to space group $I\bar{4}3d$. The small difference of the values of the diffraction angles between the compounds $Nd_6Fe_{77}B_{17}$ and $Nd_2Fe_{23}B_3$ shown in Table I may originate from a slight change of the lattice constant due to the difference in the composition.

TABLE I. The observed values of θ and I of the metastable compound $Nd_6Fe_{77}B_{17}$ (Cu $K\alpha$); (s=strong, m=medium, w=weak, v=very).

$Nd_6Fe_{77}B_{17}$		$Nd_2Fe_{23}B_3$ (Ref. 4)	
θ	I	θ	I
16.2	m	16.06	71.3
17.4	m	17.30	27.5
19.7	vs	19.54	121.1
20.7	vs	20.59	155.2
21.7	m	21.60	52.5
22.2	m	22.10	31.9
22 7	s	22.57	109.4
23.6	m	23.57	55.8
26.8	w	26.59	18.1
28.0	m	27.83	33.2

In the x-ray diffraction spectra of the sample annealed at temperatures higher than 1000 K the diffraction peaks of this phase have almost disappeared. Instead the x-ray spectra are composed of the diffraction peaks due to α-Fe and the $Nd_{1.1}Fe_4B_4$ phase. The amount of the $Nd_{1.1}Fe_4B_4$ phase increases with increasing annealing temperature. This result shows that the compound $Nd_6Fe_{77}B_{17}$ is metastable. At high temperature it decomposes into α-Fe and $Nd_{1.1}Fe_4B_4$ phases.

The metastable compound $Nd_6Fe_{77}B_{17}$ has not been obtained in cast alloys of the corresponding composition. It is well known that in the cast alloys crystalline phases have low free energy and thus they are stable. An amorphous alloy is not an equilibrium compound. They have high free energy. Stadelmater *et al.*[5] have shown that diffusion of atoms in alloys of this composition range is slow at annealing temperatures below about 1000 K. Therefore when the amorphous $Nd_6Fe_{77}B_{17}$ alloy is annealed at a temperature below 1000 K, the free energy of the amorphous alloys cannot be rapidly decreased due to the slow diffusion of atoms. So stable crystal compounds are not formed. Amorphous alloys crystallize into the metastable phase. At some higher temperature the metastable compound transforms into the equilibrium phase.

Figure 2 shows the DTA trace of the amorphous $Nd_6Fe_{77}B_{17}$ alloy. Two exotherms are observed. The sharp exothermal peak at 904 K shows the crystallization from the amorphous state into the metastable $Nd_6Fe_{77}B_{17}$ phase. Thus the crystallization temperature of amorphous $Nd_6Fe_{77}B_{17}$ al-

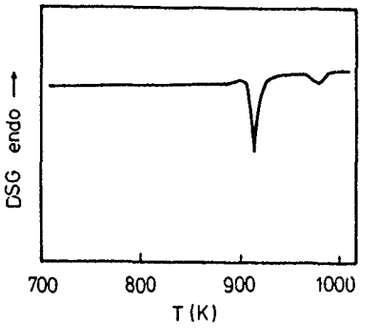

FIG. 2. The DTA trace of the amorphous $Nd_6Fe_{77}B_{17}$ alloy.

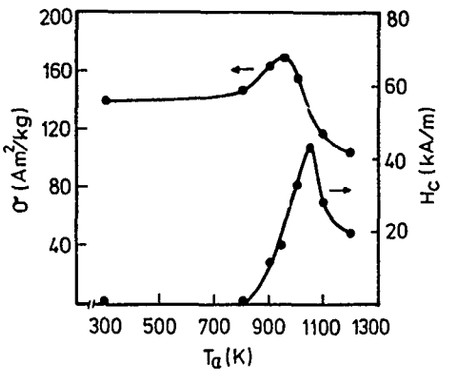

FIG. 3. The room temperature magnetization σ and coercivity Hc as a function of annealing temperature Ta.

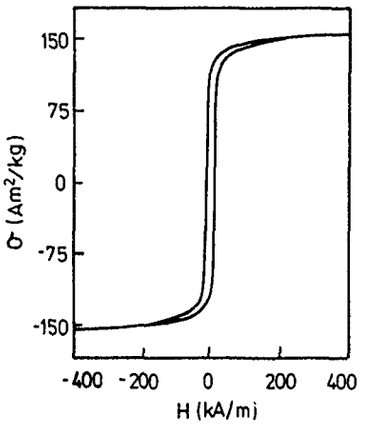

FIG. 4. Hysteresis loop of the 900 K annealed sample.

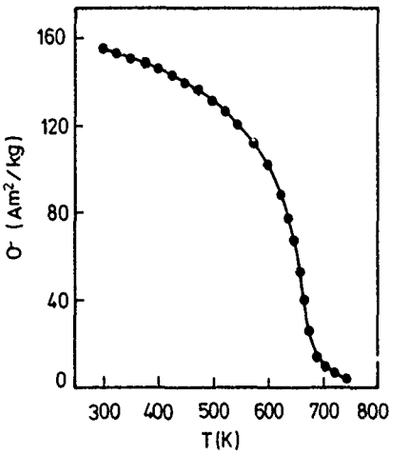

FIG. 5. Temperature dependence of the magnetization of the 900 K annealed sample.

loys is 904 K. The weak exothermal peak at about 970 K originates from the transformation from the metastable phase into the stable phases. This is in agreement with the results of x-ray diffraction.

B. Magnetic properties

Figure 3 shows the dependence of room temperature magnetization and coercivity *Hc* on the annealing temperature *Ta*. When *Ta*<950 K the magnetization increases with increasing annealing temperature. It indicates that the magnetization of the early crystallized metastable phase is larger than that of amorphous alloys. When *Ta*>950 K the magnetization decreases with increasing *Ta*. It originates from the increase of the content of the paramagnetic phase $Nd_{1.1}Fe_4B_4$ which is obtained by the decomposition of the metastable phase. The coercivity of the $Nd_6Fe_{77}B_{17}$ alloy increases with increasing annealing temperature, goes to a maximum of 44 kA/m at 1050 K, and then decreases. The room temperature magnetization and coercivity of the metastable compound $Nd_6Fe_{77}B_{17}$ are 154 A m^2/kg and 12 kA/m.

The hysteresis loop and thermomagnetic curve of the 900 K annealed sample measured at a magnetic field of 800 kA/m are shown in Figs. 4 and 5, respectively. As seen in the two figures, the magnetization changes monotonously. No kink is observed. These results show that there is only a single magnetic phase in the 900 K annealed sample. It is in agreement with the result of x-ray diffraction analysis. This confirms further that the metastable compound $Nd_6Fe_{77}B_{17}$ obtained by annealing at 900 K is single phase.

Helical anisotropy and Matteucci effect in Co-Si-B amorphous wires with negative magnetostriction (abstract)

J. Yamasaki and M. Takajo
Department of Electrical Engineering, Kyushu Institute of Technology, Tobata, Kitakyushu 804, Japan

F. B. Humphrey
Department of ECS, Boston University, 44 Cummington Street, Massachusetts 02215

The Co-Si-B amorphous wires having the negative magnetostriction comprises shell and core domains and exhibits the re-entrant flux reversal as the Fe-Si-B wire with positive magnetostriction.[1] One of the characteristic features of Co based wires is that a sharp pulse voltage generation between two wire ends (Matteucci effect) is accompanied with re-entrant flux reversal,[2] which is useful for sensor application because of no need for sense windings. In this work, we studied the origin of the large Matteucci effect of Co-Si-B wires by domain observation with a Kerr microscope and by Sixtus–Tonks experiments by driving the reverse domain propagation with the circular fields generated by the current through wires. We also tried to measure the hysteresis loop in the circular direction by integrating the Matteucci voltage. It was found that the domain patterns of the Co-Si-B wire surface is not the previously reported bamboo configuration[1] but the helical configuration. Most of the anisotropy of the amorphous materials is magnetostrictive in origin. The helical anisotropy of Co based wire seems consistent, if we assume the same residual stress distribution as in the steel rod quenched into the water.[3] Because of the helical anisotropy, the Co wire has the big circular component of magnetization in the core domain as well as in the shell domain, and both domain can interact near the interface region. It was found that reverse domain propagation along the wire axis can be caused by application of the circular field and that the shell domain moves discontinuously during the re-entrant flux reversal in the core domain. These circular magnetization components in both core and shell domains due to helical anisotropy and their interaction seems responsible for the large Matteucci effect in the Co-Si-B wires.

The rf permeability of dc planar magnetron sputtered FeNi multilayer films (abstract)

Craig A. Grimes and Catherine C. Ballantyne
Southwall Technologies, 1029 Corporation Way, Palo Alto, California 94303

Recording heads are commonly built in a multilayer stack to eliminate or reduce domain walls by allowing flux closure, or magnetostatic coupling, between the magnetic layers across nonmagnetic spacers. Use of an electrically insulating spacer material will reduce eddy current shielding increasing the high frequency performance of the head. As magnetic recording systems continue their trend to higher operating frequencies knowledge of the rf permeability of head-like multilayer materials becomes quite important. We examine the complex, rf permeability spectra of dc planar magnetron sputtered FeNi multilayer films as a function of spacer material, number of layers, and thickness of the spacer and magnetic layer. The permeability spectra are measured using a permeameter[1] over the frequency range 3–300 MHz. The spacer materials examined include several metals and metal alloys, the corresponding oxides, silicon, and silicon nitride. The magnetic layer is, by weight, 81.8% Ni and 18.2% Fe. We have found that for a constant magnetic layer thickness, as the nonmagnetic spacer thickness decreases from 30 to 10 nm the permeability magnitude of the multilayer stack increases and the resonance frequency shifts to lower values. As the spacer thickness increases above 30 nm the permeability response remains constant with a negligible value of μ''. The permeability spectra are approximately the same for spacer layers made of metal or their corresponding oxides. Spacer layers made of Si_3N_4 result in permeability spectra with the highest permeability magnitudes. For example, the permeability magnitude of a multilayer stack composed of four 120 nm FeNi layers separated by 10 nm spacers is approximately 2000 for metal spacers, 2300 for Si spacers, and 4200 for Si_3N_4 spacers. For a fixed number of multilayer pairs and constant spacer layer thickness making the FeNi layer thicker tends to increase the permeability magnitude, reduce the resonance frequency, and lower the low frequency coercive force.

Phase transitions in the one-dimensional frustrated quantum *XY* model and Josephson-junction ladders

Enzo Granato
Laboratório Associado de Sensores e Materiais, Instituto Nacional de Pesquisas Espaciais, 12225 São José dos Campos, São Paulo, Brazil

A one-dimensional quantum version of the frustrated *XY* (planar rotor) model is considered which can be physically realized as a ladder of Josephson junctions at half a flux quantum per plaquette. This system undergoes a superconductor to insulator transition at zero temperature as a function of charging energy. The critical behavior is studied using a Monte Carlo transfer matrix applied to the path-integral representation of the model and a finite-size-scaling analysis of data on small system sizes. Depending on the ratio between the interchain and intrachain couplings the system can have single or double transitions which is consistent with the prediction that its critical behavior should be described by the two-dimensional classical *XY*-Ising model.

The two-dimensional frustrated classical *XY* model has attracted considerable attention recently.[1–8] It can be related to Josephson-junction arrays in a magnetic field, where it is expected to describe the finite-temperature superconductor to normal transition in arrays with half a flux quantum per plaquette.[9] At low temperatures where capacitive effects dominate, the array undergoes a superconductor to insulator transition as a function of charging energy.[10–13] These charging effects arise from the small capacitance of the grains making up the array and leads to strong quantum fluctuations of the phase of the superconducting order parameter. The critical behavior is now described by a two-dimensional frustrated quantum *XY* model with a Hamiltonian[12]

$$H=-\frac{E_c}{2}\sum_r\left(\frac{d}{d\theta_r}\right)^2-\sum_{\langle rr'\rangle}E_{rr'}\cos(\theta_r-\theta_{r'})\,. \qquad (1)$$

The first term in Eq. (1) describes quantum fluctuations induced by the charging energy $E_c=4e^2/C$ of a non-neutral superconducting grain located at site r, where e is the electronic charge and C is the effective capacitance of the grain. The second term is the usual Josephson-junction coupling between nearest-neighbor grains. θ_r represents the phase of the superconducting order parameter and the couplings $E_{rr'}$ satisfy the Villain's "odd rule" in which the number of negative bonds in an elementary cell is odd.[14] In a square lattice this can be satisfied, for example, by ferromagnetic horizontal rows and alternating ferromagnetic and antiferromagnetic columns of bonds. This rule is a direct consequence of the constraint that, for the half-flux case, the line integral of the vector potential due to the applied magnetic field should be equal to π in units of the flux quantum.

In this work we consider a one-dimensional frustrated quantum *XY* (1D FQ*XY*) model[15] which can be regarded as the simplest 1D version of the model (1) consisting just of a single column of frustrated plaquettes as indicated in Fig. 1. This can be physically realized as a periodic Josephson-junction ladder at half a flux quantum per plaquette.[16,17] In the classical limit ($E_c=0$), the ground state of the 1D FQ*XY* model has a discrete Z_2 symmetry associated with an antiferromagnetic pattern of plaquette chiralities $\chi_p=\pm1$, as indicated in Fig. 1, measuring the two opposite directions of the supercurrent circulating in each plaquette. For small E_c, there is a gap for creation of kinks in the antiferromagnetic pattern of χ_p, and the ground state has long-range chiral order.

Within a path-integral approach,[16] it can be shown that the effective action describing quantum fluctuations in the

1D FQXY model leads to two coupled XY models in two (space-time) dimensions which is expected to have a critical behavior in the universality class of the 2D XY-Ising model[18] defined by the classical Hamiltonian

$$\beta H=-\sum_{\langle rr'\rangle}[A(1+\sigma_r\sigma_{r'}\cos(\theta_r-\theta_{r'})+C\sigma_r\sigma_{r'})]\ . \tag{2}$$

The phase diagram of this model consists of three branches, in the ferromagnetic region. One of them corresponds to single transitions with simultaneous loss of XY and Ising order. Further away from the branch point, this line of single transitions becomes first order. The other two lines correspond to separate XY and Ising transitions. The 1D FQXY model is represented by a particular path through this phase diagram which will depend on the ratio E_x/E_y between the interchain and intrachain couplings of the model. In this work we describe the results of a finite-size scaling analysis of extensive calculations on the 1D FQXY model[15,19] which shows that, in fact, the XY and Ising-like excitations of the quantum model decouple for large interchain couplings, giving rise to pure Ising model critical behavior for the chirality order parameter. As a consequence, the universality class of the superconductor–insulator transition in the related Josephson-junction ladder should then depend on the ratio between interchain and intrachain Josephson couplings.

To study the critical behavior of the 1D FQXY model, we find it convenient to use an imaginary-time path-integral formulation of the model.[20] In this formulation, the one-dimensional quantum problem maps into a 2D classical statistical mechanics problem where the ground state energy of the quantum model of finite size L corresponds to the reduced free energy per unit length of the classical model defined on an infinite strip of width L along the imaginary time direction, where the time axis τ is discretized in slices $\Delta\tau$. After scaling the time slices appropriately in order to get a space-time isotropic model one obtains a classical partition function where the parameter $\alpha=(E_y/E_c)^{1/2}$ plays the role of an inverse temperature in the 2D classical model. The scaling behavior of the energy gap for kink excitations (chiral domain walls) of the 1D FQXY corresponds to the interface free energy of an infinite strip in this classical model. For large α (small charging energy E_c), there is a gap for creation of kinks in the antiferromagnetic pattern of χ_p and the ground state has long-range chiral order. At some critical value of α, chiral order is destroyed by kink excitations, with an energy gap vanishing as $|\alpha-\alpha_c|^{\nu}$, which defines the correlation length exponent ν. Right at this critical point, the correlation function decays as a power law $\langle\chi_p\chi_{p'}\rangle=|p-p'|^{-\eta}$ with a critical exponent η. The free energy per unit length $f(\alpha)$ of the Hamiltonian on the infinite strip can be obtained from the largest eigenvalue λ_0 of the transfer matrix between different time slices as $f=-\ln\lambda_0$. To obtain λ_0, we used a Monte Carlo transfer-matrix method[21] which has been shown to lead to accurate estimates of the largest eigenvalue even for models with continuous symmetry. The implementation of this method is similar to the case of the 2D frustrated classical XY model[8] and further details can be found in that work.

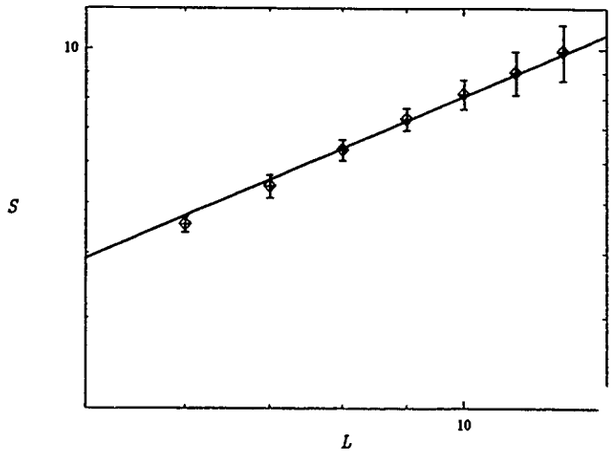

FIG. 2. $S=\partial\Delta F(\alpha,L)/\partial\alpha$ evaluated near the critical coupling α_c. The slope of the straight line gives an estimate of $1/\nu$.

The interfacial free energy for domain walls can be obtained from the differences between the free energies for the infinite strip with and without a wall. To obtain the critical exponents and critical coupling we employ the finite-size scaling $\Delta F(\alpha,L)=A(L^{1/\nu}\delta\alpha)$ where A is a scaling function and $\delta\alpha=\alpha-\alpha_c$. In a linear approximation for the argument of A, we have

$$\Delta F(\alpha,L)=a+bL^{1/\nu}\delta\alpha \tag{3}$$

which can be used to determine the critical coupling α_c and the exponent ν independently.[16] The change from an increasing trend with L to a decreasing trend provides and estimate of α_c. Once the critical coupling is known, the correlation function exponent η can be obtained from the universal amplitude a in Eq. (3) through a result from conformal invariance,[22] $a=\pi\eta$. To estimate the correlation length exponent ν we first obtain the derivative $S=\partial\Delta F/\partial\alpha$ near α_c, then it can easily be seen that a log–log plot of S vs L gives an estimate of $1/\nu$ without requiring a precise determination of α_c. In Fig. 2 we show this kind of plot for $E_x/E_y=3$ from where we get the estimate $\nu=1.05(6)$. Of course, this is only valid in the linear approximation of Eq. (3). To ensure that higher-order terms can safely be neglected, the data for $\Delta F(\alpha,L)$ must be obtained in a sufficiently small range near α_c. We also checked, using a more general finite-size scaling analysis,[8] that allowing for higher-order terms gives results agreeing within the errors. The results for the critical coupling α_c and critical exponents ν and η for two different values of the ratio $E_x/E_y=1$ and 3 are indicated in Table I.

For equal couplings $E_x=E_y$, the results for the critical exponents η and ν differ significantly from pure 2D Ising

TABLE I. Critical couplings $[\alpha_c=(E_y/E_c)^{1/2}]$ and critical exponents (ν,η), obtained from finite-size scaling analysis of interfacial free energies for two values of the ratio between interchain and intrachain couplings (E_x/E_y).

E_x/E_y	α_c	ν	η
1	1.04(1)	0.81(4)	0.47(4)
3	1.16(2)	1.05(6)	0.27(3)

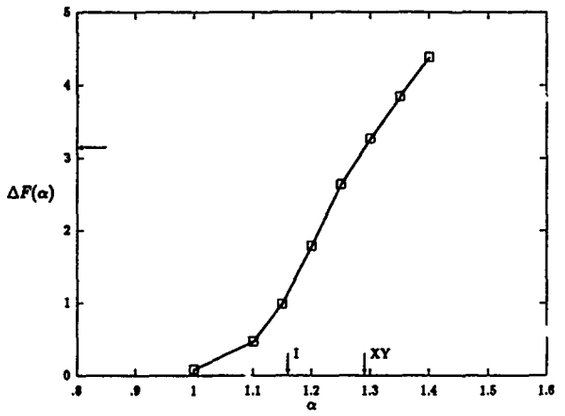

FIG. 3. Behavior of the interfacial free energy $\Delta F = L^2 \Delta f$ for a system of size $L=12$ resulting from an imposed phase twist of π. Vertical arrows indicate the locations of the Ising and XY transitions and the horizontal arrow the value $\Delta F = \pi$ from where the XY transition is located.

exponents ($\nu=1$, $\eta=0.25$). This result points to a single transition scenario. In fact, they are consistent with a point along the line of single transitions in the XY-Ising model.[18] It is interesting to note that this result is also consistent with similar calculations for the 2D frustrated classical XY model.[8] In general, the critical behavior of a d dimensional quantum model is in the same universality class of the $d+1$ dimensional classical version. However, the 1D FQXY model, apparently, is not the Hamiltonian limit of the 2D classical model. Yet, their critical behavior appears to be in the same universality class.

For the case of unequal couplings $E_x/E_y=3$, the results indicated in Table I are in good agreement with pure 2D Ising values. From the relation between the 1D FQXY model and the 2D XY-Ising model this then implies that the XY and Ising-like excitations have decouple in this region of parameters. To show that in fact one has two decoupled and, at the same time, separated transitions we show in Fig. 3 the results for the helicity modulus which measures the response of the system to an imposed twist. The helicity modulus is related to the free-energy differences ΔF between strips with and without any additional phase mismatch of π along the strip and is given by $\gamma = 2\Delta F/\pi^2$ for large system sizes. If the model is decoupled then the transition should be in the universality class of the 2D classical XY model, where one knows that the transition is associated with a universal jump of $2/\pi$ in the helicity modulus.[23] The critical coupling can be estimated as the value of α at which $\Delta F = \pi$ which gives $\alpha_c = 1.29$. This is to be compared with the critical coupling for the destruction of chiral order in Table I, $\alpha_c = 1.16$. This clearly indicates the transitions are well separated and thus one expects they are decoupled. We have also performed less detailed calculations at other values of the ratio E_x/E_y from which we can estimate that the Ising and XY transitions merge into a single transition roughly at $E_x/E_y \sim 2$. Since, the superconductor to insulator transition is to be identified with the loss of phase coherence[24] we reach the interesting result that in the 1D FQXY, or alternatively, a Josephson-junction ladder, the universality class of the superconductor–insulator transition depends on the ratio between inter- and intrachain couplings.

Penetration of circularly polarized electromagnetic fields into superconductors with gradual resistive transitions

I. D. Mayergoyz
Electrical Engineering Department and Institute for Advanced Computer Studies, University of Maryland, College Park, Maryland 20742

Critical state-type models of superconducting hysteresis are based on analytical study of penetration of electromagnetic fields into hard superconductors. This study has been carried out under the assumption of ideal (sharp) resistive transition. In the paper, the attempt is made to study the penetration of electromagnetic fields into hard superconductors for gradual resistive transitions described by the "power law." This requires the solution of nonlinear partial differential equations. It is shown that the exact analytical solution can be found in the case of circular polarization of electromagnetic fields due to the high degree of symmetry of the posed problem. In the limiting case of sharp transition, the obtained solutions are reduced to the solution previously asserted by Bean.

Models of superconducting hysteresis are based on analytical study of penetration of electromagnetic fields into hard superconductors. In critical state-type models,[1–3] this study has been carried out under the assumption of ideal (sharp) resistive transition. However, actual resistive transitions are gradual and they are usually described by the following "power law"

$$E=(j/k)^n, \quad (n>1), \tag{1}$$

where E is an electric field, j is a current density, and k is the parameter which coordinates the dimensions of both sides of Eq. (1).

The exponent "n" is a measure of the sharpness of the resistive transition and it may vary in the range 4–1000. At first, the power law was regarded only as a reasonable empirical description of the resistive transition. However, recently there has been a considerable research effort focused on the theoretical justification of power law (1). As a result, models based on flux creep,[4] Josephson-junction coupling between grains,[5] sausaging,[6] and spatial distribution of critical current[7] have been proposed. In the paper, power law (1) is used as a constitutive equation for superconductors. By using this equation, the penetration of electromagnetic fields into superconductors with gradual resistive transition is analytically investigated. This investigation requires the solution of nonlinear partial differential equations of parabolic type. It is shown below that the exact analytical solutions can be found in the case of circular polarization of electromagnetic fields due to the high degree of symmetry of the problem under consideration. In the limiting case of sharp (ideal) transition, these solutions are reduced to those previously asserted by Bean.[8] The discussion presented below closely parallels the analytical technique developed for the calculation of eddy currents in magnetically nonlinear media.[9]

To start the discussion, consider a plane circularly polarized electromagnetic wave penetrating superconducting half-space $z>0$ (see Fig. 1). This implies the following boundary conditions:

$$E_x(0,t)=E_m\cos(\omega t+\varphi), \quad E_y(0,t)=E_m\sin(\omega t+\varphi), \tag{2}$$

$$E_x(\infty,t)=E_y(\infty,t)=0. \tag{3}$$

The distribution of electric field $\mathbf{E}$ in half-space $z>0$ is governed by the equations

$$\frac{\partial^2 E_x}{\partial z^2}=\mu_0\frac{\partial}{\partial t}\left[\sigma\left(\sqrt{E_x^2+E_y^2}\right)E_x\right], \tag{4}$$

$$\frac{\partial^2 E_y}{\partial z^2}=\mu_0\frac{\partial}{\partial t}\left[\sigma\left(\sqrt{E_x^2+E_y^2}\right)E_y\right], \tag{5}$$

where according to (1)

$$\sigma\left(\sqrt{E_x^2+E_y^2}\right)=\sigma(E)=kE^{1/n-1}. \tag{6}$$

We next prove that the electromagnetic field is circularly polarized everywhere in the superconducting half space. Indeed, by assuming that the solution of the boundary value problem (2)–(5) is in the form

$$E_x(z,t)=E(z)\cos[\omega t+\theta(z)], \tag{7}$$

$$E_y(z,t)=E(z)\sin[\omega t+\theta(z)], \tag{8}$$

and by introducing the phasors

$$\mathscr{E}_x(z)=E(z)e^{i\theta(z)}, \quad \mathscr{E}_y(z)=-iE(z)e^{i\theta(z)}, \tag{9}$$

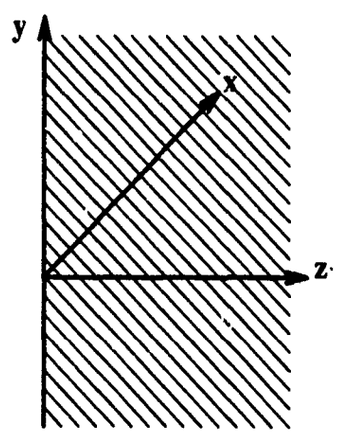

FIG. 1. Superconducting half-space.

 0021-8979/94/75(10)/6963/3/$6.00 © 1994 American Institute of Physics

we can exactly transform the above boundary value problem into two decoupled and mathematically identical boundary value problems for ordinary differential equations with respect to phasors $\mathscr{E}_x(z)$ and $\mathscr{E}_y(z)$:

$$\frac{d^2\mathscr{E}_x(z)}{dz^2}=i\omega\mu_0\sigma(|\mathscr{E}_x(z)|)\mathscr{E}_x(z), \tag{10}$$

$$\mathscr{E}_x(0)=\mathscr{E}_m, \quad \mathscr{E}_x(\infty)=0, \tag{11}$$

and

$$\frac{d^2\mathscr{E}_y(z)}{dz^2}=i\omega\mu_0(|\mathscr{E}_y(z)|)\mathscr{E}_y(z), \tag{12}$$

$$\mathscr{E}_y(0)=-i\mathscr{E}_m, \quad \mathscr{E}_y(\infty)=0, \tag{13}$$

where $\mathscr{E}_m=E_m e^{i\varphi}$.

The above exact transformation is possible because in the case of the circularly polarized electromagnetic fields $E=\sqrt{E_x^2+E_y^2}$ and $\sigma(E)=\sigma(\sqrt{E_x^2+E_y^2})$ do not change with time. Such an exact transformation can be construed as a mathematical proof that the circular polarization is preserved everywhere within the superconducting medium. As a result, there are no higher order harmonics of the electromagnetic field anywhere within the medium despite its nonlinear properties. This fact can be easily understood on the physical grounds if we take into account the circular symmetry of the posed problem.

From (6) and (9) we derive

$$\sigma(|\mathscr{E}_x(z)|)=\sigma(|\mathscr{E}_y(z)|)=\sigma_m\left|\frac{\mathscr{E}_x(z)}{\mathscr{E}_m}\right|^{1/n-1}=\sigma_m\left|\frac{\mathscr{E}_y(z)}{\mathscr{E}_m}\right|^{1/n-1}, \tag{14}$$

where $\sigma_m=kE_m^{1/n-1}$ is the value of σ on the boundary. By using (14) in (10), we find

$$\frac{d^2\mathscr{E}_x(z)}{dz^2}=i\omega\mu_0\sigma_m\left|\frac{\mathscr{E}_x(z)}{\mathscr{E}_m}\right|^{1/n-1}\mathscr{E}_x(z). \tag{15}$$

We shall employ the following trick to solve Eq. (15). Consider the equation

$$\frac{d^2\mathscr{E}_x(z)}{dz^2}=i\omega\mu_0\sigma_m\left(1-\frac{z}{z_0}\right)^{-2}\mathscr{E}_x(z), \tag{16}$$

where z_0 is a parameter which will be chosen later in such a way that the solution of Eq. (16) will also be the solution of Eq. (15). The solution of Eq. (16) which satisfies the boundary conditions (11) is given by

$$\mathscr{E}_x(z)=\mathscr{E}_m\left(1-\frac{z}{z_0}\right)^{\alpha}, \tag{17}$$

where $\alpha=\alpha'+i\alpha''$ is a root of the characteristic equation

$$\alpha(\alpha-1)=i\omega\mu_0\sigma_m z_0^2. \tag{18}$$

From (17) we find

$$\left|\frac{\mathscr{E}_x(z)}{\mathscr{E}_m}\right|=\left(1-\frac{z}{z_0}\right)^{\alpha'}, \quad (\alpha'=\mathrm{Re}\ \alpha). \tag{19}$$

This leads to

$$\left(1-\frac{z}{z_0}\right)^{-2}=\left|\frac{\mathscr{E}_x(z)}{\mathscr{E}_m}\right|^{-2/\alpha'} \tag{20}$$

Now, it is evident that the solution (17) to Eq. (16) will be also the solution to Eq. (15), if

$$\alpha'=\frac{2n}{n-1}. \tag{21}$$

Next, we represent characteristic Eq. (18) as two equations (for real and imaginary parts, respectively)

$$\alpha'(\alpha'-1)-(\alpha'')^2=0 \tag{22}$$

$$\alpha''(2\alpha'-1)=\omega\mu_0\sigma_m z_0^2. \tag{23}$$

By substituting (21) into (22), we find

$$\alpha''=\frac{\sqrt{2n(n+1)}}{n-1}, \tag{24}$$

which then, according to (23), leads to

$$z_0=\frac{\sqrt[4]{2n(n+1)(3n+1)^2}}{\sqrt{\omega\mu_0\sigma_m}\,(n-1)}. \tag{25}$$

Formulas (17), (21), (24), and (25) completely define the solution of the boundary value problem (10), (11). The solution of the boundary value problem (12), (13) has a similar form:

$$\mathscr{E}_y(z)=-i\mathscr{E}_m\left(1-\frac{z}{z_0}\right)^{\alpha}. \tag{26}$$

By using equations

$$\frac{d\mathscr{E}_x}{dz}=-i\omega\mu_0\mathscr{H}_y, \quad \frac{d\mathscr{E}_y}{dz}=i\omega\mu_0\mathscr{H}_x, \tag{27}$$

from (17) and (26) we derive

$$\mathscr{H}_x(z)=\mathscr{H}_m\left(1-\frac{z}{z_0}\right)^{\alpha-1}, \quad \mathscr{H}_y(z)=i\mathscr{H}_m\left(1-\frac{z}{z_0}\right)^{\alpha-1}, \tag{28}$$

where

$$\mathscr{H}_m=\mathscr{H}_x(0)=\frac{\alpha}{\omega\mu_0 z_0}\mathscr{E}_m. \tag{29}$$

Since z_0 depends on σ_m [see Eq. (25)] and $\sigma_m=k|\mathscr{E}_m|^{1/n-1}$, expression (29) can be construed as nonlinear impedance boundary condition for circularly polarized waves. This nonlinear relationship can also be used to determine $\mathscr{E}_m$ when $\mathscr{H}_m$ is given. For this reason, we can always choose such $\mathscr{E}_m$ that $\mathscr{H}_m=H_0$ is real. Then from (28), (21), and (24) we derive

$$H_x(z,t)=H_0\left(1-\frac{z}{z_0}\right)^{(n+1)/(n-1)}\cos\left[\omega t+\frac{\sqrt{2n(n+1)}}{n-1}\ln\left(1-\frac{z}{z_0}\right)\right], \tag{30}$$

$$H_y(z,t)$$

$$=H_0\left(1-\frac{z}{z_0}\right)^{(n+1)/(n-1)}\sin\left[\omega t+\frac{\sqrt{2n(n+1)}}{n-1}\ln\left(1-\frac{z}{z_0}\right)\right]. \tag{31}$$

Next, we shall show that, in the limiting case of sharp transition ($n=\infty$), the above expressions are reduced to those which were asserted (rather than derived) by Bean.[8] To this end, from (29) we find the following expression for the peak value j_0 of superconducting current on the boundary $z=0$:

$$j_0=\frac{\omega\mu_0\sigma_m z_0}{|\alpha|}H_0. \tag{32}$$

By substituting (25) into (32), we obtain

$$\sqrt{\omega\mu_0\sigma_m}=\frac{|\alpha|(n-1)}{\sqrt[4]{2n(3n+1)^2(n+1)}}\frac{j_0}{H_0}. \tag{33}$$

By substituting (33) back into (25), we arrive at the expression

$$z_0=\frac{(3n+1)\sqrt{2n(n+1)}}{(n-1)^2|\alpha|}\frac{H_0}{j_0}. \tag{34}$$

It is well known that

$$\delta=\frac{H_0}{j_0} \tag{35}$$

is the field-dependent penetration depth is the case of ideal resistive transition and linearly polarized electromagnetic field. It is also clear that

$$\lim_{n\uparrow\infty}\frac{(3n+1)\sqrt{2n(n+1)}}{(n-1)^2}=3\sqrt{2},\quad \lim_{n\uparrow\infty}|\alpha|=\sqrt{6}. \tag{36}$$

From (34), (35), and (36), we find

$$\lim_{n\uparrow\infty} z_0=\sqrt{3}\delta. \tag{37}$$

By using (37), we find that, in the limiting case of $n\to\infty$, expressions (30) and (31) can be written as follows:

$$H_x(z,t)=H_0\left(1-\frac{z}{\sqrt{3}\delta}\right)\cos\left[\omega t+\sqrt{2}\ln\left(1-\frac{z}{\sqrt{3}\delta}\right)\right]. \tag{38}$$

$$H_y(z,t)=H_0\left(1-\frac{z}{\sqrt{3}\delta}\right)\sin\left[\omega t+\sqrt{2}\ln\left(1-\frac{z}{\sqrt{3}\delta}\right)\right]. \tag{39}$$

The last expressions are identical to those published in Ref. 8.

Magnetic shielding from alternating magnetic field by NbTi/Nb/Cu superconducting multilayer composite cylinder

Hiroaki Otsuka and Ikuo Itoh
Advanced Materials & Technology Research Laboratories, Nippon Steel Corporation, 1618 Ida, Nakahara-ku, Kawasaki 211, Japan

Magnetic shielding from alternating magnetic field by a NbTi/Nb/Cu superconducting multilayer composite cylinder was investigated at liquid-helium temperatures. The specimen employed in this study was a slender seamless cylinder about 15 mm in diameter and having an aspect ratio of 6. The frequency of the alternating magnetic field was in the range of 40–500 Hz, and the maximum amplitude was 1000 G rms at 40 and 50 Hz owing to the capacity of the ac generator. The magnetic shielding efficiency of the cylinder, defined as the ratio of the magnetic field strength with and without the cylinder, was found to be of the order of 10^{-4}. It was also found that the magnetic shielding effect depends upon the frequency investigated in this study. These shielding effects were mainly due to the shielding current originating from the superconductivity, which turned out to give superior shielding effect than that of a Cu cylinder.

I. INTRODUCTION

In our previous paper,[1] we reported that dc magnetic field as strong as 3 T can be effectively shielded by a NbTi/Nb/Cu superconducting multilayer composite cylinder. This shielding material has an advantage of shielding higher magnetic field and having a lower ac loss because of its cryogenic stabilization due to its multilayer structure in comparison with the conventional one made of only superconductor.

In this paper, we report the ac magnetic shielding properties of this multilayer composite cylinder, since the ac component of the applied magnetic field plays an important role in real applications such as magnetic levitation (Maglev). Many investigators reported the ac shielding of only weak magnetic field mainly for superconducting quantum interference device (SQUID), system.[2,3] However, only a few reports are available for strong ac magnetic field shielding.[4] In a Maglev system it is essential to protect the superconducting coil from the ac magnetic field originating from the propulsion coil. The strength of this magnetic field is about several hundred gauss and the frequency is in the range of 50–400 Hz. Taking this application into consideration, we investigated the basic ac magnetic shielding property using our superconducting multilayer composite cylinder.

II. EXPERIMENT

The NbTi/Nb/Cu superconducting multilayer composite cylinder was fabricated by the following processes. First, 30 NbTi sheets and 29 Cu sheets were alternately stacked and were interleaved with Nb sheets in a box made of Cu, and the box was sealed by electron beam welding in a vacuum. Next, the box was hot rolled and subsequently cold rolled to a sheet of 1 mm in thickness. The Nb layers prevent the generation of an intermetallic compound comprising Cu and Ti while the box is hot rolled.[5] This intermetallic compound has an influence on workability of cold rolling. Welding cannot be used for fabricating the cylinder since the weld would impair the shielding properties of the cylinder. In order to overcome the above difficulty, a deep-drawing process and a spinning process were employed in this study, and a seamless slender cylinder was successfully fabricated as shown in Fig. 1. The cylinder was 15.3 mm in inside diameter, 90.0 mm in length, and 0.5 mm in wall thickness. The magnetic shielding property of Cu (purity was 99.9%) cylinder manufactured by the same method was also measured as a reference and was compared with that of NbTi/Nb/Cu.

The solenoid coil to generate ac magnetic field was made of an NbTi multiple wire, and was 25.0 mm in average diameter and 72.0 mm in length. The above coil was wound on to a fiber reinforced plastic cylinder, which also served as a sample holder. The experimental arrangement is shown in Fig. 2. The cross marks indicate the positions of the magnetic field measured by the search coil, and 0, ±13, ±23, ±31, and ±39 mm distances from the axial center of the cylinder, respectively. The number of turns of wire for the solenoid coil was 484 and that of the search coil was 94. The source of magnet current was an ac voltage and current standard (YEW, type 2558). A digital multimeter (Takeda Riken TR6861) was used to measure the voltage generated by the

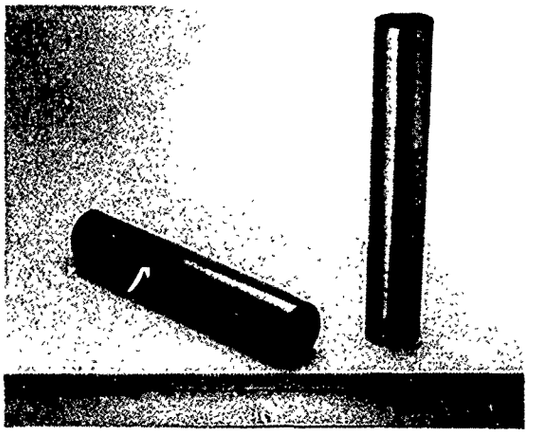

FIG. 1. The NbTi/Nb/Cu cylinder and cup fabricated by a deep-drawing and a spinning method. They are 0.5 mm in thickness, 15.3 mm in inside diameter, and 90.0 mm in length.

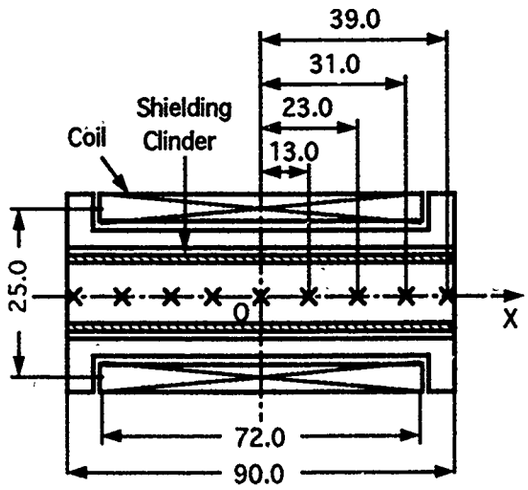

FIG. 2. Sample holder and solenoid coil generating ac magnetic field. The cross marks are the points of measurement.

search coil. The maximum amplitudes and frequencies of the applied ac magnetic field were 1000 G rms at 40 and 50 Hz, 600 G rms at 100 Hz, 200 G rms at 300 Hz, and 150 G rms at 500 Hz. The maximum amplitude, which depends upon the frequency, is limited due to the capacity of the ac generator used in this study. The precision of the voltage measurement was ±0.001 mV, which is accurate enough for this study and the contribution from the thermal noise could be completely ignored.[6]

III. RESULT AND DISCUSSION

A. Structure of the stacked layers

Figure 3 shows the cross section of the middle part of the cylinder in the length direction. Cu layers can be seen as white and NbTi layers as black. The thickness of both layers is about 5 mm. Nb layers cannot be seen in this figure as the thickness is so thin. From this figure it can be seen that both layers are almost straight, indicating that the process of working was successful.

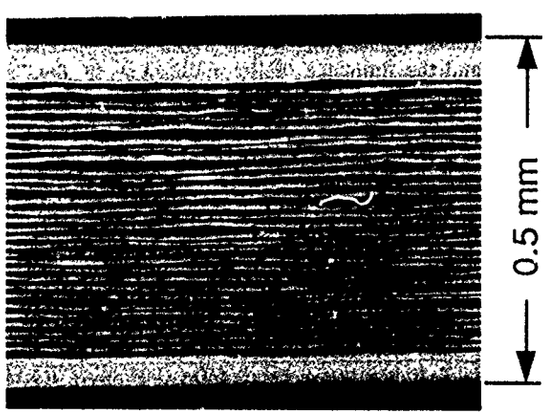

FIG. 3. Cross section of middle part of NbTi/Nb/Cu cylinder in length direction.

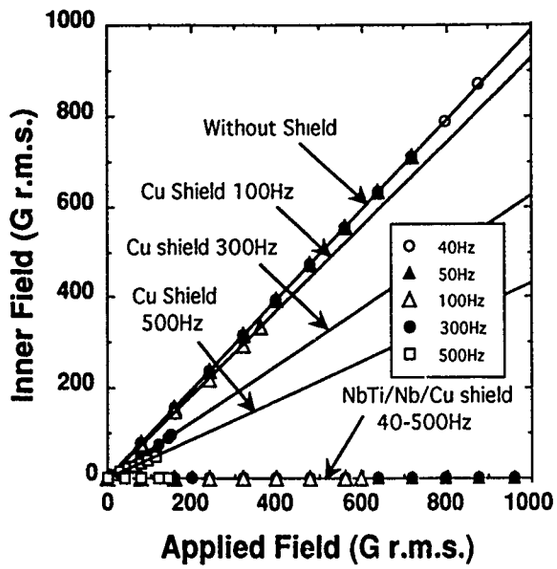

FIG. 4. Shielding properties of NbTi/Nb/Cu cylinder, Cu cylinder, and without shielding.

B. Measurement of magnetic field by the search coil

First, the ac magnetic field without shielding cylinders was measured at liquid-helium temperature (4.2 K) by the search coil. The inner magnetic field was estimated by the voltage of the search coil according to Faraday's law of induction. In the range of frequency from 40 to 500 Hz, an agreement within 1% was obtained between the calculated values and the measured ones.

C. Basic property

The shielding property of the NbTi/Nb/Cu cylinder 90 mm in length at its axial center is shown in Fig. 4. The inner magnetic fields of the cylinder are plotted as a function of the applied magnetic fields in this figure. They are also plotted in the cases with shielding cylinder and with Cu one. The lines through the Cu data were fitted by the method of the least squares. It is known that Cu shows a shielding effect against ac magnetic field due to an eddy current. However, from Fig. 4 it was observed that the Cu cylinder shows only 8% reduction at 100 Hz and 50% at 500 Hz. From these shielding effects of Cu, it can be said that the Cu cylinder cannot be used at the relatively low-frequency range such as considered in this study.

The inner magnetic field was carefully checked to evaluate the precise shielding efficiency. In Fig. 5, the scale of the inner field is more magnified than that in Fig. 4. It can be clearly seen that the inner field is less than 0.1 G until the applied field reaches about 1000 G rms. The inner field increases with increasing applied field. There is a frequency dependence of the alternating magnetic shielding. The inner magnetic field increases with applied field more steeply at higher frequencies. According to Thomasson and Ginsberg[7] the increase of inner magnetic field accompanying the increase of the applied uniform dc magnetic field takes place because of the leakage of field from both open ends of the

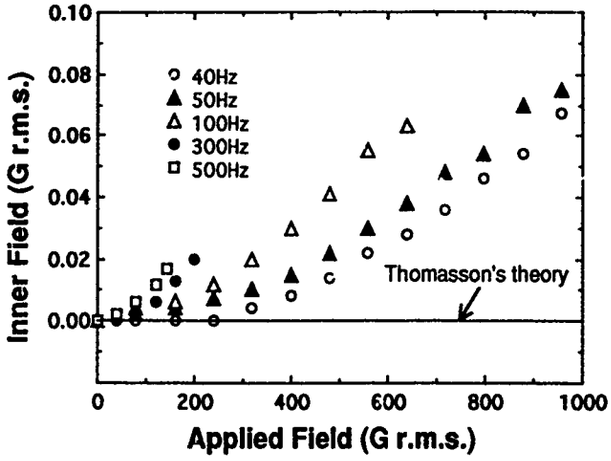

FIG. 5. Inner magnetic field at center of NbTi/Nb/Cu cylinder. Straight line is expressed by Thomasson's theory.

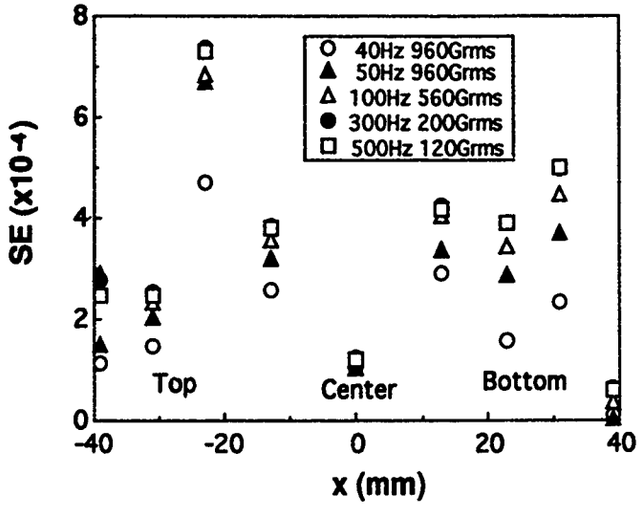

FIG. 6. Difference of shielding effect (SE) due to position in NbTi/Nb/Cu cylinder.

type 1 superconducting cylinder. The ratio of the inner magnetic field B_{in} to the outer one B_{ex} at the center of a cylinder is expressed by the following equation:

$$B_{in}/B_{ex}=1.13\times10^{-(5L/3D)}, \quad (1)$$

L is the length of cylinder and D is the diameter in this equation. Supposing the alternating magnetic field is uniform and parallel to the cylinder axis at the center of the shielding cylinder, this theory can be applied to the alternating magnetic field measurement. The inner magnetic fields are calculated based on this theory, and shown in Fig. 5 as straight line since the aspect ratio of the cylinder is as large as 6. From Fig. 5 it can be seen that the measured leakage of the external magnetic field cannot be explained only by the leakage from the open ends. There must be some reason for the larger leakage than the theoretical estimation. One of the reasons is that magnetic flux lines go through the portion of the cylinder since this material is type 2 superconductor. The other possibility is that the magnetic field penetrates into the cylinder from a position somewhere on it. In order to clarify the above issue, the following experiments were carried out.

D. Influence of position in the cylinder on shielding effect

Shielding effect (SE) is defined here as follows:

$$SE=V_s/V_0. \quad (2)$$

The voltage of the search coil without shielding cylinder is expressed as V_0 and that with shielding cylinder as V_s. Figure 6 shows the SEs at positions where the distances from the axial center of the cylinder are 0, ±13, ±23, ±31, ±39 mm. The SEs shown in Fig. 6 are of maximum ac external magnetic field at each frequency. From the figure, the SEs around the positions a quarter of the length of the cylinder are a little inferior to those at the center and the ends. The reason for this is considered that the magnetic field penetrates into the cylinder bore from those positions. We are going to investigate the relation between the internal structure and SE after this study. Although the SE at each position is various in detail, it can be said that the shielding effect is good enough to shield from ac magnetic field of the order of several hundred gauss since all SEs are in the order of 10^{-4}.

IV. CONCLUSION

The slender cylinder with an aspect ratio of 6 can be manufactured by a deep-drawing and a spinning method from NbTi/Nb/Cu sheet of multilayer structure. Although there are slight variations in shielding effect at several positions in the cylinder, they are all of the order of 10^{-4} in the range of frequency from 40 to 500 Hz when the applied field is less than 1000 G rms. These shielding effects are superior to those of the Cu cylinder. There is a frequency dependence of alternating magnetic shielding. The magnetic field inside the superconducting cylinder increases more steeply with applied magnetic field at higher frequencies. In this study, we investigated the shielding effect of our material in the extent of magnitude of magnetic field and frequency demanded in the shielding of external alternating magnetic field of Maglev system. However, there remain some interesting points, for example, frequency dependence of the limit of magnetic shielding and the influence of the addition of dc magnetic field to ac magnetic field. We will study these points from now on.

A method of increasing magnetic energy of superconducting magnetic energy storage

T. Morisue and T. Yajima
Nagoya University, Chikusa-ku, Nagoya 464-01, Japan

A solenoidal-type superconducting magnetic energy storage (SMES) using ferromagnetic material as an exterior magnetic circuit can store about 30% more magnetic energy than that using no ferromagnetic material. The amount of pure iron needed is 3.4 ton/MJ or 12 000 ton/MWH for the operating magnetic flux density of the solenoid between 4 and 5 T. Low grade ferromagnetic material containing more than 50% pure iron may be available for the SMES.

I. INTRODUCTION

The operating magnetic flux density of a solenoidal-type superconducting magnetic energy storage (SMES) will be greater than 4 T, and consequently the use of ferromagnetic material as the core of the magnetic circuit of the SMES is meaningless since its saturation magnetic flux density is below 2 T. However, the SMES using ferromagnetic material as an external magnetic circuit as shown in Fig. 1 will increase stored magnetic energy.

In this paper, the energy amplification by using ferromagnetic material is studied theoretically and by the computer simulation for various permeabilities and shapes of ferromagnetic material. A design example of the SMES using ferromagnetic material is presented.

II. SMES USING NO FERROMAGNETIC MATERIAL

The stored magnetic energy of a single layer solenoidal-type SMES is expressed as

$$E=LI^2/2, \tag{1}$$

where L and I are the inductance and the superconducting current of the solenoid, respectively. The inductance L is written as

$$L=F(a/h)\mu_0\pi a^2N^2/h, \tag{2}$$

where a and h are the radius and the height of the solenoid, respectively, μ_0 is the permeability of free space, N is the number of the windings of the solenoid, and $F(a/h)$ is Nagaoka's coefficient[1] and is written as

$$F(a/h)=\frac{4}{3\pi}\frac{1}{k'}\left[\frac{k'^2}{k^2}[K(k)-E(k)]+E(k)-k\right], \tag{3}$$

where $k=4(a/h)^2/[4(a/h)^2+1]$, $k'=\sqrt{1-k^2}$, and K and E are the complete elliptic integral of the first kind and the second kind, respectively.

Under the constraint that the ampere-turn per unit height and the total length of the superconducting wire are constant:

$$NI/h=c_1 \quad \text{and} \quad 2\pi ah=c_2 \tag{4}$$

(c_1 and c_2 are constants), the stored magnetic energy for a thin layer solenoid is written from (1), (2), and (4) as

$$E=c_3F(2\pi a^2/c_2)a \quad (c_3=\mu_0c_1^2c_2/4). \tag{5}$$

Equation (5) has a maximum at $a/h\doteqdot 1$. [Note that $F(x)$ is a decreasing function of x.] Therefore, the optimum solenoid has the radius which is nearly equal to the height.

III. SMES USING FERROMAGNETIC MATERIAL

First, we consider the case that ferromagnetic material fills the unbounded region: $r\geqslant a$, $-\infty<z<+\infty$. For this case, an analytical solution is obtained by using the Fourier transform method[2] and the inductance is given as,[3]

$$L(\mu)=c\int_0^\infty\left[\frac{I_0(\omega)}{I_1(\omega)}+\frac{\mu_0}{\mu}\frac{K_0(\omega)}{K_1(\omega)}\right]^{-1}\times\frac{\sin^2[\omega/(2a/h)]}{\omega^3}\,d\omega, \tag{6}$$

where $c=4\mu_0a^2N^2/h$, μ is the permeability of ferromagnetic material, and I_n and K_n are the nth-order modified Bessel function of the first kind and the second kind, respectively.

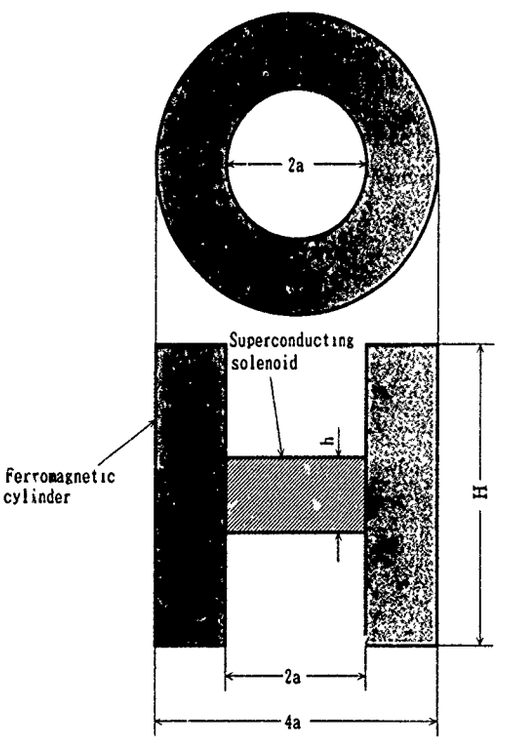

FIG. 1. SMES using ferromagnetic material as an exterior magnetic circuit.

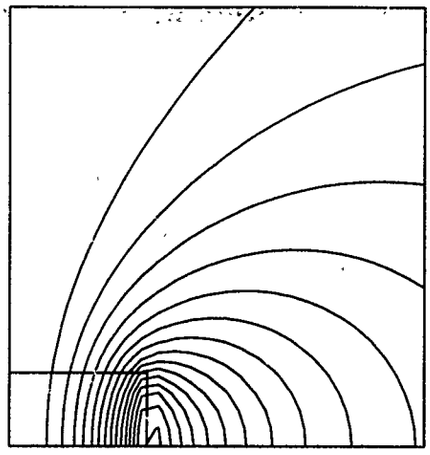

FIG. 2. Magnetic lines of force for the relative permeability of 1, $a/h=1$ and $H/h=3$.

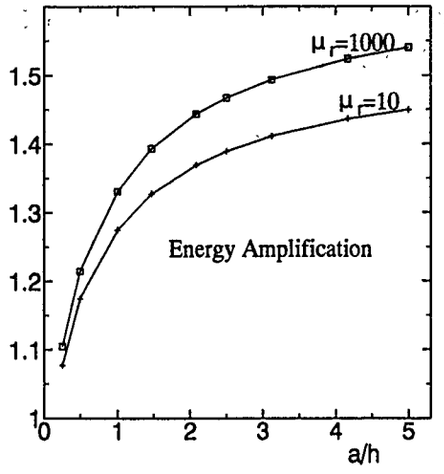

FIG. 4. Energy storage amplification with respect to a/h for the relative permeability of 10 and 1000.

From Eq. (6) it follows that $L(\mu)/L(\mu_0)=1.33$ for $a=h$ and $\mu \geq 1000\mu_0$, where $L(\mu)$ and $L(\mu_0)$ represent the inductance of the solenoid with and without ferromagnetic material, respectively. The energy storage amplification is, therefore, greater than 30%.

Second, we consider the case that ferromagnetic material fills the bounded region: $a \leq r \leq 2a$, $-H/2 \leq z \leq H/2$ (see Fig. 1). We assume that the operating magnetic flux density of the solenoid is between 4 and 5 T, and the saturation magnetic flux density of ferromagnetic material is between 1.6 and 1.8 T. From Fig. 1 the area of the cross section of the solenoid is πa^2 and that of the ferromagnetic material is $3\pi a^2$. Consequently, the magnetic flux density inside the ferromagnetic material is below the saturation almost everywhere.

The magnetic fields in the solenoid and ferromagnetic material are calculated by using the boundary integral equation method. The boundary integral equation in terms of the magnetic vector potential is written as[4]

$$cA(\mathbf{r})=\int_\Omega \frac{\mu_0 j_0(\mathbf{r}')}{4\pi|\mathbf{r}-\mathbf{r}'|}\,d\Omega' - \int_\Gamma A(\mathbf{r}')\frac{\partial}{\partial n'}\left(\frac{1}{4\pi|\mathbf{r}-\mathbf{r}'|}\right)d\Gamma' + \int_\Gamma \frac{\partial}{\partial n'}A(\mathbf{r}')\frac{1}{4\pi|\mathbf{r}-\mathbf{r}'|}\,d\Gamma', \tag{7}$$

where $c=1$, $\mathbf{r}$ in the domain; $=1/2$, $\mathbf{r}$ on the boundary, $\mathbf{j}_0$ is the exciting current density, Ω is free space, and Γ is the boundary (interface) between the ferromagnetic material and free space.

The computed magnetic lines of force are shown in Figs. 2 and 3 for the relative permeability of 1 and 1000, respectively (for $a=h$ and $H=3h$). The energy storage amplification with respect to a/h is shown in Fig. 4 for the relative permeability of 10 and 1000. The energy storage amplification with respect to various shapes of the ferromagnetic cylinder is shown in Fig. 5 for the relative permeability of 10.

We obtain from Fig. 5 that, for $a/h=1$ and $H/h=2$,

$$L(10\mu_0)/L(\mu_0)=1.28. \tag{8}$$

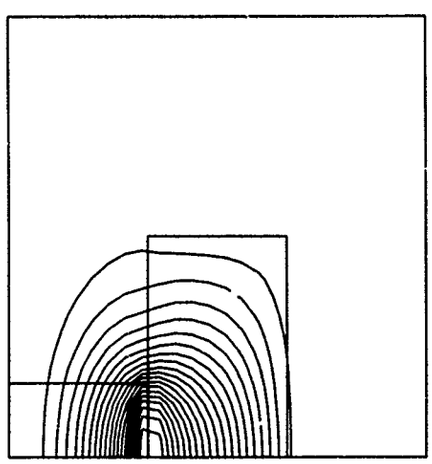

FIG. 3. Magnetic lines of force for the relative permeability of 1000, $a/h=1$ and $H/h=3$.

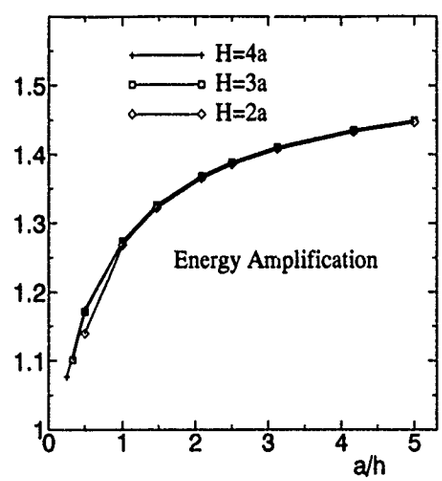

FIG. 5. Energy storage amplification with respect to various shapes of the ferromagnetic cylinder with outer diameter $4a$ and a relative permeability of 10.

TABLE I. Design example of SMES using ferromagnetic material as an exterior magnetic circuit (see Fig. 1). The saturation magnetic flux density of pure iron is assumed to be 1.7 T.

Superconducting solenoid:
radius $a=0.4$ m, height $h=0.4$ m,
ampere-turn per meter=5×10^6 A/m,
magnetic flux density=4.2 T.
Ferromagnetic cylinder:
inner radius $a=0.4$ m, outer radius $2a=0.8$ m,
height $H=2h=0.8$ m, volume=1.2 m^3,
relative permeability=10 (volume concentration of iron=0.75),
amount of iron=7.1 ton.
Stored magnetic energy=2.1×10^6 J.
(energy storage amplification=1.28).

According to the Clausius–Mossotti equations,[5] the permeability is related to the polarizability per sphere iron particle as

$$(\mu-\mu_0)/(\mu+2\mu_0)=4\pi n\rho^3/3, \tag{9}$$

where ρ is the radius of the sphere iron particle and n is the number of the particles in a unit volume. It follows from Eq. (9) that the relative permeability of 10 corresponds to the volume concentration of 75% of pure iron. (This fact agrees well with the result obtained by a computer simulation.)

A design example is shown in Table I. The amount of ferromagnetic material is exactly proportional to stored magnetic energy under the constant ampere-turn per meter and the constant aspect ratio a/h.

IV. CONCLUSIONS

A solenoidal-type SMES using ferromagnetic material as an exterior magnetic circuit can store about 30% more magnetic energy than that using no ferromagnetic material. The amount of pure iron needed is 3.4 ton/MJ or 12 000 ton/MWH for an operating magnetic flux density between 4 and 5 T. Low grade ferromagnetic material containing more than 50% iron may be available for SMES.

A SMES using ferromagnetic material wil require more space than a conventional SMES. However, this drawback may be compensated by the cost performance.

A 30% increase in the inductance or stored energy means a 30% increase in the operating magnetic flux density (for example, from 4 to 5.2 T), and the superconducting wire will be loaded heavier. Such an increase should lead to progress in SMES technology.

Synthesis of high-temperature superconducting thin films in microwave field

Victor I. Kojuharoff
Institute of Electronics, Bulgarian Academy of Sciences, 72 Tsarigradsko Shosse Boulevard, Sofia 1784, Bulgaria

The most widely used technique to obtain high-temperature superconducting (HTSC) thin films at present, i.e., the *in situ* method, has the disadvantage of heating the substrate up to 700–800 °C. This paper proposes a novel, low-temperature method for HTSC synthesis that is capable of producing new types of multilayer structures. The technique is based on the use of microwave (MW) field to treat a thin film deposited on a single-crystal substrate. The process of superconductor formation depends on the MW power, the sample volume, and the dielectric constant. The nature of the synthesis in MW field differs significantly from the ordinary high-temperature baking, since the solid-state reaction is initiated simultaneously in the entire volume and runs at a relatively high rate. Aerosol deposition proved to be the most suitable technique, especially when combined with ultrasonic aerosol homogenization. Scanning electron microscopy observations show that the film surface consists of comparatively densely ordered, almost round grains with sizes between 100 and 130 nm. X-ray diffraction analysis clearly demonstrates that no admixtures from the substrate have penetrated the layer. The resistance versus temperature characteristic is measured by four-probe technique and the critical current densities were 2×10^5 and 0.8×10^5 A/cm^2 at 77 and 4.2 K, respectively.

I. INTRODUCTION

The most promising applications of high-temperature superconducting (HTSC) structures appear to be in hybrid electronic circuits, microwave (MW) linear switches, and frequency mixers and detectors.[1–3] The most widely used technique at present is the *in situ* method, allowing a substantial lowering of the final synthesis temperature without removing the sample from the technological equipment. A disadvantage of this technique is the necessity of heating the substrate up to 700–800 °C during the film deposition. This temperature is sufficiently high to make the *in situ* method almost inapplicable to the production of sandwich-type structures. On the other hand, the HTSC film structure is strongly influenced by the changes occurring in the substrate, such as thermal expansion, polymorphic transformations, as well as other heat-induced phenomena. A typical example is $LaAlO_3$, which is characterized by low thermal expansion and lattice parameters close to those of the superconductor (the difference does not exceed 1.5%). A drawback of the $LaAlO_3$ substrates is the existence of various temperature transitions accompanied by lattice parameter changes.[4] In view of these disadvantages of the *in situ* technique, a novel low-temperature method for HTSC film synthesis is proposed in the present paper allowing varieties of new multilayer structures to be obtained.

II. EXPERIMENT

The experimental technique is based on the use of MW field for treating the thin film deposited on a single-crystal substrate. A necessary condition for carrying out such synthesis is to have a substrate material with suitable dielectric loss. For instance, $LaAlO_3$, $SrTiO_3$, and YSZ substrates have $\tan\delta \lesssim 10^{-4}$ at $\epsilon' \approx 15$–20, considerably differing from those of the HTSC film formed through "cold" deposition. The process of superconductor formation is proportional to the MW field power W and the function $f(\rho/\nu\tau)$, where ν is the thin-film sample volume, τ is the exposure time, and $\rho=\epsilon''/\epsilon'$ is the dielectric loss tangent.

The nature of the synthesis in MW field differs significantly from the ordinary high-temperature baking. In the former, the solid-state reaction of superconducting compound formation is initiated simultaneously in the entire volume and runs at a relatively high rate. This means that the kinetic energy of the effective collision between the molecules participating in the oxides exceeds considerably that of the ordinary thermal process. Therefore the second necessary condition for obtaining high-quality HTSC compounds is high degree of layer homogeneity ensuring a homogeneous medium for the MW field. The experiments showed that the absence of such medium leads to local overheating resulting in multiphase structures. Therefore, the formation of HTSC compounds with the use of MW field is volume limited, i.e., depends strongly on the film thickness. The experiments performed showed satisfactory results with thicknesses less than 3 μm. During the tests we used different deposition techniques: screen printing,[5] paint on,[6] and aerosol deposition[7] of salts of organic and inorganic acids. Aerosol deposition proved to be the most suitable method, especially when ultrasonic aerosol homogenization was used. The latter made it possible to control accurately the size of the aerosol particles and, therefore, determined to a large extent the high homogeneity of the film produced. The equipment is shown schematically in Fig. 1. In the experiments we used ⟨110⟩- and ⟨001⟩-oriented $LaAlO_3$ substrates. The solution was sprayed through a 0.04-μm-diam nozzle; 10–15 ml of solution with a concentration of 0.27 m mol/ml was needed to form one layer. The solution was made up of oxalates of Bi, Sr, Ca, Cu, Pb, or Sn in deionized water in a ratio corresponding to the formula $Bi_2Me_{0.5}Sr_{1.5}CaCu_3O_8$, where Me

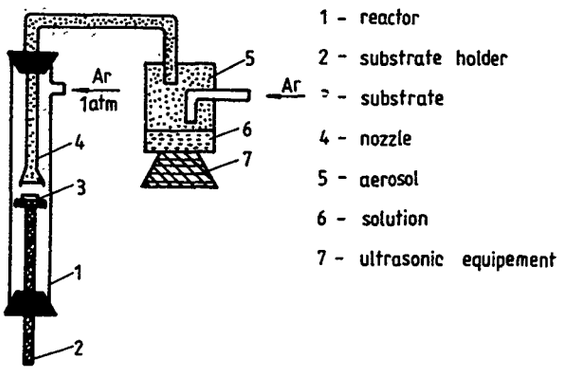

FIG. 1. The experimental equipment.

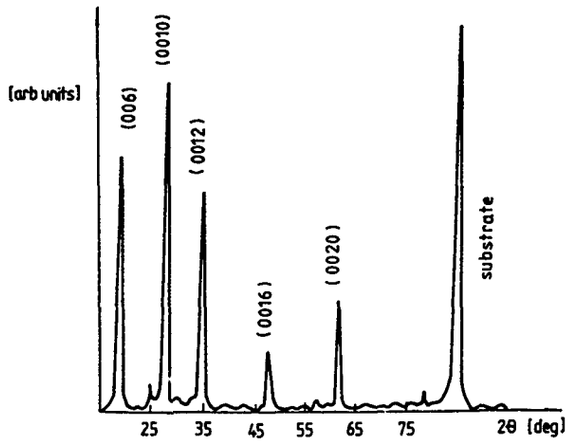

FIG. 2. The data from the x-ray diffraction analysis of the $Bi_2Pb_{0.5}Sr_{1.5}CaCu_3O_{8+}$ film.

=Pb or Sn. The films thus obtained were placed in a drier for 30 min at a temperature of 60 °C. After drying, the samples were placed on a holder made of aluminum ceramics in a "Linn High Therm" type MW furnace.

In order to establish the best MW film treating mode, a series of experiments was carried out on layers with thicknesses from 0.5 to 5 μm treated for different exposure times and different MW field powers. In general, the experiments showed best results in terms of T_c and film morphology for (a) MW field power 0.6 kW, (b) exposure time 15 min, (c) frequency 2500 MHz, and (d) oxygen atmosphere P_O=1.5 atm.

III. RESULTS AND DISCUSSION

The investigation of the structure and morphology of the HTSC thin films (1 μm×1 mm) obtained on $LaAlO_3$ substrates were carried out using well-known surface analysis techniques. The scanning electron microscopy (SEM) observation showed that the sample surface consisted of comparatively densely ordered, almost round grains with sizes between 100 and 130 nm. These films were dense and uniform, the surface was not mirror like, and the gaps existing between the grains were smaller than the grains themselves (30–50 nm).

X-ray diffraction analysis was used to identify the different crystal phases present in the thin film (Fig. 2). The diffraction pattern shown corresponds to a single-phase superconductor $Bi_2Pb_{0.5}Sr_{1.5}CaCu_3O_{8+}$ with T_c=85 K. The diagram clearly demonstrates that no admixtures from the substrate have penetrated the layer. We should also point out that, in microscopic volumes, the film is predominantly oriented along the "c" axis indicating the presence of a texture. This is a rather unexpected result, bearing in mind that the substrate is not heated and does not interact with the film. Most probably, the thermal energy released during the synthesis as a result of the MW field interaction with the film molecules affects the substrate surface crystal field and gives rise to certain crystalline orientation.

A standard four-probe technique with mechanically pressed silver contacts was used to obtain the $R=f(T)$ function. The results from the measurement of a $Bi_2Pb_{0.5}Sr_{1.5}CaCu_3O_{8+}$ thin film are shown on Fig. 3. The R_{300}/R_{100} ratio was ~1.5. The critical current density of the film studied was 2×10^5 A/cm^2, measured at 77 K, while at 4.2 K the critical current density was 0.8×10^5 A/cm^2.

IV. CONCLUSIONS

This work demonstrates the possibility of using a MW field in the synthesis of superconducting materials. This technique, combined with the "cold" methods of HTSC thin-film deposition, makes it possible to produce a homogeneous single-phase superconductors characterized by high accuracy of the dosage of participating components. The time needed for the superconductor synthesis is significantly shorter than times cited in the literature.

The basic advantage of the MW synthesis is the absence of substrate heating. The film is not contaminated through diffusion of substrates components, the substrate is not subjected to any morphological transformations, and the thermal expansion is close to zero. The choice of substrates for HTSC films growth is limited only by the dielectric properties of the substrate.

In order to obtain a uniform, dense, and single-phase film, one should create conditions for uniform MW field dis-

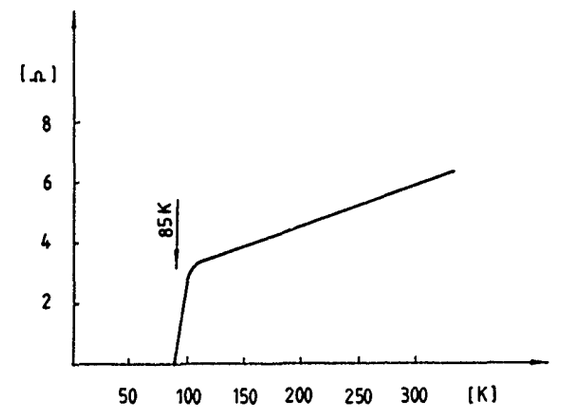

FIG. 3. Results from the measurement of the resistance of the $Bi_2Pb_{0.5}Sr_{1.5}CaCu_3O_{8+}$ film as a function of temperature.

tribution along all directions in the sample, i.e., the film deposited should exhibit uniform impedance and density over its entire volume. Therefore, the medium homogeneity is in practice inversely proportional to the film thickness.

All studies performed on bulk samples (thickness $\leqslant 1$ mm) showed that they are predominantly multiphase systems, although some of them exhibited superconducting properties.

Estimation of fatigue exposure from magnetic coercivity

Z. J. Chen, D. C. Jiles, and J. Kameda
Ames Laboratory and Center for NDE, Iowa State University, Ames, Iowa 50011

An investigation of the effects of fatigue on A533B steel under constant load amplitude is reported in this paper. It was found that the plastic strain of the sample accumulated logarithmically with the number of stress cycles after initial fatigue softening. Based on the fact that plastic strain is often linearly related to the coercivity of material, at least for small changes of H_c, a phenomenological relationship has been developed and tested to correlate the number of stress cycles to this magnetic parameter. This result represents the first successful attempt to relate the fatigue exposure directly to a magnetic parameter.

I. INTRODUCTION

Metallic fatigue failure is a very difficult and serious problem due to its insidious nature. It has been estimated that fatigue failure is the primary cause of at least 90% of all service failures due to mechanical causes. Magnetic nondestructive evaluation techniques, such as magnetic hysteresis measurements and Barkhausen effect measurements have been proven to be powerful methods of detecting changes in mechanical properties.[1,2] However, due to the fact that so many external factors can influence the magnetic properties, quantitative characterization of fatigue damage remains a very difficult problem.

In this paper, a phenomenological relationship relating coercivity to the number of stress cycles has been developed through the study of the results of fatigue tests under constant load amplitude. One of the significant results of this relationship is that, for the first time, the number of stress cycles was shown to be related directly to the magnetic parameter of coercivity and therefore the measurement of coercivity provides a way to estimate fatigue damage.

II. EXPERIMENTAL PROCEDURE

The material used in this investigation was a medium strength structural steel alloy (ASTM code A533B) whose mechanical properties are given in Table I. Fatigue tests were carried out on smooth tensile specimens with constant load amplitude, using a computer controlled, 10 kN, servo-hydraulic MTS system. Magnetic hysteresis parameters, such as coercivity, remanence, and initial permeability were measured by the Magnescope, a computer controlled magnetic inspection system.[3] These measurements were made at predetermined intervals throughout the fatigue life under zero load.

TABLE I. Mechanical properties of ASTM A533B steel.

Young's modulus	0.2% Yield stress	UTS	Hardness, R_b
170 Gpa	369 Mpa	536 Mpa	88.0

III. TEST RESULTS AND PREDICTIONS

Fatigue damage is a progressive effect, during which the microstructures of material, such as dislocation density, plasticity, and density of vacancy undergo continuous change before final catastrophic failure. Under cyclic stress at constant load amplitude, it was found that the maximum tensile and compressive strain increased continuously throughout the whole fatigue life, after the initial few hundred stress cycles which caused fatigue softening. A linear relationship between the magnitude of the strain amplitude and number of stress cycles was observed on a semilog graph, as shown in Figs. 1 and 2. This result indicated that the plastic strain accumulated logarithmically with the number of stress cycles.

Correlations between mechanical properties and magnetic properties have been studied previously.[4,5] It was found for example that the coercivity H_c was generally linearly

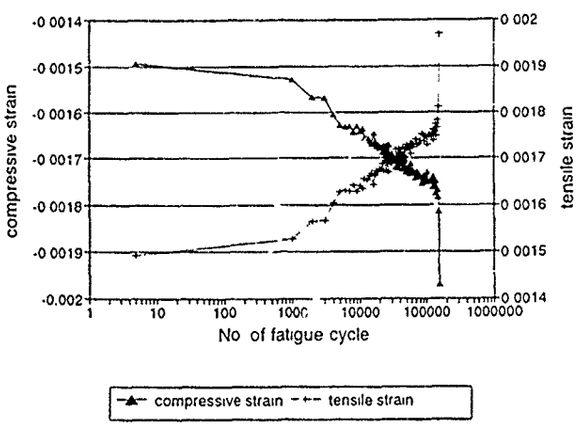

FIG. 1. Maximum tensile and compressive strain as a function of number of stress cycles at a fixed stress amplitude of 272 MPa.

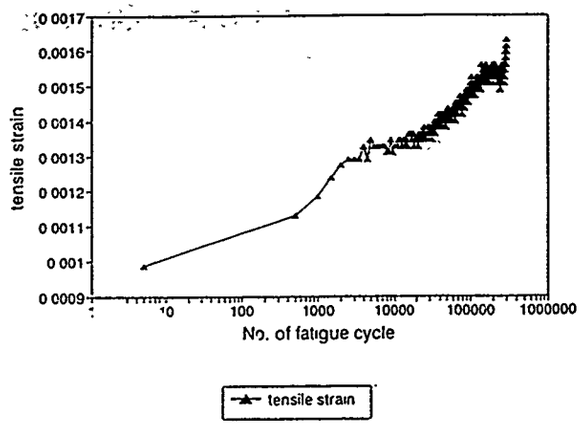

FIG. 2. Maximum tensile strain as a function of number of stress cycles at a fixed stress amplitude of 243 MPa.

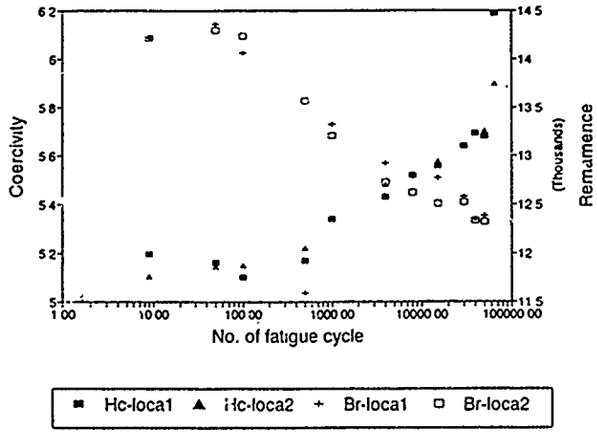

FIG. 4. Magnetic properties as a function of the number of stress cycles.

related to the plastic strain of a material, and this relationship can be understood theoretically because increased plastic strain results in a linear increase in dislocation density, which increases the pinning term k in the theory of hysteresis.[6] If this relation also holds in the fatigue process, then according to the experimental discovery of the logarithmic relationship between plastic strain and number of stress cycles, the same logarithmic relation between coercivity and number of stress cycles should be expected.

From Figs. 1 and 2, the strain amplitude and the number of stress cycles N can be related by following equation:

$$\epsilon - \epsilon_0 = a \ln(N), \tag{1}$$

where ϵ_0 is the intercept along the strain axis and a is the slope of the line. Assuming the linear relationship between the coercivity and the plastic strain, the following equation is obtained:

$$H_c - H_{c0} = b \ln(N), \tag{2}$$

where H_{c0} and b are constants under the specific test condition. Equation (2) can also be expressed as

$$N = c_1 \exp(c_2 H_c), \tag{3}$$

where C_1 and C_2 are determined by H_{c0} and b.

Magnetic measurements were performed under the same test conditions. Results are shown in Figs. 3 and 4. A linear

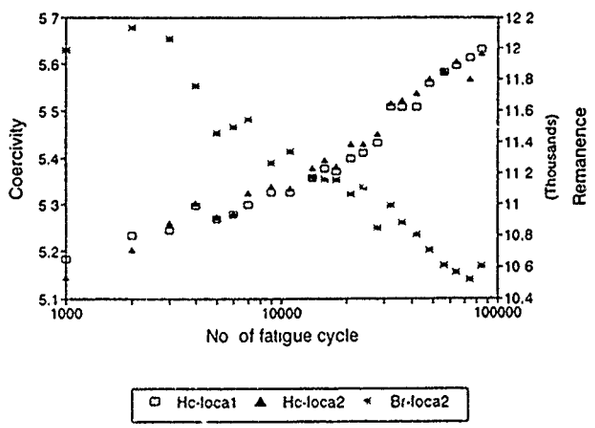

FIG. 3. Magnetic properties as a function of the number of stress cycles.

relation between coercivity and number of stress cycles is quite apparent on the semilog graph after the initial few hundred cycles of fatigue softening. This relation matches the prediction described by Eq. (2). Similar results were also found on the fatigue test at different stress amplitudes in the high cycle fatigue regions under constant stress amplitude.

IV. DISCUSSION

The relationship expressed in Eq. (1) was determined from the fatigue tests under load control. It applies to high cycle fatigue on A533B material. However, the generality of this relation between the accumulated plastic strain and the number of stress cycles should be tested on different materials, and furthermore the dependence of the parameters on the test conditions should also be investigated.

The assumption of a linear relation between plastic strain and coercivity through the theory of hysteresis leads from Eq. (1) to Eq. (2). The linear relationship between plastic strain and coercivity has been observed previously and can be explained by the fact that plastic strain introduces extra dislocations which pin domain walls and therefore increase the hysteresis loss parameter k. In our A533B material, fatigue softening was observed which indicated that there was a decrease in dislocation density. However, the fatigue induced local yielding (and therefore residue stress), and the resulting extra density of vacancies acted as additional wall pinning sites. The overall effect of fatigue can therefore still increase the hysteresis loss parameter k.

The parameters C_1 and C_2 in Eq. (3) can be experimentally determined by three measurements of (N_0, H_{c_1}), $(N_0+\Delta N, H_{c_2})$, $(N_0+\Delta N', H_{c_3})$, where ΔN and $\Delta N'$ are two intervals of the number of stress cycles between successive measurement. N_0 is the number of accumulated stress cycles when the first measurement is taken. Practically, N_0 is also an unknown number. Although Eq. (3) does not indicate the final value of fatigue life, it does show how to estimate accumulated fatigue damage by measuring coercivity. If the total fatigue life can be predetermined by an alternative method, then this relationship can be used to monitor fatigue damage.

V. CONCLUSIONS

A relationship for determining the number of stress cycles under constant stress amplitude by magnetic measurement of the coercivity has been presented. This relationship is based on experimental evidence. According to the relationship, the number of stress cycles is logarithmically related to the coercivity of the material. Although the sensitivity of the result so far is not completely satisfactory for practical applications especially during the later stages of fatigue life, the relationship demonstrated in this paper gives a connection between the magnetic properties and fatigue damage. It therefore provides a clue for further development of models for validation of nondestructive evaluation techniques for fatigue based on magnetic property measurements.

Overview of applications of micromagnetic Barkhausen emissions as noninvasive material characterization technique

L. B. Sipahi
Institute for Physical Research and Technology, Center for Nondestructive Evaluation, Iowa State University, Ames, Iowa 50011

In this concise overview, the physical principles of magnetic Barkhausen effect will be briefly discussed and its recent applications in material characterization will be considered. There are new trends in micromagnetic Barkhausen effect emissions and its applications in the material characterization area. These emissions take place in magnetic materials subjected to changing applied magnetic field, and can be used, for instance, to study noninvasively surface characterization of materials. Since these emissions are quite sensitive to changes in the microstructure and subsurface stress states in magnetic materials, various applications of these of micromagnetic emissions have been found in areas such as nuclear, aerospace, and automotive technologies which use magnetic materials.

I. INTRODUCTION

The Barkhausen effect is now being widely employed as a material characterization technique for magnetic materials. The micromagnetic emissions can be detected as voltage pulses caused by discontinuous changes in magnetization in the material, and are the result of spontaneous motion of domain walls or rotation of magnetization within domains. Since pinning of domain walls is the principal cause of hysteresis, one may easily comprehend how magnetic materials which show hysteresis also display micromagnetic Barkhausen emissions as the external magnetic field is varied.

A. Importance and applicability of micromagnetic Barkhausen emissions in material characterization

The magnetization process in magnetic materials has been an important and difficult research subject for many years because of the many factors contributing to the process. This process, which can be described on both macroscopic and microscopic scales, can be analyzed by different techniques. The magnetic hysteresis loop, Fig. 1, is mainly representative of averaged macroscopic dependence of magnetization M on field H. The micromagnetic Barkhausen effect, Fig. 1, is indicative of microscopic changes in magnetization on the domain scale. Magnetic domains, which are the regions of parallel aligned atomic magnetic moments, form the entire volume of the material. The boundary between domains is not a sharply defined geometric surface but consists of an intermediate zone with a continuous variation of the spin magnetic moment orientations with position. This width is nearly in the order of 10^2–10^3 Å.

As the magnetization is increased towards saturation more complicated processes play a role such as movements of 90° Bloch walls, the nucleation of new domain walls, the mutual annihilation of pairs of walls, and disappearance of walls swept to the surface of the specimen. When the magnetization reaches saturation, the domain structure becomes simpler because the material becomes a single domain. If magnetization is increased further, change in magnetization occurs essentially through the rotation of the magnetization vector within a domain against the internal anisotropy forces. The mobility of the Bloch walls is related to the total magnetostatic energy which varies with the size and shape of specimen, and its microstructure. Irreversible domain wall motion is strongly influenced by the defect structure such as voids, second phase inclusions, dislocations, clusters of point imperfections, and also stresses.

B. Applications of Barkhausen effect in material characterization

Polycrystalline ferromagnetic materials such as steels are the most crucial of industrial commodities. For instance more steel is produced than any other metal. When alloyed with silicon it is used for electronic applications such as transformers, inductors, and motors. It is also alloyed with carbon and other metals for use as a constructional material on large-scale projects such as pipelines, railroads, and bridges. It is desirable to inspect these structures because of the likely high cost of failures which could be avoided through appropriate nondestructive evaluation methods. The detection of corrosion cracks and other defects and the evaluation of stresses, elastic and plastic deformation, and the likelihood of failure due to creep or fatigue are all important

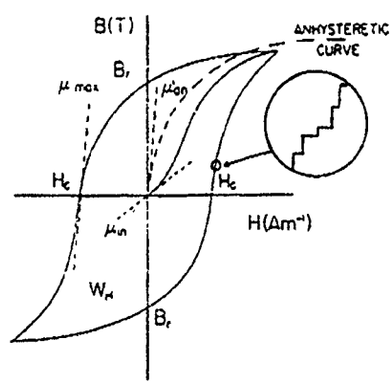

FIG. 1. The essential parameters of a BH loop with steplike Barkhausen discontinuities along the hysteresis curve by amplifying the magnetization.

reasons for developing these inspection techniques. Thus the potential catastrophic failures may be preventable by monitoring the condition of structures.

The Barkhausen effect can be used for indirect measurement of fundamental properties of magnetic materials, such as the coercive force and the demagnetizing field, and also for determining the elastic limit in ferromagnets. In the present work, applications are considered in two different categories: microstructure and stress analysis.

1. Microstructure analysis

A primary concern of the steel industry is to consistently produce large quantities of steel with well controlled and uniform mechanical or electrical properties. If calibration is possible, the magnetic Barkhausen effect can be used for assessing changes in these properties as a result of processing and service.[1–5]

The mechanical properties of steel are determined by microstructural parameters such as the concentration, shape, chemical composition, and dispersion characteristics of precipitates, grain boundaries, dislocations, point defects such as interstitial or substitutional impurities, and vacancies. The dependence of the magnetic Barkhausen effect emissions on distribution of grain sizes can be explained since polycrystalline iron and steel consist of a number of inhomogeneities and pinning points such as cavities, inclusions, precipitates, dislocations, and other lattice defects which impede the motion of domain walls.[6,7] In electrical steels, the most significant pinning points are located at grain boundaries. In electrical steel sheets the influence of grain orientation on the texture can be determined using the magnetic Barkhausen effect measurements.

Recent work has indicated that this technique has the potential to be employed in noninvasive monitoring of neutron-irradiation-induced changes in ferritic alloys in order to ensure safe operation of nuclear reactor pressure vessels by means of magnetic inspection techniques.[8–10] The magnetic Barkhausen effect has been already used for flaw detection in steel plates.[11] By generating magnetic Barkhausen emissions at different frequencies and combining them with hysteresis measurements, the determination of the surface decarburization in steels has been studied.[12] The dependence of Barkhausen emissions on micromagnetic hardness, hardening depth for production of critical components in the automotive industry, has been also investigated.[13] The results showed that an increase in hardness resulted in a decrease in the micromagnetic emissions.

Another important application for the magnetic Barkhausen effect is fatigue testing. If magnetic parameters at the surface are measured, information on the fatigue damage can be predicted. This technique to detect fatigue damage during cyclic loading or after a single overloading cycle has been reviewed.[14]

In advanced magnetic materials, such as the ternary alloy $Tb_{0.3}Dy_{0.7}Fe_2$, Terfenol-D, magnetic Barkhausen effect measurements have been carried out to locate the onset of discontinuous rotation of domain magnetizations before[15] and after[16] applying stress.

Using the Barkhausen effect to determine the easy axis of magnetization in steels[17] was studied. Since there are several factors which affect the magnetic Barkhausen emissions, the magnetizing parameters to generate these emissions were also investigated.[18] This investigation revealed that not only the choice of wave form and frequency of magnetic field excitation to generate the micromagnetic emissions within material but also the choice of detecting method were quite crucial. Further, the new analysis techniques of these emissions were discussed.

2. Stress analysis

As is well known, the magnetization of ferromagnets is influenced by stress states of material through magnetostriction because plastic deformation gives rise to regions of high dislocation density which impede domain wall motion.

Elastic stresses also affect the magnetic Barkhausen effect emissions because of the effect of elastic deformation. This deformation in material leads one to arrange the energetically favorable domain configuration due to magnetoelastic energy minimization when the domain magnetization aligns with respect to the principal axes of lattice strain.

The stress axis in a polycrystalline material is rarely along one of the crystallographic axes of a grain. Therefore, in materials with positive $d\lambda/dM$, where λ and M are the magnetostriction and magnetization, respectively, tension causes alignment of the domains with directions along the crystallographic axis nearest the stress axis, but compression makes domain directions along these same axes less favorable. Thus, when the magnetizing field is applied along the stress axis, tensile stress will increase the number of magnetic Barkhausen emissions while the compressive stress has the converse effect. But if the magnetizing field is perpendicular to the stress axis, the effects of stress on hysteresis and Barkhausen effect are reversed. Investigation of the dependence of the magnetic Barkhausen emissions on the stress and the angle between the stress and the magnetization directions[19] and angular dependence of magnetic properties of polycrystalline iron under the action of uniaxial stress[20] were conducted. These investigations concluded that the amplitude of these emissions was nearly isotropic and independent of the direction of the applied magnetic field. On the other hand, this amplitude showed an anisotropic trend and was dependent on the angle between the stress and applied magnetic field when stress was applied. Brief coverages of the effect of stress on the magnetic Barkhausen effect emissions[21,22] were reported. These studies were mainly investigations of the influence of shot peening, which introduces a compressive stress on surface, and tensile stress on the emissions. The results indicated that the shot peening process as a cold surface treatment decreased the amplitude of the micromagnetic emissions.

It has been observed that the number of magnetic Barkhausen emissions increases when tensile stress is applied up to the elastic limit. Then these emissions at the elastic limit will either increase or decrease according to whether the magnetostriction is positive or negative. Figures 2 and 3 show how compressive and tensile stresses affect the domains and amplitude of the magnetic Barkhausen emis-

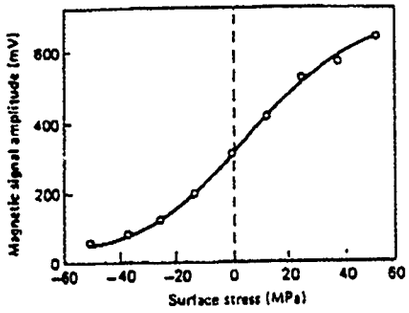

FIG. 2. Magnetic Barkhausen signal amplitude against surface stress (Ref. 23).

sions in an AISI 4340 steel[23] and bearing races.[24] This technique has been utilized for residual stress measurement and magnetic material characterization. Moreover, automated control of the camshaft grinding process by means of the magnetic Barkhausen effect was proposed, and it was found that fatigue strength is decreased with tensile grinding stress and increased with compressive stress.[25]

On the other hand, there are some difficulties which researchers experience to study the micromagnetic Barkhausen emissions. These are mainly related to the very sensitive nature of the emissions to microstructural changes in specimen. A small change not only in one of the microstructural parameters but also in one of the generating or detecting parameters of these emissions of an experimental system may result in additional challenges to interpret the results. Moreover, the calibration curves of each specific case are necessary.

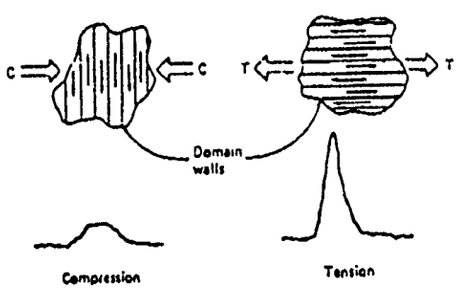

FIG. 3. Influence of compression and tension on Barkhausen effect signals in bearing races. These signatures were obtained after processing the Barkhausen emission pulses as explained by Barton *et al.* (Ref. 24).

II. CONCLUSIONS

Due to the strong dependence of the magnetic Barkhausen emissions on microstructure and stress conditions of magnetic materials and due to its ease of measurement, the magnetic Barkhausen effect will continue being an important noninvasive magnetic material characterization method. As discussed above, this technique has been employed in many different technologies. Moreover, new potential application areas have yet to be exploited.

Monitoring neutron embrittlement in nuclear pressure vessel steels using micromagnetic Barkhausen emissions

L. B. Sipahi, M. R. Govindaraju, and D. C. Jiles
Center for Nondestructive Evaluation, Iowa State University, Institute for Physical Research and Technology, Ames, Iowa 50011

In nuclear power plants, neutron embrittlement of pressure vessel steels has been one of the main concerns. The use of micromagnetic Barkhausen emissions is a promising method to monitor the variations in microstructural and subsurface stress states due to their influence on these emissions. Measurements of these emissions can reveal neutron irradiation degradation in nuclear power plant components. Samples which were irradiated at different neutron fluences and annealed at different temperatures were obtained from three reactor surveillance programs. The results of different neutron fluences and annealing procedures showed noticeable fractional changes in the magnetic Barkhausen effect signal parameter, ΔMBE/MBE, and in the mechanical properties of these specimens. For example, increased intensity of neutron fluence decreased the ΔMBE/MBE as well as impact energy and upper-shelf energy, but increased Rockwell hardness and yield strength. Typical changes in this parameter were in the range from −20% to −45% for fluences of up to 25×10^{18} n cm^{-2}.

INTRODUCTION

The nuclear industry has been investigating inspection methods to ensure safe operation of nuclear reactors beyond their projected life span. Previous work has concentrated not only on destructive techniques such as Charpy tests but also on noninvasive methods such as x-ray, eddy current, hysteresis, positron annihilation, and magnetoacoustic emission measurements.[1–3] Neutron bombardment creates point defects distributed throughout the irradiated material. Magnetic properties such as remanence, coercivity, maximum differential permeability, and hysteresis loss are sensitive to the presence of these defects,[4] as are Barkhausen emission spectra which were employed to characterize microstructure and subsurface stress states of the materials.[5–7]

EXPERIMENTAL

The samples investigated were mainly broken Charpy specimens of A533 grade B class 1 pressure steels. Some measurements also were taken on unbroken Charpy samples ($27.5\times10\times10$ mm^3). Classification of the samples was made on the basis of the original surveillance program data at three different nuclear reactor plants. All the magnetic hysteresis[8] and magnetic Barkhausen measurements on base or weldment portions of the irradiated samples were taken in the radioactive "hot cell" using a commercial Barkhausen effect device, which has been described elsewhere.[9]

RESULTS AND DISCUSSION

Measurements at Westinghouse Electric Corp., Pittsburgh, PA were conducted on the specimens from the first surveillance program where they had been irradiated to three different levels of neutron fluences: 3.9×10^{18}, 17.7×10^{18}, and 23.7 n cm^{-2}. The analysis showed that magnetic Barkhausen signals at each measurement depth were influenced by neutrons.

To investigate the response of Barkhausen emissions to the changes in the mechanical properties of the samples as a result of neutron embrittlement, the fractional change in the magnetic Barkhausen signal was compared to change in Rockwell hardness, upper-shelf energy, yield strength, and impact energy over the range of neutron irradiation fluence. On these same specimens, the effect of sample orientation with respect to rolling direction was also studied. The samples were denoted as transverse and longitudinal. Weldment specimens from the first surveillance program were also measured.

Similar measurements were carried out on the samples from the second surveillance program where fluence of neutrons was 13.3×10^{18} n cm^{-2}. As summarized in Table I, the Barkhausen signal as well as the impact energy and upper-shelf energy decreased with neutron influence, whereas Rockwell hardness and yield strength were found to increase with neutron fluence over the range $0–25\times10^{18}$ n cm^{-2}. It was expected that higher hardness would result in lower magnetic Barkhausen emissions due to the increased number of defect pinning centers which impede both the movement of dislocations and magnetic domain walls.

The second part of investigation was to study the influence of successive neutron irradiation and annealing processes on magnetic Barkhausen signals from the samples from the third surveillance program. Barkhausen voltage wave forms from the unirradiated sample, [Fig. 1(a)], from the sample irradiated at 8.4×10^{18} n cm^{-2}, [Fig. 1(b)], and from the sample annealed at 850 F for 168 h, [Fig. 1(c)] correspond to changes in micromagnetic emissions in the materials of interest. Before irradiation, the rms Barkhausen voltage was 6 V while after irradiation it was 2.5 V. Anneal-

TABLE I. The changes in magnetic Barkhausen signal parameter and mechanical properties.

	Change in magnetic Barkhausen signal	Change in Rockwell hardness	Change in yield strength	Change in impact energy	Change in upper-shelf energy
Transverse samples from the 1st surveillance program	−45%	48%	18.5%	−26%	−16.5%
Longitudinal samples from the 1st surveillance program	−19%	41%	19.5%	37%	−13%
Weldment samples from the 1st surveillance program	−42%	40%	9.5%	−52%	−26%
Samples from the 2nd surveillance program	−21%	37%	7%	−64%	−16%

ing resulted in a signal of 5 V. It was also found that the magnetic Barkhausen signal parameter decreased as a result of the first irradiation at 8.4×10^{18} n cm^{-2} at all measurement frequencies and hence at all depths. The first anneal, 168 h at 850 °F, restored the Barkhausen parameter. On the other hand, the second irradiation, an additional 6.6×10^{18} n/cm^2, did not cause noticeable change in the Barkhausen signal. However, the second annealing step with some experimental conditions, as in the first annealing, further restored the magnetic Barkhausen signal as seen in Fig. 2. The magnetic Barkhausen signal together with the Rockwell hardness, impact energy, and upper-shelf energy have been plotted for each case in Fig. 2. As can be seen in Fig. 2(a), the first irradiation led to a decrease in magnetic Barkhausen signal while Rockwell hardness increased. On the other hand, the first annealing process decreased the Rockwell hardness but increased the magnetic Barkhausen signal. The impact energy, Fig. 2(b), and the upper-shelf energy, Fig. 2(c), in every

Identification of radiation and heat treatments on specimens as follows: spec. Id. 1: unirradiated; spec. Id. 2: 1st irradiation, 8.4×10^{18} n/cm^2; spec. Id. 3: 1st irradiation and 1st annealing, 850 F/168 h.; spec. Id. 4: 2nd irradiation, 6.6×10^{18} n/cm^2/spec. Id. 5: 2nd irradiation and 2nd annealing, same as the 1st annealing conditions.

case showed the same trend as the magnetic Barkhausen signal. The results of previous work[8] on the same samples, which included magnetic hysteresis measurements are shown in Fig. 3 for comparison. The *BH*-loop parameters, coercivity, remanence, and differential permeability were plotted for each individual sample. As was indicated previously,[10] the magnetic Barkhausen voltage maximum was proportional to the differential susceptibility. This is clearly seen in Fig. 3.

CONCLUSIONS

This investigation revealed the existence of a relationship between the extent of radiation damage by neutrons and the Barkhausen emission signals. There were significant correlations between mechanical properties of these materials and magnetic Barkhausen signals and these have been interpreted in terms of the effects of defects on both magnetic domain wall motion and dislocation movement. The results indicated that irradiation with neutrons caused damage throughout the volume of the material. It was anticipated that increased hardness would give rise to lower Barkhausen emissions due to increased pinning of domain walls. Successive neutron irradiation and annealing procedures also revealed a relationship between Rockwell hardness and the magnetic Barkhausen signal which resulted from neutron embrittlement.

Experimental study on opening compensation for magnetic shields by current superposition

I. Sasada and Y. Oonaka
Department of Electronics, Kyushu University 36, Fukuoka 812, Japan

A new method is studied experimentally by which magnetic fields coming in through an opening of a magnetic shield can be compensated. The horizontal component of the earth's field is targeted as an external magnetic field to be compensated by the method, in which a single figure-eight coil is used. A cylindrical shielding case is developed for this study using a Permalloy cylindrical case (outer diameter=68 cm, length=180 cm) with an opening at an end and Metglas 2705M amorphous ribbons, which are wound helically on the outer surface of the Permalloy case by 16 layers. A magnetic shaking field of 200 Hz is applied to only the amorphous layers by a toroidal shaking coil of 36 turns. The size of the figure-eight coil used is 74 cm in diameter with 30 turns. Residual magnetic field measured by a flux gate magnetometer in the horizontal center plane of the shielding case shows that the area where the amplitude of the residual magnetic field is within ±0.15 mG is extended by about 30 cm toward the opening.

I. INTRODUCTION

Magnetic shielding rooms of high performance are required for precise magnetic field measurements such as brain magnetic field measurements by superconducting quantum interference device magnetometers. Most of the magnetic shielding rooms presently used are built relying on the ferromagnetic enclosures to isolate the area to be shielded from the outside. As a result, they become heavy and expensive. If magnetic shielding rooms are allowed to have openings by incorporating a compensation technique, the above problems can be solved. In addition to that, we can get an easy access to the working space of the shielding room through the opening.

We have proposed a new method of compensating incoming magnetic field through an opening of magnetic shields by current superposition.[1] In this paper, we evaluate this method against the horizontal component of the earth's magnetic field (0.32 G in Fukuoka) using a cylindrical magnetic shielding case with an opening at an end and a single figure-eight coil. A large cylindrical shielding case (diameter=68 cm, length=180 cm) was developed for this study incorporating the magnetic shaking technique.[2,3] The uniformly shielded area where the amplitude of the horizontal magnetic field was within ±0.15 mG was extended by about 30 cm toward the opening by adjusting the compensation current.

The frequency characteristics of the shielding factor of the developed shielding case are also presented.

II. CYLINDRICAL SHIELDING CASE

A large cylindrical shielding case was developed using Metglas 2705M amorphous ribbons (width=5 cm, thickness≅22 μm) and a Permalloy cylindrical case (outer diameter=68 cm, length=180 cm, thickness=1.6 mm, weight≅60 kg), incorporating the magnetic shaking technique.[2,3]

Metglas 2705M amorphous ribbons were wound helically on the Permalloy case by 16 layers (total weight≅12.1 kg) to cover the circumferential surface. A main reason we used a Permalloy cylinder inside is to attenuate unwanted leakage of the magnetic shaking field into the area to be shielded. Two coils to give magnetic shaking field to the amorphous layers were installed. One is a toroidal coil of 36 turns surrounding only the amorphous layers and the other is a meander coil (line space=3 cm) consisting of a pair of meander coils connected in series, one of which is inserted between the fourth and the fifth layer and the other between the 12th and the 13th layer. One end of the Permalloy cylinder is left open and the other end is closed with the same Permalloy plate welded at all edges, on which there is a square hole of 6 cm×6 cm having been used during fabrication.

III. EXPERIMENT

The shielding case was laid on the floor perpendicularly to the direction of the earth's magnetic field as shown in Fig. 1. The coordinate system is defined with the origin at the center of the opening surface; z axis along the axis of the cylinder, x axis along the horizontal, and y axis along the vertical direction, respectively. We used the toroidal shaking coil rather than the meander one to obtain a large shaking effect. The amplitude of the shaking current was tuned to 110 mA (rms) at 200 Hz, because the shaking effect shows a peak for the shaking current.[2] The leakage flux density of the

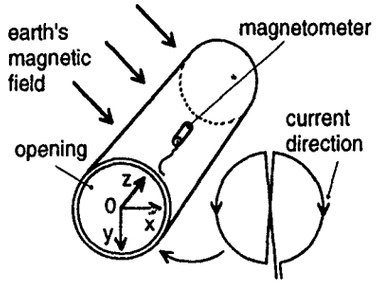

FIG. 1. Experimental setup. The opening is covered with the figure-eight coil.

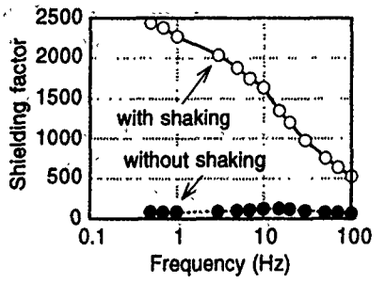

FIG. 2. Shielding factor of the developed cylindrical shielding case.

shaking field was less than 40 μG in most of the area inside the case. The shielding factor, as a basic characteristic of the developed shielding case, was measured as a function of frequency of the external magnetic field. In this case, the external magnetic field with an amplitude of 100 mG (rms) was applied transversely to the case by using a large Helmholtz coil of square shape (4 m×2 m×1.5 m), and the magnetic field was measured at the center of the case. In the experiments of this paper, the magnetic field was measured by a triaxial flux gate magnetometer. The flux pattern appearing near the opening due to the horizontal component of the earth's magnetic field was also measured in the x-z plane.

To compensate the horizontal component of the earth's magnetic field (0.32 G in Fukuoka), a single figure-eight coil of 74 cm in diameter with 30 turns was set to cover the opening with the crossing part of the figure-eight coil being vertical as shown in Fig. 1. Horizontal components of residual earth's fields, B_x and B_z, inside the case were measured in the x-z plane.

Compensation current was adjusted by matching numerically the magnetic fields to be generated by the figure-eight coil with those measured inside the shielding case along the z axis, and we got 77 mA as the compensation current.

IV. RESULTS AND DISCUSSION

The shielding factor of the developed shielding case is shown in Fig. 2 for the frequency of the external magnetic field. The shielding factor (a ratio of external magnetic field versus residual magnetic field in the shield) with magnetic shaking on is 2400 at 0.5 Hz, which is enhanced 30 times as large as that with magnetic shaking off. This large enhancement cannot be explained by a single shell model of an infinite cylindrical shield. Spaces introduced to the magnetic shell for separating the Permalloy case and the amorphous ribbon layer and for inserting shaking coils bring about a multilayer structure. As the space between the Permalloy case and the innermost amorphous layer is largest (about 1 cm), using a double shell model,[4] the Permalloy shell and the amorphous layer shell, the effective permeability of the amorphous layer is estimated as large as 6.3×10^5 at 10 Hz, and 9.3×10^5 at 0.5 Hz in relative permeability. The frequency characteristics of the enhanced incremental permeability at low frequency has already been reported.[3]

The flux pattern measured in the x-z plane near the opening is shown in Fig. 3. For the area $z\geq40$ cm, the vector

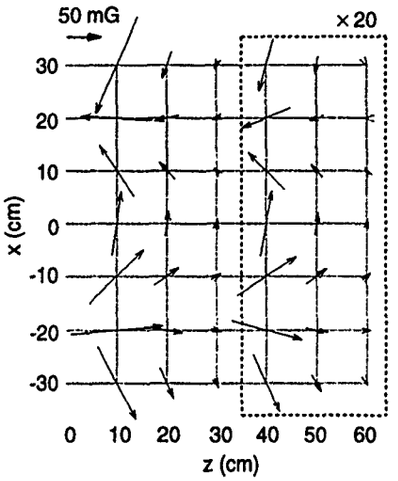

FIG. 3. Vector plot of the magnetic field measured near the opening of the cylindrical shielding case.

plot is magnified by 20 times. Although it is ideal to generate the magnetic field as close as possible to this but opposite in sign, it is also important to approach this by using as simple a coil as possible. Figure 4(a) shows the distributions of Bx along the z axis in the x-z plane with compensation off. Figure 4(b) shows those with compensation on. Similarly those for B_z are snown with compensation off in Fig. 5(a) and with compensation on in Fig. 5(b). From these results, we can see the uniformly shielded area is extended to about 30 cm toward the opening. It should be noted that the uniformly shielded area is extended toward the opening by

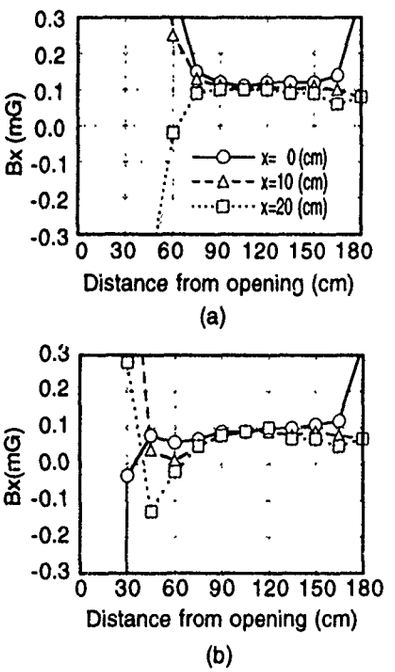

FIG. 4. Distributions of Bx, where the opening compensation is off in (a) and on in (b).

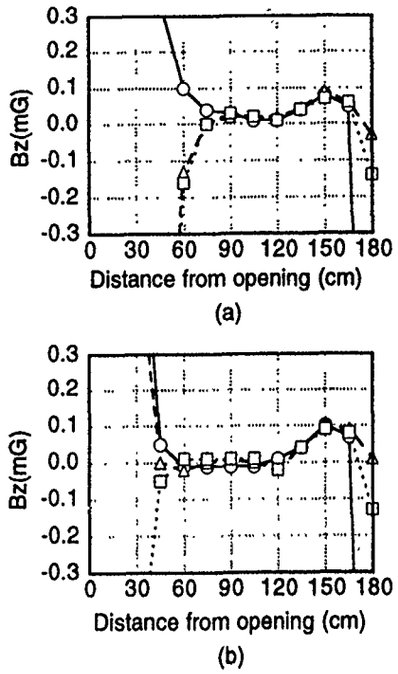

FIG. 5. Distributions of B_z, where the opening compensation is off in (a) and on in (b). Symbols are the same as in Fig. 4.

about half of the diameter of the case with a simple figure-eight coil. Disturbances found near distance=180 cm in all four figures are due to the square hole in the Permalloy plate aforementioned. Due to the symmetry, these results also hold to vertical components. In this case, a figure-eight coil needs to be rotated by 90°.

Residual magnetic fields inside an infinite magnetic shield are theoretically uniform against uniform external fields. This is a very important nature of the cylindrical magnetic shield, because we can use gradiometer to measure very low magnetic field. The opening compensation discussed in this paper would be most suitable for cylindrical shields.

V. CONCLUSION

We demonstrated experimentally that the transverse magnetic field to the opening of cylindrical magnetic shields can be compensated by a figure-eight coil. The uniformly shielded area recovered by this method toward the opening is about half of the diameter in length.

Effects of pole flux distribution in a homopolar linear synchronous machine

M. J. Balchin, J. F. Eastham, and P. C. Coles
School of Electronic & Electrical Engineering, University of Bath, Bath BA2 7AY, United Kingdom

Linear forms of synchronous electrical machine are at present being considered as the propulsion means in high-speed, magnetically levitated (Maglev) ground transportation systems. A homopolar form of machine is considered in which the primary member, which carries both ac and dc windings, is supported on the vehicle. Test results and theoretical predictions are presented for a design of machine intended for driving a 100 passenger vehicle at a top speed of 400 km/h. The layout of the dc magnetic circuit is examined to locate the best position for the dc winding from the point of view of minimum core weight. Measurements of flux build-up under the machine at different operating speeds are given for two types of secondary pole: solid and laminated. The solid pole results, which are confirmed theoretically, show that this form of construction is impractical for high-speed drives. Measured motoring characteristics are presented for a short length of machine which simulates conditions at the leading and trailing ends of the full-sized machine. Combination of the results with those from a cylindrical version of the machine make it possible to infer the performance of the full-sized traction machine. This gives 0.8 pf and 0.9 efficiency at 300 km/h, which is much better than the reported performance of a comparable linear induction motor (0.52 pf and 0.82 efficiency). It is therefore concluded that in any projected high-speed Maglev systems, a linear synchronous machine should be the first choice as the propulsion means.

INTRODUCTION

Linear induction motors (LIMs) have received much attention as the means of propulsion in many projected high-speed, ground transport systems. While this form of machine has many inherent advantages, it suffers from two major detractions. The first of these is due to the large mechanical clearances necessary in high-speed ground transport schemes. This demands a high reactive power component from the supply. An additional reactive power component is made necessary by the second disadvantage of LIMs, which is the longitudinal end effect. This effect is due to persistent induced transient current components in the induction motor secondary member. A convenient way of avoiding the problems associated with LIMs is to consider the advantages offered by synchronous machines. These machines are magnetized by direct current, and so large clearances (air gaps) will not demand ac reactive input. In addition it is not necessary to rely on induced secondary currents for torque (force) production in synchronous machines. This means that any practical method can be used to reduce or eliminate unwanted secondary currents. The choice of the form of a linear synchronous machine is important. In conventional synchronous machines the dc winding is normally on the rotating secondary member. This form of construction may be expensive to produce. An economical form of construction is offered by one of the "ac side excited" types of machine which are related to the inductor alternator. Two forms of this machine, known as the "heteropolar" and "homopolar" types have been developed and tested.[1–4] This paper concerns work performed on a homopolar type of machine, the details of which are shown in Fig. 1. The figure shows that the dc excitation winding is conveniently located on the primary member. This leaves the extended secondary as simple passive steel blocks which can be constructed in any convenient way to reduce induced currents.

On the basis of earlier work a design for a drive motor for a 100 passenger, 400 km/h vehicle has been produced. This machine has 40 poles and is approximately 12 m in length. Experimental work on such a large machine would clearly require an extensive and expensive test installation. It is, however, not necessary to test a complete machine. Because the persistence and magnitude of secondary induced currents can be made small, it is only necessary to perform measurements on short representative sections of the actual machine. In the apparatus constructed for this work a short 4-pole section of machine is used when the magnitude of end effects is of interest. When the part of the machine remote from the ends is of interest an 8-pole cylindrical form of machine is used. Measurements from the two forms of machine can be combined to give a very good indication of the performance of the actual 40-pole machine. In addition, the

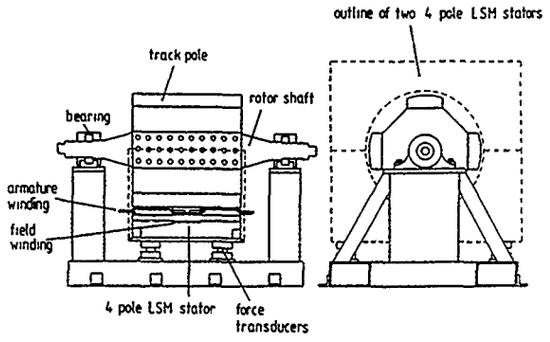

FIG. 4. Arrangement of LSM test rig.

separate sets of results can be used in the verification of mathematical models. Figure 2 shows the novel "figure-eight"[3] layout adopted for the ac armature winding, and Fig. 3 is a photograph of one of the complete 4-pole primary sections.

HIGH-SPEED HOMOPOLAR LSM TEST RIG

The testing of the two parts of the full-sized LSM is facilitated by using either one or two semicircular 4-pole primaries as shown in Fig. 4. The primaries have exactly the same transverse cross-section as the full-sized design of machine referred to in the Introduction. Electromagnetic forces produced by the machine are measured using piezoelectric transducers.

One of the more difficult parts of the design of this test apparatus has been that for the rotating secondary. It is necessary for this component (which has an o.d. of about 700 mm) to rotate at 3000 rev/min in order to achieve a linear speed of 400 km/h. It is also necessary to suspend the secondary steel pole pieces in magnetic isolation. Figure 5 shows the scheme adopted. The whole secondary assembly is supported on a mild steel shaft. Onto this shaft is shrunk a nonmagnetic stainless-steel boss. This part then supports the pole pieces (which are secured by radial bolts) which may be of either solid or laminated construction. The complete test stand of Fig. 4 is housed within a safety cell fabricated from approximately 300 Tonne of reinforced concrete. The cell is closed with doors manufactured from material designed to withstand ballistic impact.

A variable voltage and frequency electrical supply is necessary to power a LSM. One approach is to use a power electronic invertor, as has been demonstrated by the Toshiba Co. of Japan. In the LSM test apparatus being described, a corresponding form of supply is produced by an alternator which is coupled to the rotor shaft (Fig. 4). With this form of supply power can circulate between the machines in either electrical or mechanical form. By altering the angle between the LSM and alternator field poles the LSM torque (force) angle can be set up. Power to supply the ac and mechanical losses of the LSM and alternator system is provided by a dc drive on the same shaft. This is part of a Ward Leonard system with a speed control system to facilitate measurements at fixed frequency settings.

FIELD WINDING LEAKAGE

There are two possible positions for the dc excitation coils on the primary member, and they are shown in Fig. 6. The position shown at (A) is the more convenient from the point of view of mechanical construction, and it also has the benefit of slightly lower resistance. The position shown at (B) promises lower leakage. In order to explore this possibility both configurations were investigated practically using search coils and an integrating fluxmeter. The fluxes mea-

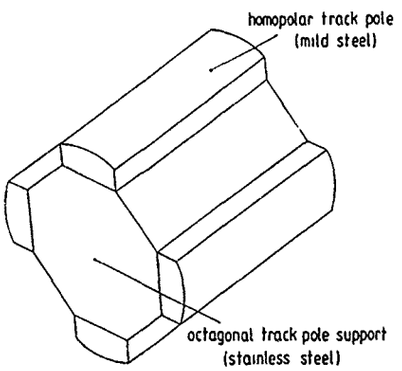

FIG. 5. Schematic of test LSM secondary member.

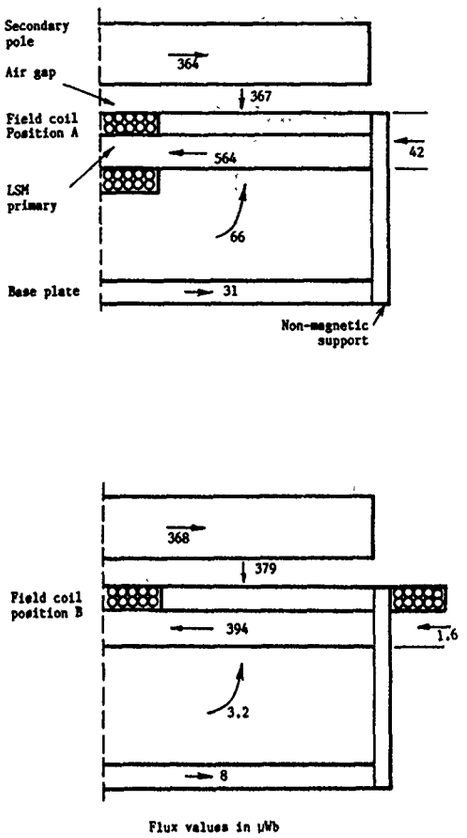

FIG. 6. Possible dc field coil positions for a homopolar LSM.

sured in the various parts of the machine are shown in Fig. 6. It will be observed that the amount of leakage is much smaller in position (B). This leads to the possibility of decreased primary iron core weight.

MEASUREMENT AND CALCULATION OF THE LONGITUDINAL END EFFECT

The excitation pole flux build up was measured using the short stator configuration provided by one primary member. The measurements were taken using a rectangular search coil

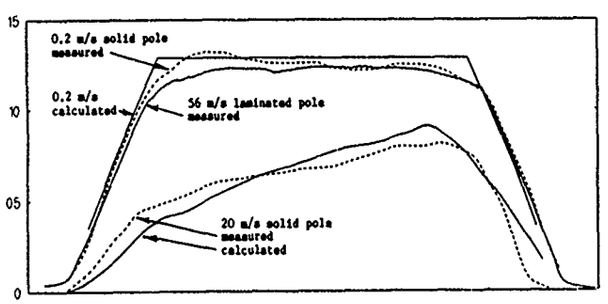

FIG. 7. Air gap longitudinal flux distribution at different speeds, with solid and laminated secondary poles.

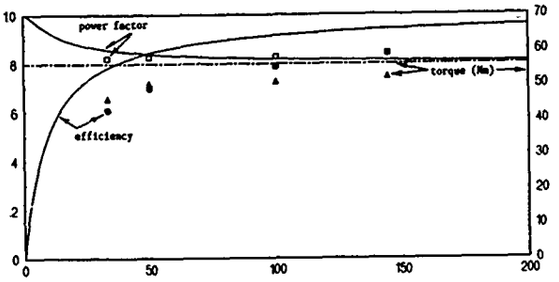

FIG. 8. LSM terminal characteristics at a 90° motoring torque (force) angle.

which spans one rotor pole. Figure 7 illustrates the test results. It is evident that the build up of flux using solid poles is considerably delayed even at 20 m/s (18% of the top speed). With laminated poles the flux builds up almost immediately. This behavior has been confirmed over the speed range of the tests. As an example, the results taken at 56 m/s are also shown on Fig. 7. The calculated results for the behavior of solid poles were obtained using a mesh calculation method which incorporates rotor movement.[4]

MOTORING CHARACTERISTICS

Variation of power factor, efficiency and torque with frequency is shown in Fig. 8. On this figure 200 Hz is equivalent to 112 m/s or 400 km/h. The results are given for a torque angle of 90°. It will be observed that the results are in broad agreement with the calculated values which are shown as continuous lines on Fig. 8. These calculated values were obtained using simple "round-rotor" synchronous machine theory neglecting pole face losses (due both to eddy currents induced by the entry and exit edges and the normal pole face loss which occurs in cylindrical machines).

In a previous paper[4] results were given for a cylindrical machine. These showed closer agreement with the simple calculated lines. It can be inferred from this that the values which will be obtained from a 40-pole machine will lie in between the four pole short stator results shown on Fig. 8 and those taken earlier. This means that, for example, 300 km/h speeds will result in power factors and efficiencies in excess of 0.8 and 0.9, respectively. This is a much better performance than would be expected from a comparable linear induction motor, for which calculated results of 0.52 pf and 0.82 efficiency are given in Ref. 5.

Compensation of field distortion with ferromagnetic materials and permanent magnets

Manlio G. Abele, Henry Rusinek, Franco Bertora,[a] and Alessandro Trequattrini[a]
Department of Radiology, New York University School of Medicine, New York, New York 10016

This paper discusses a technique for improving the homogeneity of the magnetic field in structures of permanent magnets designed for magnetic resonance imaging, achieved by inserting layers of ferromagnetic plates and permanent magnets along the cavity of the structure. The analysis of the field in the magnet is performed using a boundary integral equation method. An example of optimization of the geometry and the amount of the magnetic material is presented.

I. INTRODUCTION

To design a permanent magnet for medical magnetic resonance imaging (MRI) applications one must determine the geometry and the distribution of magnetization that generate a nearly uniform field within a given region of interest. The exact solution of generating a perfectly uniform field is possible only if the magnetic structure totally encloses the volume of interest.[1]

In a practical magnet used for imaging applications several factors contribute to the perturbation of the field inside the cavity. The most important cause of the field distortion is the opening of the magnet to access the cavity. For instance, ideal two-dimensional structures must be truncated at both ends. Since magnets used in MRI require high field uniformity within the region of interest, any field distortion must be compensated for.

There are several approaches to compensate for the effects of the magnet opening. In a traditional magnet the generation of the desired field characteristics, and in particular the achievement of the desired uniformity is accomplished by the design of the pole pieces, which are high magnetic permeability structures inserted within the cavity.

In the case of the magnetic structures introduced by the first author, the compensation of the effect of the magnet opening can be achieved by either the modification of the magnet geometry and the change in the distribution of magnetization or by addition of new components of high permeability materials.[1]

This paper describes a technique based on the use of plates of high permeability materials which contain inserts of active components consisting of magnetized materials. Since the plates "sandwich" the active elements, these structures will be referred to as magnetic sandwiches. Magnetic sandwiches are inserted at the interface between the magnetic structure and the inner cavity and are arranged in layers perpendicular to the main field.

The mathematical procedure for determining geometry and composition of the layers is based on the elimination of increasing order of spatial harmonics in the potential expansion within the region of interest. The optimization of the magnetic structures will be illustrated below in the example of a prismatic hybrid magnet designed around a rectangular cavity.[1]

II. MAGNETOSTATIC POTENTIAL GENERATED BY SANDWICH STRUCTURE

A basic schematic of the combination of plates and active material is presented in Fig. 1, which shows the two sandwich structures perpendicular to the direction of the field inside the cavity inserted within a rectangular cavity indicated by the dashed line in the figure. The plates are assumed to be built with an infinite magnetic permeability material and have zero thickness. As seen in the figure, the outer plate of each structure is continuous, and therefore maintained at a constant potentials Φ_1 and $-\Phi_1$. The inner layer is composed of several sections separated from each other. The figure also shows magnetic material polarized along the y axis and filling a portion of the peripheral section of the sandwiches. The magnetic material generates potential Φ_2 and $-\Phi_2$ on the peripheral section of the inner plates. It is assumed that the central portions of the inner plates are connected with the corresponding outer plates and therefore maintained at potential Φ_1 and $-\Phi_1$, as indicated in Fig. 1.

The potential difference $\Delta\Phi=\Phi_1-\Phi_2$ depends on the geometry of the sandwich layers as well as the amount of the magnetic material inserted within the sandwich. The effect of the location of the active elements within the two plates is first investigated. The magnitude of the remanence J of the magnetic material and its orientation are kept fixed while the coordinates y_s, z_s shown in Fig. 2 are variable, simulating the amount of active material contained within the peripheral section of each plate.

The analysis is performed using a boundary integral equation method,[2] in which the surface charges σ on the

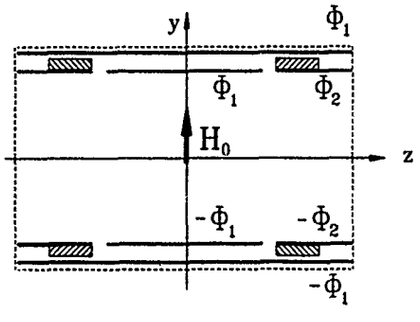

FIG. 1. A basic schematic of two sandwich structures containing active material in the peripheral section. The dashed line indicates the cavity of the magnet designed to generate a uniform field $\mathbf{H}_0$.

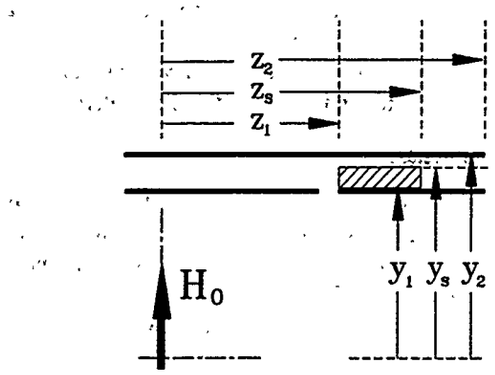

FIG. 2. Geometry of the active material in the peripheral section.

plates are first computed and then used to derive the scalar potential Φ as

$$\Phi=\frac{1}{4\pi\mu_0}\int\frac{\sigma}{\rho}\,dS. \tag{1}$$

Figure 3 illustrates the effect of filling the peripheral section with an increasing amount of the magnetized material. The plot corresponds to varying the z-axis filling, i.e.,

$$z_1<z_s<z_2,\quad y_s=y_2. \tag{2}$$

The same plot is obtained by varying the y-axis filling of the peripheral plate

$$y_1<y_s<y_2,\quad z_s=z_2. \tag{3}$$

The linearity of $\Delta\Phi$ versus the extent of the active material in both y and z directions implies that $\Delta\Phi$ is the function only of the amount of material, rather than of the location of the active material within the sandwich.

III. HYBRID MAGNET AND THE EFFECT OF OPENING

A methodology introduced by the first author led to the theoretical design of a novel permanent magnet device based on magnetic materials with linear demagnetization characteristics.[1] Structures designed using this methodology

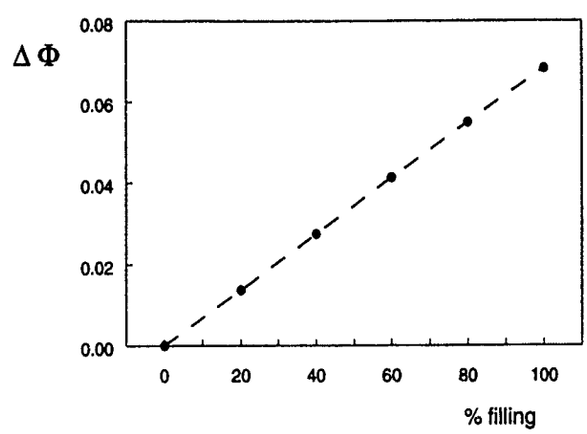

FIG. 3. The potential difference generated by increasing horizontal coverage of active material in the peripheral section on the sandwich structure.

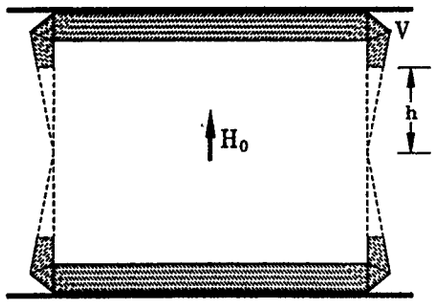

FIG. 4. Hybrid magnet with an opening. The heavy line represents the partial yoke.

generate uniform fields in arbitrary cavities completely enclosed by the magnetic material. Of practical interest is the category of hybrid magnets.[3]

In the particular case of a rectangular cavity of dimensions $z_0=1.5y_0$, the termination introduced by the hybrid magnet consists of two triangular prisms shown in Fig. 4. The coordinate of the vertex V of the magnet is given by

$$\begin{cases} y_V=\dfrac{y_0\sqrt{1-K^2}}{K\sqrt{K(2-K)}+(1-K)\sqrt{1-K}} \\ z_V=z_0+\dfrac{Ky_0}{K\sqrt{K(2-K)}+(1-K)\sqrt{1-K}} \end{cases}, \tag{4}$$

where K is a parameter of the design defined as

$$K=\frac{\mu H_0}{J}. \tag{5}$$

Assume that an increasingly large access to the magnet is created by removing a portion of the larger triangle of the height h as indicated in Fig. 4. The effect of the opening on the uniformity of magnetic field is analyzed by expanding the magnetostatic potential in a series of spherical harmonics within a region of cavity close to the origin. In the two-dimensional configuration the harmonic expansion of the potential in polar coordinates r, ψ reduces to

$$\Phi=\frac{1}{2\pi\mu_0}\sum_j q_j r^j\cos(j\psi). \tag{6}$$

The fundamental term q_1 provides the intensity of the field at the origin. The $j>1$ terms, i.e., the distortion of the field, converge to 0 as $z_0\to\infty$.

The values of coefficients q_j for the lowest order harmonics are listed in Table I for increasingly large value of the opening h. The results demonstrate a decrease in field homogeneity caused by the opening.

TABLE I. The effect of magnet opening on the lowest order harmonics.

h	q_1	q_3	q_5	q_7
0.2	0.1913	0.0004	0.000 24	−0.000 09
0.4	0.1871	0.0006	−0.000 15	−0.000 14
0.6	0.1848	0.0021	−0.000 84	−0.000 02
0.8	0.1834	0.0030	−0.001 40	0.000 19

TABLE II. The effect of increasing length of active element.

z_2-z_1	q_1	q_3	q_5	q_7
1.0	−0.0055	−0.0099	0.0008	0.0013
0.8	−0.0061	−0.0065	0.0017	0.0010
0.6	−0.0057	−0.0037	0.0015	0.0003
0.4	−0.0043	−0.0018	0.0009	−0.0000

The values of the coefficient q_j of the harmonic expansion of Φ caused by the presence of a sandwich structure of different length z_2-z_1 are listed in Table II. As seen by comparing Tables I and II, a significant improvement of the field uniformity, in particular a total elimination of the coefficient q_3 is possible. For example, in an open magnet characterized by $h=0.8y_0$, elimination of coefficient q_3 is achievable either with a sandwich structure having length $z_2-z_1>0.6$ and a partial filling of the peripheral compartment, or with a shorter length and active material of remanence larger than in the main magnetic structure. It should be noted that this compensation of the field distortion is achieved at the expense of a minor (approximately 3%) reduction of the field intensity at the center of the magnet.

A sandwich structure containing three compartments in each quadrant separated using two gaps has two degrees of freedom and can therefore be used to compensate the open magnet for the harmonics q_3 and q_5 simultaneously. Neglecting the cross coupling between the two sections, the field generated by each section can be computed as the linear superposition of the individual fields, and the elimination of q_3 and q_5 in the open magnet can be achieved with practical values of the geometry and amount of active material.

IV. CONCLUSIONS

Active material placed between layers of ferromagnetic plates can be designed to eliminate the lowest order coefficients q_j of the open magnet. Because the active elements are shielded by layers of ferromagnetic material, a sandwich structure act as a spatial filter, eliminating lower order spatial harmonics without introducing high-order coefficients in the harmonic expansion.

Compared to the insertion of magnetic material alone, such sandwich structures offer the advantage that the precision of the fabrication procedure is confined to the shape of the ferromagnetic components. The final shimming of the magnet is achieved by changing the amount of magnetic material within the sandwich without concern about its location.

Equivalent structures of permanent magnets and electric currents designed to generate uniform fields

M. G. Abele
Department of Radiology, New York University School of Medicine, New York, New York 10016

Generation and confinement of a magnetic field by means of permanent magnets as well as time-independent electric currents are analyzed, and the conditions of existence of uniform field solutions are established in the general case of structures that enclose a region of arbitrary geometry. Basic properties of distributions of the electric currents are compared with the properties of yokeless structures of permanent magnets intended to generate the same uniform field within the same region.

I. INTRODUCTION

Both permanent magnets as well as electric currents can be designed to generate and confine the field without the need for shields of high magnetic permeability materials. In particular, a uniform field of intensity $\mathbf{H}_0$ can be generated in a volume V_0 of air, totally enclosed by a volume V_m which contains either a distribution of magnetized material or windings of electric currents designed to generate no field outside V_m. In the case of permanent magnets, if the magnetic material is assumed to have a linear demagnetization characteristic with zero magnetic susceptibility, the medium has the magnetic permeability of air everywhere.

II. STRUCTURES OF PERMANENT MAGNETS

Assume that $\mathbf{H}_0$ is uniform and V_m is composed of magnetized material where remanence $\mathbf{J}$, intensity $\mathbf{H}$, and induction $\mathbf{B}$ satisfy the equation

$$\mathbf{B}=\mu_0\mathbf{H}+\mathbf{J}, \tag{1}$$

where μ_0 is the magnetic permeability of a vacuum.

A uniform field $\mathbf{H}_0$ can be generated in a closed polyhedral region V_0 of arbitrary geometry.[1] In Fig. 1 s_h is a face of the polyhedron that interfaces with region V_m. In general V_m is a structure of polyhedrons V_{h1} that interfaces with V_0 and polyhedrons V_{h2} that interface with the surrounding medium. Vectors $\mathbf{J}_{h1}$ and $\mathbf{J}_{h2}$ are the remanences of regions V_{h1}, V_{h2} and the dotted line is the line of flux of $\mathbf{B}$. The computation of the remanences is provided by the vector diagram of Fig. 2, where μ_0 is assumed to be unity. One observes that $\mathbf{B}_{h2}$ in region V_{h2} is parallel to interface u_h between V_{h2} and the surrounding medium.

On an interface between media of remanences $\mathbf{J}_{h-1}$, $\mathbf{J}_h$ the remanences induce a surface charge density σ_h

$$\sigma_h=\boldsymbol{\eta}_h\cdot(\mathbf{J}_{h-1}-\mathbf{J}_h), \tag{2}$$

where $\boldsymbol{\eta}_h$ is a unit vector perpendicular to the interface and oriented from the medium of remanence $\mathbf{J}_{h-1}$ to the medium of remanence $\mathbf{J}_h$. A uniform field is generated everywhere if the values of σ_h and the orientations of the interfaces satisfy the condition

$$\sum_{h=1}^{n}\sigma_h\boldsymbol{\tau}_h=0 \tag{3}$$

at a point common to n interfaces.[1] On each interface unit vector $\boldsymbol{\tau}_h$ is parallel to the interface and is pointing away from the interface. An example of a yokeless permanent magnet that satisfies Eq. (3) and encloses a rectangular prismatic cavity is shown in Fig. 3.

III. STRUCTURES OF ELECTRIC CURRENTS

Assume now that the same polyhedral region V_0 is enclosed by a distribution of electric currents and assume an ideal situation where the currents reduce to surface distributions over the plane interfaces. In Fig. 4 surface current densities $\boldsymbol{\iota}_h$, $\boldsymbol{\iota}_{h+1}$ flow on interfaces s_h, s_{h+1} that are parts of the boundary of V_0. Interfaces s_h, s_{h+1} intersect each other along a line that passes through point S_h and is perpendicular to the plane of Fig. 4. The normal components of the intensities are continuous across s_h and the tangential components suffer a discontinuity

$$\boldsymbol{\iota}_h=\boldsymbol{\eta}_h\times(\mathbf{H}_h-\mathbf{H}_0), \tag{4}$$

where $\boldsymbol{\eta}_h$ is the unit vector perpendicular to s_h and oriented from the region of intensity $\mathbf{H}_0$ to the region of intensity $\mathbf{H}_h$. The currents on all the interfaces are perpendicular, and the magnetic field is parallel to the plane of Fig. 4. A surface current density must be generated on an interface ν_h in Fig. 4 in order to satisfy the boundary condition between the two regions of intensities $\mathbf{H}_h$, $\mathbf{H}_{h+1}$.

Assume that point S_h is common to n interfaces whose orientations are given by the unit vectors $\boldsymbol{\tau}_h$ defined in Eq. (3). Assume that S_h coincides with the origin O of a polar coordinate system. The intensity $\mathbf{H}$ of the magnetic field at a point P of coordinates (r,ψ) can be written in the form

$$\mathbf{H}=-\frac{1}{2\pi}\sum_{h=1}^{n}\boldsymbol{\iota}_h\left[(\ln r)\,\boldsymbol{\eta}_h+\left(\frac{\pi}{2}-\phi_h+\psi\right)\boldsymbol{\tau}_h\right]+\mathbf{H}_e, \tag{5}$$

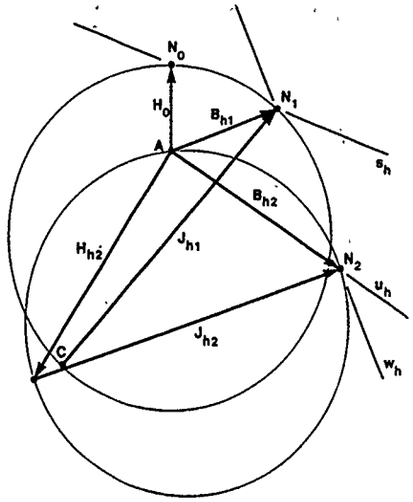

FIG. 2. Vector diagram of a yokeless magnetic structure.

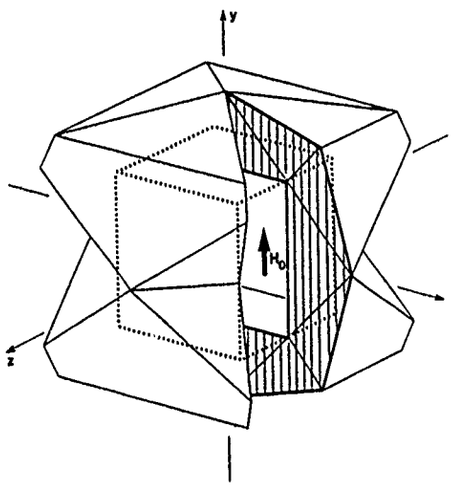

FIG. 3. Example of a permanent magnet. One octant is removed to show the details of the structure.

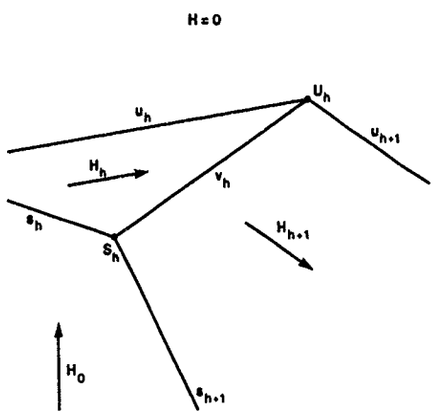

FIG. 4. Schematic of a yokeless structure of electric currents.

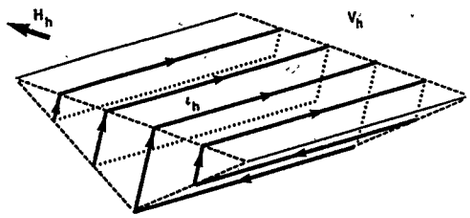

FIG. 5. Individual components of a structure of currents.

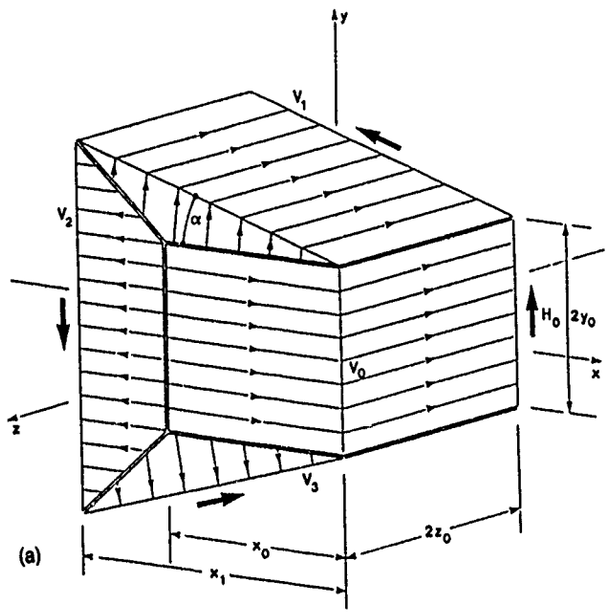
where ϕ_h is the orientation of the hth interface relative to $\psi=0$ and $\mathbf{H}_e$ is the field intensity generated by the other edges of the n interfaces and all other sources.

In Eq. (5), the singularity of $\mathbf{H}$ at $r=0$ cancels if the



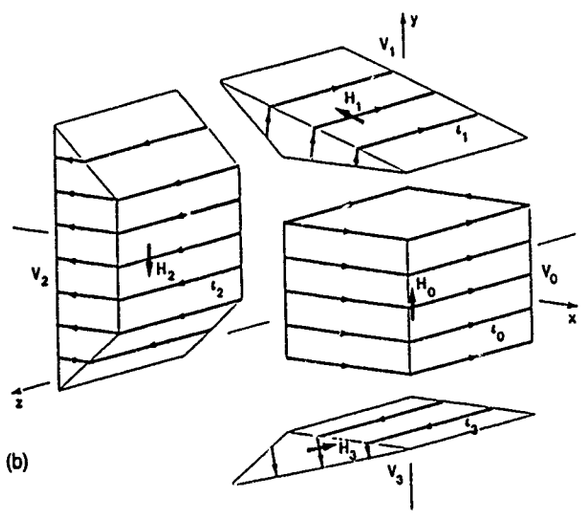


FIG. 6. Structure with rectangular prismatic cavity. Total structure (a). Exploded view (b).

current densities ι_h and the orientation of the interfaces satisfy the condition

$$\sum \iota_h \eta_h \quad \times \sum \iota_h \tau_h = 0, \tag{6}$$

where ζ is the unit vector oriented along the line common to the n interfaces. If $\mathbf{H}_e$ in Eq. (5) is uniform and Eq. (6) is satisfied at all points common to all the interfaces, a uniform field is generated in a region of arbitrary geometry enclosed by a structure of surface current densities, as in the case of a structure of magnetic materials described by Eq. (3).

The current distribution can be generated by a structure of independent windings around each region V_h where the field has the intensity $\mathbf{H}_h$ (Fig. 5). The current density on the surface of V_h is perpendicular to $\mathbf{H}_h$ and on each face of V_h it is equal to

$$\iota_{hk} = -\eta_{hk} \times \mathbf{H}_k, \tag{7}$$

where unit vector η_{hk} is perpendicular to the face and oriented outwards with respect to V_h. The superposition of the currents of the individual windings over the interfaces satisfies the boundary conditions between the regions of the structure. In particular, if interfaces u_h, u_{h+1} in Fig. 4 are parallel to $\mathbf{H}_h$, $\mathbf{H}_{h+1}$ and if current densities on u_h, u_{h+1} satisfy Eq. (6), then u_h, u_{h+1} can be the boundary of the structure of electric currents and the external medium where the field is zero.

Figure 6(a) shows a structure of four windings designed to generate a uniform intensity $\mathbf{H}_0$ within the rectangular prismatic cavity V_0, and to confine the field within the structure. Intensity $\mathbf{H}_0$ is assumed to be perpendicular to a face of V_0. Volume V_0 is enclosed by a winding with current density of magnitude $\iota_0 = H_0$ oriented perpendicular to $\mathbf{H}_0$. The other three windings around regions V_1, V_2, V_3 channel and close the flux of $\mathbf{B}$. The exploded view of the structure is shown in Fig. 6(b), with heavy arrows indicating the field intensities in the four components of the structure. The current distribution on the faces of V_1, V_3 perpendicular to $\mathbf{H}_0$, performs the function of deflecting the flux generated inside V_0.

The quality of a magnet is measured by its figure of merit, M, defined as the ratio of the energy of the field inside the region of interest V_0, to the total energy stored in the structure.[1] In the case of a permanent magnet

$$M = \frac{W_0}{W_m}, \tag{8}$$

where W_0 is the energy inside V_0 and W_m is the energy stored within the magnetized material during the magnetization process. The absolute maximum of M is 0.25 for structures of permanent magnets.[2] In a three-dimensional structure M is usually of the order of 0.1 or smaller. In structures of electric currents

$$M = \left(1 + \frac{1}{H_0^2 V_0} \sum_h H_h^2 V_h \right)^{-1}, \tag{9}$$

where the sum is extended to all components V_h of the structure with the exception of V_0. In the example of Fig. 6, Eq. (9) yields

$$M = \left[1 + \frac{x_1}{y_0} \frac{1}{\sin 2\alpha} + \frac{x_0}{x_1 - x_0} \left(1 + \frac{x_1}{2y_0} \tan \alpha \right) \right]^{-1}. \tag{10}$$

In the particular case of a cubic cavity V_0 with $x_0 = 2y_0 = 2z_0$, $x_1 = 2x_0$, and $\alpha = \pi/4$, Eq. (10) yields $M = 0.125$, which is significantly higher than what can be achieved in a three-dimensional permanent magnet.

IV. CONCLUDING REMARKS

A uniform field can be generated in a cavity enclosed by a structure of uniformly magnetized polyhedrons if the orientation of the interfaces between polyhedrons and the surface charge densities induced on the interfaces satisfy Eq. (3). The uniform field in the same cavity can be generated by a structure of electric currents uniformly distributed on plane surfaces if the orientation of these surfaces and the surface current densities satisfy the equivalent Eq. (6).

Thermal magnetic noise due to eddy currents in a strip wound ferromagnetic core at 4.2 K (abstract)

Yu. V. Maslennikov
Cryoton Co., Troitsk, Moscow

O. Snigirev
Department of Physics, Moscow University, Russia

M. Cerdonio, G. A. Prodi, and S. Vitale
Department of Physics, University of Trento, Italy

Many applications involving high impedance signal sources and use of the low input impedance SQUID magnetometer would take advantage of the use of low noise ferromagnetic cores in matching transformers. Noise in ferromagnetic cores at liquid helium temperatures has been shown to be limited by thermal fluctuation of the magnetization for the two following cases: for bulk cores,[1] where the skin effect sets a low frequency (<100 Hz) roll-off of the effective permeability, and the spectral density is white up to the roll-off, and for strip wound cores at frequencies lower than ≈100 Hz, where magnetic viscosity[2] gives origin to a frequency independent imaginary permeability and correspondingly to a $1/\omega$ shaped spectral density. Thanks to a high sensitivity dc SQUID magnetometer we have now been able to measure thermal noise due to the skin effect in a strip wound 15-μm-thick Ultraperm core where the roll-off frequency is ≈1 MHz. Data for the noise are in quite quantitative agreement with the prediction of the fluctuation dissipation formula and the measured values of $\mu(\omega)$. At frequencies lower than a corner ≈1 kHz the noise is again dominated by the $1/\omega$ tail due to magnetic viscosity. We discuss the relevance for applications.

Design of fast acting actuators for cryogenic valve applications in the ARIANE5-program (abstract)

Peter Schiebener, Alfred Pfeiffer, and Karl Smirra
Deutsche Aerospace AG, Space Transportation Systems and Propulsion, 81663 Muenchen, Germany

Presently valve developments are being carried out for the new European space launcher ARIANE5. In the case of the tank pressurization and helium supply system valve actuation times in the order of 20–50 ms, liquid hydrogen and liquid helium temperatures, pressures of up to 210 bar, and the need of a very compact volume lead to a requirement profile of the valve actuation unit which is met by directly controlled solenoid actuators with an additional permanent magnet. The modeling of the magnetic circuit comprises the elements of permanent magnets, solenoids, ferromagnetic materials, and several airgaps. The solutions of the model are gained by means of FE program the SYSMAGNA (out of SYSTUS®) which is capable of taking into account not only the time transients of the developing current in the solenoid but also moving parts in the magnetic field, which themselves contribute to the magnetic flux change. The results of major interest being calculated are the force versus stroke curves and the current versus time curves. The mechanical and magnetic properties of the employed materials are taken either from available data sources or from critically reviewed measurement data. Additionally, subsequently needed material characterizations were performed at ambient down to T=4 K. The simulation results are compared to static and dynamic test results and show good agreement. Finally the simulation proves to be very helpful to predict and explain the behavior of the complete valve unit consisting of actuator and flow part. Even effects due to cryogenic operation, which occur in the integrated valve, may be analyzed.

Barkhausen transitions in single layer and bilayer thin permalloy films

G. P. Farrell and E. W. Hill
University of Manchester, Department of Electrical Engineering, Manchester M13 9PL, England

The low coercivity of uniaxial thin nickel-iron multilayer films, prepared according to E. W. Hill, J. P. Li, and J. K. Birtwistle [J. Appl. Phys. **69**, 4526 (1991)], makes them attractive for magnetic sensor applications. Barkhausen jumps, causing noise, limit the performance of such sensors. It has been reported [R. F. Soohoo, J. Appl. Phys. **69**, 5871 (1991)] that, for any given sample under identical initial conditions, these Barkhausen jumps are deterministic rather than noisy in nature. This is consistent with the fact that the defect structure of a given sample is deterministic. This study compares power spectra and coercivity distributions from Barkhausen pulses obtained by applying varying alternating fields to thin permalloy films. The effect of an orthogonal bias field is also examined. The samples under examination consist of both single layer and bilayer films, produced as continuous layers by vacuum evaporation and ion milled into 40 mm diameter discs. The permalloy is of 80/20 composition and has a total thickness of 100 nm. The bilayer films have a nonmagnetic tantalum interlayer of thickness 5 nm. The rate of change of the applied field was varied between 2918.4 and 11.4 Oe/s, at an initial amplitude of 90 Oe. The results show that the Barkhausen pulses have a strong deterministic trend, but also contain a smaller nondeterministic component. As the frequency and amplitude are decreased, this random effect becomes larger. As might be expected when an orthogonal bias field is applied to the samples, the amplitudes of the pulses are decreased. The films also exhibit a corresponding reduction in coercivity.

INTRODUCTION

Despite the lower coercivity offered by thin nickel-iron bilayer films as compared to single layer films of the same magnetic layer thickness, the noise performance of bilayer films may be a more important consideration in considering them as thin film flux-switching sensor cores. Examination of the switching properties of both single layer and bilayer films used as cores in fluxgate-type sensors shows that although there is a large deterministic effect, which provides an envelope for the shape of the overall transition, there is also a smaller random component which produces variations from cycle to cycle (Fig. 1). This random component remains even when identical initial conditions are ensured by completely sweeping all of the domains from the material, a process which may be verified by using the Bitter colloid method for domain observation. Such observation shows that a field of 30–40 Oe is required to sweep out all of the domains from a disc sample 100 nm thick and 40 mm in diameter. By treating the deterministic effect as the signal contribution and the random component as the noise contribution, an estimation of the Barkhausen noise in a sample may be made.

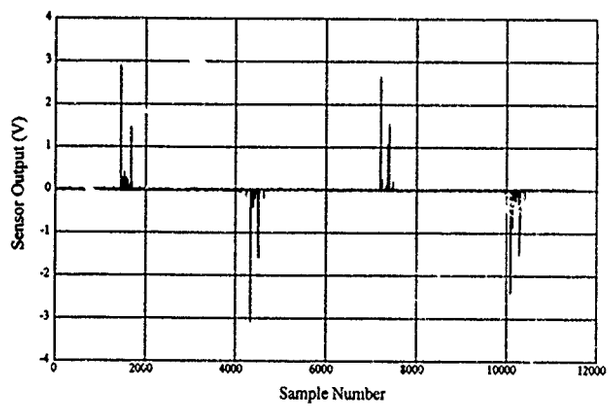

FIG. 1 Sensor output from consecutive cycles. Clear differences can be seen between the pulses, although the general shape remains similar.

BACKGROUND

As the switching process is influenced by the microstructure of the magnetic layer, which is fixed and hence deter-

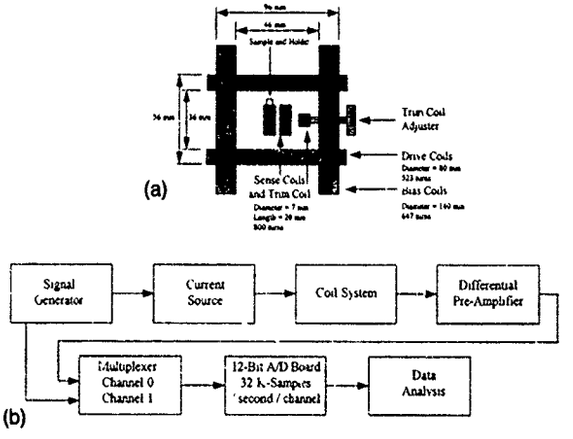

FIG. 2. (a) The coil measurement system. The sample was held in one of the sense coils and the trim coil used to balance offsets between the sense coils. The sample was swept around a hysteresis loop by the field generated by the drive coils, and an orthogonal field applied by the bias coils. (b) The data capture system. Data analysis was performed on a HP 700 workstation.

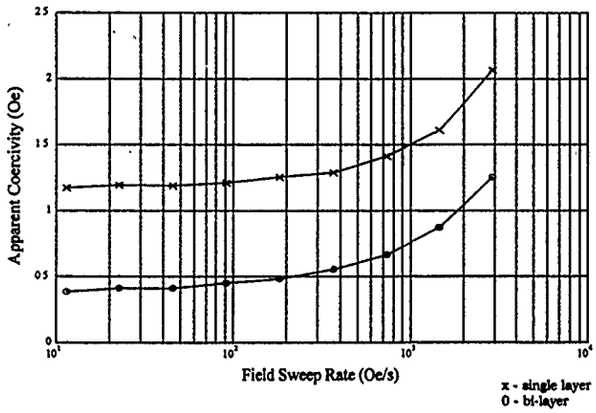

FIG. 3. The variation in coercivity with field sweep rate.

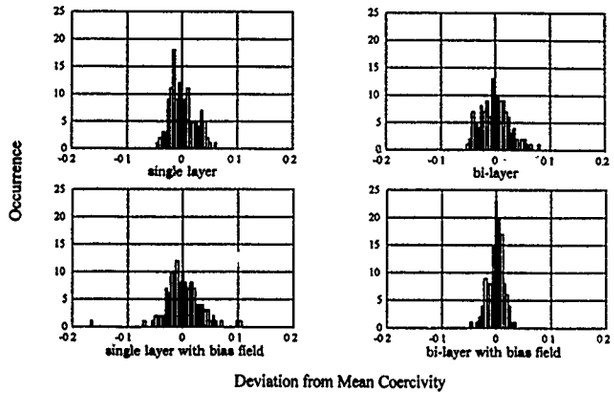

FIG. 5. (a)–(d) Distribution of coercivity from the mean value over 128 cycles. The application of a bias field causes the noise in the single layer film to increase and that in the bilayer film to decrease.

ministic for a given sample, it is reasonable to expect the Barkhausen transitions to also have a deterministic nature.[1] However, it is also important to consider the transitions as the movement of walls over energy barriers, which will be subject to the effect of random thermal perturbations. Thus, one measure of the noise in the material might be obtained by examining the variations in the coercivity from cycle to cycle. The distribution of such noise might be expected to be Gaussian, with the mean value equal to the true coercivity of the sample.

A second method of illustrating the random perturbations may be achieved by considering the integrated output of the sensor. In the absence of noise, this will have the form of a train of pulses at the same frequency as the sweep rate. If noise is present in the system, however, the pulses will exhibit small variations in frequency. Thus, a power spectrum should show an underlying trend giving the noise power, with spikes at the drive frequency and its harmonics. The ratio of the power at the fundamental frequency to the power at the same frequency, with the effect of the fundamental removed, might be used as a measure of the deterministic nature of the effect.

Assuming that one source of the noise might be a random variation in the direction of rotation of the magnetic moments during switching, it may be possible to reduce this noise by creating a preferred rotation direction. This is achieved by applying a small orthogonal hard axis bias field to the samples. One consequence of such a bias field will be a reduced output from the sensor as the dipoles will no longer be rotating through a full 180°. However, if the noise is reduced significantly, the signal to noise ratio (SNR) may be improved.

MEASUREMENT METHOD

The cores consist of 100 nm of magnetic material vacuum evaporated onto a 100 μm thick glass substrate, with a 5 nm tantalum spacer in the bilayer films.[2] Both types of film were produced on the same substrate as continuous layers, at a temperature of 300 °C and working pressure of 2×10^{-7} mbar. After the deposition, 40 nm diameter discs were masked off using a photolithographic technique and the films were ion milled to produce the disc shaped samples required. The discs were then mounted on thin plastic strips for ease of handling.

Measurements were performed by placing a sample in a coil system as shown in Fig. 2(a). The coil system was itself placed in a six layer mumetal enclosure. The field was swept linearly in time around the hysteresis loop in the direction of the easy axis of the sample, with at least 50 complete cycles

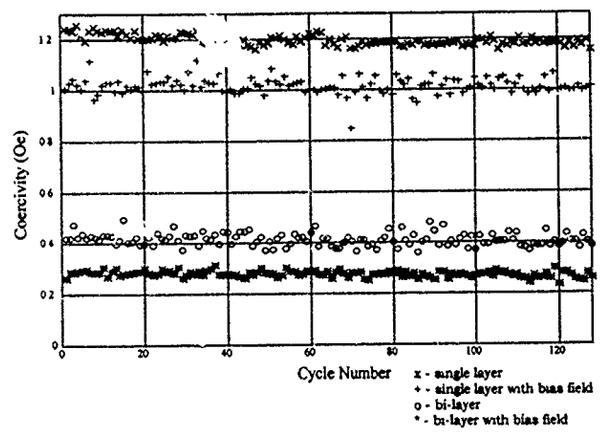

FIG. 4. (a)–(d) Variation in coercivity over 128 cycles. A reduction coercivity is observed when the bias field is applied.

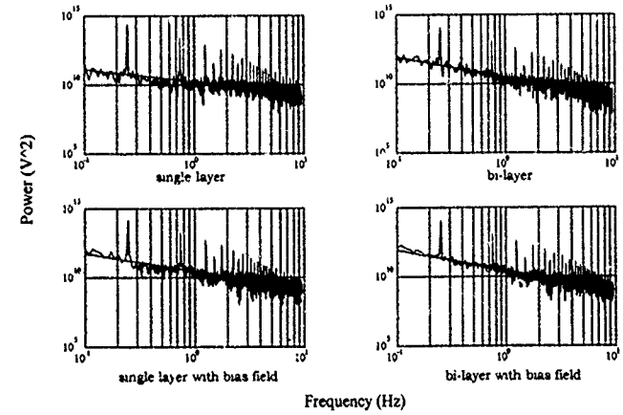

FIG. 6. (a)–(d) Power spectral densities. A linear trend to the Barkhausen noise is observed, with peaks at the effective drive frequency and its harmonics.

TABLE I. Power law dependence on frequency and signal to noise ratio results. The single layer film maintains a better SNR in the presence of a bias field, despite having an increased noise content. The bilayer film shows little change when the bias field is applied.

	Power law dependence on frequency (V^2/Hz)		Signal to noise ratio					
			0 Oe bias field			2 Oe bias field		
	0 Oe bias field	2 Oe bias field	Signal (V^2)	Noise (V^2)	SNR	Signal (V^2)	Noise (V^2)	SNR
Single layer	−0.88	−1.30	2.2×10^{14}	5.9×10^{10}	3729	1.5×10^{14}	1.7×10^{11}	882
Bilayer	−1.49	−1.47	1.1×10^{14}	2.3×10^{11}	478	1.1×10^{14}	2.2×10^{11}	500

being completed before any measurements were taken to provide a consistent starting point. The output of the sensor and the corresponding drive field were captured around each cycle via a 12-bit analog-to-digital (A/D) converter running at 32 K samples power second per channel. In all, 128 complete cycles were captured for each sample, at a range of field sweep rates varying between 2918.4 and 11.4 Oe/s with an amplitude of 90 Oe. Further measurements were then taken at a field sweep rate of 22.8 Oe/s and the same amplitude, with an orthogonal bias field of 2 Oe applied in the hard axis direction. The flow of data through the system is summarized in Fig. 2(b).

RESULTS

Figure 3 shows the apparent coercivity at each of the field sweep rates. A trend towards higher values appears at sweep rates greater then 100 Oe/s, possibly due to the inductance effects of the coil system, eddy currents in the sample, or the effect of sampling itself. Therefore, only results obtained at sweep rates lower than 100 Oe/s are considered here.

Figure 4 shows the variation in coercivity for each sample, with and without the bias field, at one sweep rate, namely, 22.8 Oe/s, over 128 cycles. The value for coercivity is obtained by integrating the pulses from each cycle, and taking the average of the field values at the median points. The mean coercivity for each sample in the absence of any bias field agrees well with the value measured by plotting the hysteresis loops on a magnetometer. Figure 5 shows the distributions of the coercivicites, centered at zero for comparison purposes. With no bias field, the single layer film has a standard deviation of 0.0224 Oe, compared with 0.0260 Oe for the bilayer, suggesting that the noise in the two films is similar. The distributions are not truly normal, as expected, but instead exhibit some positive skew. This would suggest an asymmetrical hysteresis curve as the material is swept from one saturation state to the other, with more but smaller pulses as the film re-enters saturation due to the pinning of small domains at the edges of the material. When the film is subjected to an orthogonal hard axis bias field of 2 Oe, approximately one-half of the anisotropy field of the material, the standard deviations are 0.0324 Oe for the single layer and 0.0137 Oe for the bilayer. Thus, the noise in the single layer film has increased and that in the bilayer film has decreased. This is contrary to expectations, which suggested that the noise in both films should be decreased. The distributions appear to be more normally shaped, indicating more symmetry in the hysteresis loop around the switching point.

A comparison of the graphs in Fig. 4 shows that when the bias field is applied the coercivities of each film are reduced by around 0.2 Oe, probably due to an initial partial rotation of the magnetization.

Figure 6 shows power spectra for the samples, both with and without the bias field. The power law dependence on frequency is equal to the gradient of the line, and this value and the signal to noise ratio for each sample are given in Table I below.

These results show that for the single layer the bias field has a significant effect, increasing the power law dependence on frequency and dramatically reducing the SNR due to a reduced signal level and an increased noise level. For the bilayer film, the effect of the bias field is reversed; the power dependence on frequency is reduced and the SNR is increased, although this effect is small due to a similar reduction in both the signal and noise levels. Overall, however, the single layer film still has the better SNR.

CONCLUSIONS

Both the single layer and bilayer films show deterministic and nondeterministic components, with the nondeterministic components being similar in the absence of any bias field. A small hard axis bias field reduces the nondeterministic component in the bilayer film, but increases it in the single layer. Further work is required to relate this study to actual magnetization distributions in thin films.

Equation of motion of domain walls and equivalent circuits in soft ferromagnetic materials

G. Aguilar-Sahagun, P. Quintana,[a] E. Amano, J. T. S. Irvine,[b] and R. Valenzuela
Institute for Materials Research, National University of Mexico, Apartado Postal 70-360, Mexico D. F. 04510, Mexico

The equation of motion for ferromagnetic domain walls is compared with initial permeability measurements of Co-based soft ferromagnetic amorphous ribbons at frequencies in the range 100 Hz–13 MHz. The analysis of these results by complex permeability methods leads to an equivalent circuit formed by a parallel RL arrangement in series with a small resistance R_W due to resistance of the measurement coil. This equivalent circuit, however, cannot model the irreversible magnetization behavior for fields higher than the pinning (or propagation) field. It is shown that the equation of motion is also consistent only with the reversible magnetization mechanism, if the displacement term, x, represents instead the bulging of the pinned wall. The correlations between the terms in the equation of motion and the elements of the equivalent circuit are established.

I. INTRODUCTION

Domain wall dynamics in soft ferromagnetic materials are expected to be described by an equation of the form[1,2]

$$m\ d^2x/dt^2+\beta\ dx/dt+\alpha x=2M_sH(t), \tag{1}$$

where m is the effective wall mass, β is the viscous damping factor, α the restoring force, M_s the saturation magnetization, $H(t)$ the time-dependent field, x the wall displacement, and t the time. The domain structure is assumed to have a linear geometry with 180° walls with d spacing; magnetization variations are produced by displacements of flat walls. An interesting approximation, leading to the concept of propagation or pinning field, is the displacement of domain walls at a constant velocity, v, under the "pressure" of a constant field, H. Since the acceleration and restoring force terms dissappear. Eq. (1) becomes

$$v=CH, \tag{2}$$

where $C=2M_s/\beta$ is the mobility. Experimentally, these conditions clearly showed[3] the existence of a "propagation" or "pinning" field, H_p, below which there is no wall displacement. Therefore, Eq. (2) should be written

$$v=C(H-H_p), \quad \text{(valid for} \quad H\geq H_p). \tag{3}$$

Equation (1) can be solved[4] for the stationary, forced oscillation condition of a driving field $H=H_0\ \exp(-j\omega t)$, in terms of the real and imaginary parts of the susceptibility, χ. For high-permeability materials, $4\pi\chi\sim\mu$, the real and imaginary parts of the permeability can be written as

$$\mu'=\mu_0\alpha/[\alpha^2+(\beta\omega)^2], \tag{4}$$

$$\mu''=\mu_0\beta\omega/[\alpha^2+(\beta\omega)^2], \tag{5}$$

where μ' and μ'' are the real and imaginary parts of the permeability, respectively, j is $(-1)^{1/2}$, μ_0 is the low-frequency limit of the permeability, ω is the angular frequency, and H_0 the amplitude of the applied field. Two simple cases can be considered, depending on the relative values of the effective mass and the damping terms: if $m\ll\beta$, a relaxation occurs at a relaxation frequency

$$\omega_x=\alpha/\beta. \tag{6}$$

If $m\sim\beta$, the dispersion has a resonant character with a resonance frequency

$$\omega_s=(\alpha/m)^{1/2}. \tag{7}$$

To our knowledge, however, these equations have never been used to describe domain wall displacements ($H>H_p$) as a result of cyclic fields. Experimental spectra corresponding to the bulging mechanism (or initial permeability, $H<H_p$) are usually closer to the relaxation behavior, both in ceramic materials[5,6] and in amorphous, metallic alloys;[7] in a few cases, a resonant character has been observed,[4,8] but this also for the initial permeability conditions.

In this article, we present measurements of complex permeability as a function of frequency in amorphous soft ferromagnetic ribbons for ($H<H_p$); these results are analyzed in terms of an equivalent circuit and compared with the equation of motion.

II. EXPERIMENT

The preparation of toroids by wound ribbons of Vitrovac® 6025 (nominal composition $Co_{66}Fe_4Mo_2Si_{16}B_{12}$, prepared by melt spinning by Vacuumschmelze), as well as the measurement techniques have been described elsewhere.[7] Prior to magnetic measurements, ribbons were annealed at 300 °C for 2 h in argon atmosphere to relieve stresses produced during the preparation process. Complex permeability, μ^*, is determined from impedance, Z^*, by

$$\mu^*=(-jK/\omega)Z^*, \tag{8}$$

where K is the geometrical factor.[7]

III. EXPERIMENTAL RESULTS

Real permeability spectra at low fields showed a constant behavior at low frequencies, followed by a dispersion with a relaxation character, Fig. 1. A small permeability value subsists for the high frequency range studied. All ex-

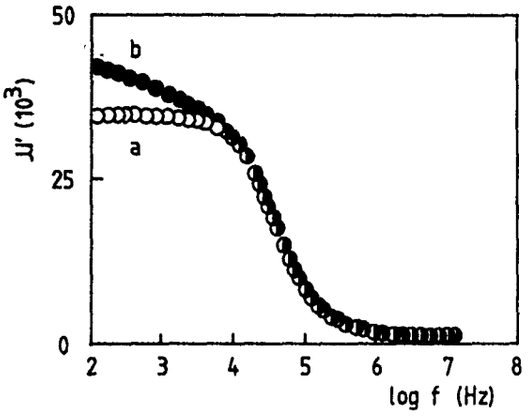

FIG. 1. Real permeability spectra (a) for field amplitude of $H=0.5$ A/m ($H_p \sim 0.6$ A/m), and (b) $H=0.8$ A/m.

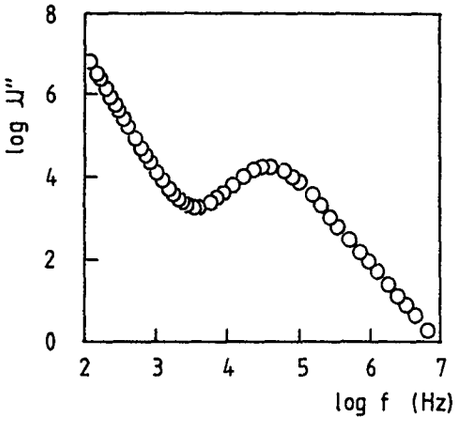

FIG. 3. Imaginary part of the permeability as a function of frequency for the low field experiment.

periments performed at $H<0.4$ A/m (5 mOe) resulted in the same curve. For higher fields, the permeability for low frequencies depended on the field value, but as frequency increased, all the curves merged into the low field plot, and therefore the relaxation behavior was the same for all of them, independently of the field, Fig. 1. A useful data representation is the complex permeability plot, μ' vs μ'', Fig. 2. For $H<H_p$, a vertical spike is followed by a semicircle, as frequency increases, whereas for fields higher than H_p, the spike becomes inclined and deviates from the semicircle beginning. A third, complementary plot is the μ'' spectrum, Fig. 3, where the relaxation frequency appears as a maximum. In simple cases, it is possible to guess the equivalent circuit describing the experimental results from the geometry of this plot. In the present case, the obtained semicircle can be associated with a parallel, RL arrangement. The presence of a vertical "spike" in Fig. 2 and a (-1) slope for the low frequency range in Fig. 3 indicate an additional resistance term, R_W, in series with the parallel arrangement. It can be shown[9] that this term is simply the coil resistance.

The permeability behavior at fields higher than the propagation field cannot be modeled by means of an equivalent circuit with ideal RL elements, since inclined spikes such as those in Fig. 2 involve impedances where the real part also depends on frequency. Warburg impedances of the form $Z_W=(1+j)\omega^{\delta}A$, where δ and A are constants, have been suggested[10] to represent these results.

The relaxation frequency, ω_x, can be determined from the maximum in $\mu''(\omega)$ plots, Fig. 3; it corresponds to the condition $\mu'=\mu''=\mu_0/2$ and is therefore related to the equivalent circuit elements given by the relationship

$$\omega_x=R/L. \tag{9}$$

Relaxation frequency ω_x has been verified[9] to correspond to the intrinsic domain wall relaxation frequency and not to a parasitic, electrical relaxation.

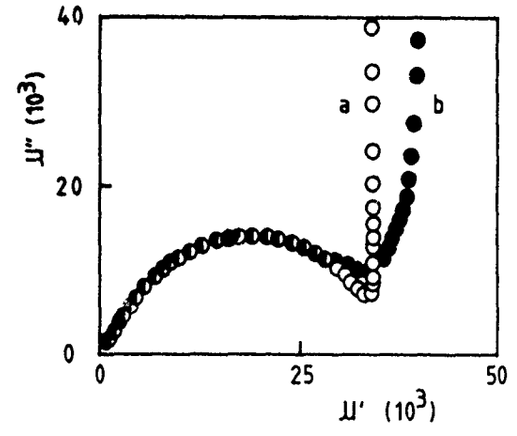

FIG. 2. Complex permeability plot for samples of Fig. 1.

IV. DISCUSSION

The complex permeability analysis allows the resolution of three magnetization mechanisms; at $H<H_p$, domain walls are pinned to defects and the field produces a reversible bulging, responsible for initial permeability. As frequency increases, a relaxation occurs resulting in a decrease of permeability; a small permeability value, presumably due to the spin rotation mechanism, which is expected to have the smallest time constant, persists at the highest measuring frequency in our system.

For high fields ($H>H_p$), domain walls are unpinned and displaced; however, this mechanism, possessing a large time constant, involves several steps (bulging, unpinning, displacement, repinning in a new position, debulging, etc.) in each cycle, and cannot be modeled by means of ideal elements in the equivalent circuit.

From this analysis, it appears that the mechanism responsible for the observed relaxation is wall bulging. If x is the bulging of the wall (and assuming a given geometry for the deformation), experimental results can be represented by Eq. (1), as well as by the parallel RL circuit. Since the use of the equivalent circuit approach has many advantages, it would be very useful to find some associations with the terms in the equation of motion approach.

The term of equivalent inductance L is clearly related to initial permeability by the geometrical factor ($\mu_0=KL$). The

permeability value therefore depends on the extent of wall bulging, which in turn depends on the domain wall energy, γ. A domain wall pinned along two edges with a cylindrical bulging has a dc permeability[1]

$$\mu_0=(8\pi M_s^2 d)/(9\gamma), \tag{10}$$

where d is the distance between pinning edges and γ is the wall energy. The restoring force terms depends[1] on the wall energy as

$$\alpha=18\gamma/d^2. \tag{11}$$

L is therefore related to α by the expression

$$L=[16\pi M_s^2/Kd](1/\alpha). \tag{12}$$

Due to its dissipative nature, the damping term, β, should be related to the equivalent resistance, R. From the expressions for the relaxation frequency, Eqs. (6) and (9), and taking into account Eqs. (10)–(12)

$$R=[16\pi M_s^2/Kd](1/\beta). \tag{13}$$

In order to obtain a resonance, a non-negligible effective mass and a capacitance are needed in the equation of motion and the equivalent circuit approaches, respectively. At this point, and taking into account the form of Eq. (7) and that of a resonant circuit, $\omega_s=(1/LC)^{1/2}$, it can be shown that

$$C=[Kd/16\pi M_s^2]m. \tag{14}$$

These correlations are extremely useful since some of the microscopic parameters such as wall energy, damping, and pinning can therefore be evaluated through the circuit elements from simple, macroscopic measurements as a function of frequency.

V. CONCLUSIONS

It has been shown that the equation of motion for domain walls, in its simple form, can describe the dynamics of pinned domain walls if the displacement term, x, represents instead the wall bulging. Domain wall displacements in real materials, involving a threshold field and bulging are too complex to be described by this equation. It has also been shown that the equivalent circuit approach is consistent with the equation of motion for the bulging mechanism. Finally, the correlations between the terms in both models, Eqs. (12), (13), and (14), have been established.

Pinned domain-wall structure in magnetic field

Chai Tak Teh, Huei Li Huang, and Vladimir L. Sobolev[a)]
Department of Physics, National Taiwan University, Taipei, Taiwan, Republic of China

The pinned domain-wall (DW) structure is investigated using a perturbational approach in terms of the inverse quality factor $1/Q$ and the ratio of $H_\parallel/H_k$ ($H_\parallel$ being the component magnetic field parallel to the anisotropy axis, H_k being the anisotropy field). The parallel component field gives rise to asymmetric boundary conditions which asymmetrize the DW structure. Dependence of the DW energy, static DW structure, and width on the orientation and the strength of the magnetic field has been evaluated and the corresponding Kondorsky function obtained.

I. INTRODUCTION

The structure of a resting domain wall (DW) under the action of an external magnetic field has already been treated in a number of articles (see Refs. 1 and 2 and the references therein). Nevertheless, the case of having the magnetic field arbitrarily oriented with respect to the wall normal and the anisotropy axis has not been sufficiently investigated to date. Such a problem may be considered as a reasonable one if the material has a high enough coercivity since otherwise, the presence of a component field along the anisotropy axis could lead to the DW movement.

Consider a uniaxial magnetic material with the material quality factor Q ($Q=K/2\pi M_s$, K being the anisotropy constant and M_s the saturation magnetization) larger than unity and a high enough coercivity field, but far less than the anisotropy field, $H_c<H_K$ ($H_K=2K/M$). The DW is considered to be pinned and parallel to the x-z plane, and the z axis coincides with the anisotropy axis of the ferromagnet. The orientation of the external magnetic field is

$$\mathbf{H}=H(\sin\theta_H\cos\psi_H,\sin\theta_H\sin\psi_H,\cos\theta_H).$$

The polar axis is along the anisotropy axis. There is one restriction imposed on the external field. It requires the component field along the anisotropy axis, denoted as $H_\parallel$, to be less than the coercivity field of the material, $H_\parallel<H_c$.

In this article we present a detailed analysis of the effect of external field on the distribution of the magnetization inside domains and the DW. The variation of the DW energy, etc., are expounded. A new Kondorsky function[4-6] based on the DW energy obtained herewith is also presented.

II. DOMAIN-WALL STRUCTURE

The energy density for a DW in a uniaxial ferromagnet may be written as follows:

$$W=K[\Delta_B^2(\vartheta'^2+\sin^2\vartheta\varphi'^2)+(\sin\vartheta\sin\varphi-\mu)^2Q^{-1}-2h_t\sin\vartheta\cos(\varphi-\psi_H)+\sin^2\vartheta-2h_\parallel\cos\vartheta], \quad (1)$$

where ϑ is the polar angle, φ the azimuthal angle of the magnetization vector, $\Delta_B^2=A/K$ is the width of the Bloch wall; A is the exchange stiffness constant; $\vartheta'\equiv d\vartheta/dy$, $\varphi'\equiv d\varphi/dy$; $h_t=h\sin\theta_H$ is the transverse external field component; $h_\parallel=h\cos\theta_H$ is the longitudinal field component; $h=H/H_K$; and μ is the limiting value of the magnetization component normal to the DW when it is at a distance from the DW inside domains. The term proportional to Q^{-1} describes the demagnetization field contribution to the energy. This term can be obtained naturally by means of solving the demagnetization integral[3] subjected to continuity conditions normal to the DW plane.

The equilibrium orientations of the magnetization vectors inside domains are obtained by means of the variation of the energy density,

$$W_D=K[\sin^2\vartheta-2h_t\sin\vartheta\cos(\varphi-\psi_H)-2h_\parallel\cos\theta], \quad (2)$$

from which it is easy to obtain

$$\sin\vartheta\cos\vartheta-h_t\cos\vartheta+h_\parallel\sin\vartheta=0, \quad (3)$$

$$\varphi=\psi_H. \quad (4)$$

It is worthy of note that two solutions of the Eq. (3) have the form

$$\vartheta_1=\vartheta_{10}, \quad \text{and} \quad \vartheta_2=\pi-\vartheta_{20}, \quad (5)$$

which serve as the boundary conditions for the determination of the magnetization distribution inside DW. The angles ϑ_{10} and ϑ_{20} are the solutions of the equations[5]

$$\sin\vartheta_{j0}\cos\vartheta_{j0}-h_t\cos\vartheta_{j0}+(-1)^{j-1}h_\parallel\sin\vartheta_{j0}=0, \quad j=1,2. \quad (6)$$

The equations describing the distribution of the magnetization inside the DW may be obtained by the variation of Eq. (1). As a result we obtain

$$\Delta_B^2\vartheta''-\sin\vartheta\cos\vartheta\varphi'^2-\sin\vartheta\cos\vartheta-Q^{-1}(\sin\vartheta\sin\varphi-\mu)\cos\vartheta\sin\varphi+h_t\cos\vartheta\cos(\varphi-\psi_H)-h_\parallel\sin\vartheta=0, \quad (7)$$

$$(\sin^2\vartheta\varphi')'-Q^{-1}(\sin\vartheta\sin\varphi-\mu)\sin\vartheta\cos\varphi-h_t\sin\vartheta\sin(\varphi-\psi_H)=0. \quad (8)$$

To look for the solution of Eqs. (7) and (8) for materials with a large Q value we represent the magnetization angles in the following form:

$$\vartheta(y)=\vartheta^{(0)}(y)+Q^{-1}\vartheta(y), \quad \varphi=\varphi^{(0)}(y)+Q^{-1}\phi(y), \quad (9)$$

where $\vartheta^{(0)}(y)$ and $\varphi^{(0)}(y)$ are the zeroth-order solution, respectively, of ϑ and φ. Upon substitution of Eq. (9) into Eqs.

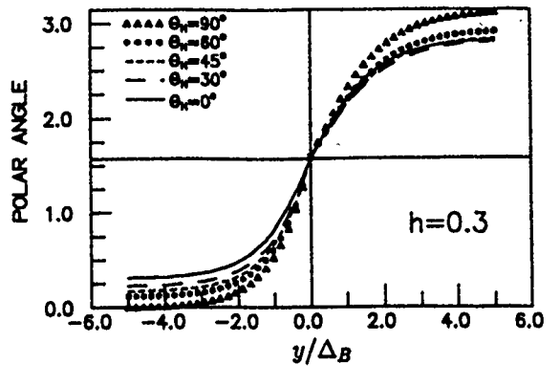

FIG. 1. Variation of the polar angle of the magnetization along the wall normal u $(=y/\Delta_B)$ for several values of θ_H at $h=0.3$.

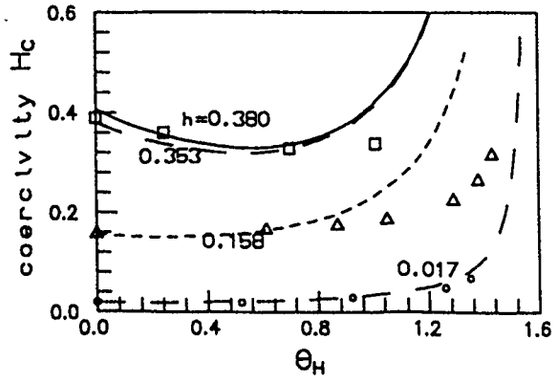

FIG. 3. Variation of the Kondorsky function vs the field angle θ_H for several h values. The data points were from Ref. 3 for barium ferrite.

(7) and (8) we get a new system of equations in accordance with the order parameter Q^{-1}. In the zeroth order, we obtain

$$\Delta_B^2\vartheta^{(0)\prime\prime}-\sin\vartheta^{(0)}\cos\vartheta^{(0)}\varphi^{(0)\prime 2}-\sin\vartheta^{(0)}\cos\vartheta^{(0)}$$
$$-h_t\cos\vartheta^{(0)}\cos(\varphi^{(0)}-\psi_H)-h_\parallel\sin\vartheta^{(0)}=0, \quad (10)$$

$$(\sin^2\vartheta^{(0)}\varphi^{(0)\prime})'-h_t\sin\vartheta^{(0)}\sin(\varphi^{(0)}-\psi_H)=0. \quad (11)$$

Equation (11) has a solution $\varphi^{(0)}=\psi_H$ corresponding to a deviation of the azimuthal angle inside domain from its initial equilibrium value $\varphi=0$ due to the action of an external field. Substituting this into Eq. (10) we obtain

$$\Delta_B^2\vartheta^{(0)\prime\prime}-\sin\vartheta^{(0)}\cos\vartheta^{(0)}-h_t\cos\vartheta^{(0)}-h_\parallel\sin\vartheta^{(0)}=0, \quad (12)$$

This equation is exact. To solve this equation we need the boundary conditions set forth in Eq. (6) which describes the magnetization distributions inside domains. Note that $h_\parallel$ is assumed to be small, satisfying the condition $H_\parallel<H_c$, $H_\parallel\ll H_K$, in keeping with the earlier assumption. From ϑ_{01} and ϑ_{02} given in Eqs. (5) and (6) one obtains

$$\sin\vartheta_{10}=\sin\vartheta_0-h_\parallel\tan\vartheta_0+h_\parallel^2\tan\vartheta_0/\cos\vartheta_0,$$
$$\sin\vartheta_{20}=\sin\vartheta_0+h_\parallel\tan\vartheta_0+h_\parallel^2\tan\vartheta_0/\cos\vartheta_0. \quad (13)$$

These equations describe the boundary conditions for the magnetization distributions inside domains 1 and 2, in which

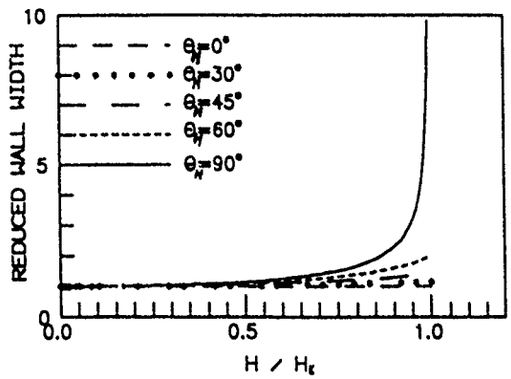

FIG. 2. Variation of the reduced DW width, Δ/Δ_B, vs the field strength for several field angle θ_H's.

$\sin\vartheta_0=h_t$. Thus, the corresponding first integral in domains 1 and 2 is slightly different from each other. The first integral of Eq. (12) is expressed as

$$\left(\frac{d\vartheta}{du}\right)^2=(\sin\vartheta-\sin\vartheta_0)^2-2h_\parallel(\cos\vartheta\mp\cos\vartheta_0)$$
$$+h_\parallel^2\tan\vartheta_0, \quad (14)$$

where $\vartheta(u)\equiv\vartheta^{(0)}(u)$ and $u=y/\Delta_B$ for brevity; the minus and plus sign refers to domains 1 and 2, respectively, separated by the DW.

The solutions describing the distribution of the magnetization inside domains 1 and 2, lying in the intervals $-\infty<u\leq 0$ and $0\leq u\leq\infty$, are

$$\sin\vartheta_1=\sin\vartheta_0+\frac{\cos^2\vartheta_0}{\cosh w_1+\sin\vartheta_0}$$
$$+\frac{h_\parallel}{2}\frac{\sinh w_1}{\cosh w_1+\sin\vartheta_0}\left(\tan\vartheta_0+e^{w_1}\sec\vartheta_0\right.$$
$$\left.+\frac{3\tan\vartheta_0\sinh w_1}{\cosh w_1+\sin\vartheta_0}\right), \quad (15)$$

$$\sin\vartheta_2=\sin\vartheta_0+\frac{\cos^2\vartheta_0}{\cosh w_2+\sin\vartheta_0}$$
$$-\frac{h_\parallel}{2}\frac{\sinh w_2}{\cosh w_2+\sin\vartheta_0}\left(\tan\vartheta_0+e^{-w_2}\sec\vartheta_0\right.$$
$$\left.-\frac{3\tan\vartheta_0\sinh w_2}{\cosh w_2+\sin\vartheta_0}\right), \quad (16)$$

up to the first order in $h_\parallel$. In these formulae $w_{1,2}=u\cos\vartheta_0/(1\mp ah_\parallel)$, $a=1+2\sin^2\vartheta_0/2\cos^3\vartheta_0$. For small $h_\parallel$, the above results reduce exactly to the earlier one.[7]

III. DW ENERGY AND DW WIDTH

Equations (15) and (16) describe an asymmetric DW structure. Making use of these expressions the energy density of the DW is expressed as

$$\epsilon_{DW}=\int dy(W_{DW}-W_D)$$

$$=K\left(\frac{\Delta_B^2}{\Delta\cos\vartheta_0}f+\Delta g\cos\vartheta_0\right) \tag{17}$$

where Δ is a field-dependent DW width, and

$$f(\vartheta_0,h_\parallel)=2\left[\cos\vartheta_0-\left(\frac{\pi}{2}-\vartheta_0\right)\sin\vartheta_0\right]+h_\parallel^2F(\vartheta_0), \tag{18}$$

$$g(\vartheta_0,h_\parallel)=2\frac{Q+\sin^2\psi_H}{Q}\left[\cos\vartheta_0-\left(\frac{\pi}{2}-\vartheta_0\right)\sin\vartheta_0\right]$$

$$+h_\parallel^2G(\vartheta_0). \tag{19}$$

In these expressions

$$F(\vartheta_0)=-\sec^3\vartheta_0\left[1-\sin^4\vartheta_0-\frac{1+\sin^2\vartheta_0}{2}\right.$$

$$\left.\times\left((\sqrt{2}-1)\tan^2\vartheta_0+\ln\frac{1-\sin\vartheta_0}{2\cos^2\vartheta_0}\right)\right], \tag{20}$$

$$G(\vartheta_0)\simeq\sec^3\vartheta_0\left\{\frac{2\ln 2\sin^2\vartheta_0+\ln 2-2}{4}\right. \tag{21}$$

$$\left.+\frac{1+\sin^2\vartheta_0}{4\cos^3\vartheta_0}\left[\cos\vartheta_0-\left(\frac{\pi}{2}-\vartheta_0\right)\sin\vartheta_0\right]\right\}, \tag{22}$$

in which the contributions on the order of Q^{-1} are omitted from the above expressions.

Upon minimization of Eq. (17) with respect to Δ the effective DW width can be expressed as

$$\Delta^2=\frac{\Delta_B^2f(\vartheta_0,h_\parallel)}{\cos^2\vartheta_0g(\vartheta_0,h_\parallel)}, \tag{23}$$

and the DW energy density is

$$\sigma=\tfrac{1}{2}\sigma_0\sqrt{f(\vartheta_0,h_\parallel)g(\vartheta_0,h_\parallel)}, \tag{24}$$

where $\sigma_0=4\sqrt{AK}$ is the Bloch wall energy density in the absence of the external magnetic field.

The dependence of the DW energy on the external field orientation can be obtained easily by substitution of the expression $\sin\vartheta_0=h\sin\theta_H$ into

$$\sigma=\sigma_0\left[\cos\vartheta_0-\left(\frac{\pi}{2}-\vartheta_0\right)\sin\vartheta_0\right]+O(h_\parallel^2)$$

$$=\sigma_0\left[\sqrt{1-h^2\sin^2\theta_H}-h\sin\theta_H\right.$$

$$\left.\times\left(\frac{\pi}{2}-\arcsin(h\sin\theta_H)\right)\right]+O(h_\parallel^2). \tag{25}$$

Using Eq. (25) a new Kondorsky function can be expressed as

$$H_P(\vartheta)=\frac{H_P(0)}{\cos\theta_H}\left[\sqrt{1-h^2\sin^2\theta_H}-h\sin\theta_H\right.$$

$$\left.\times\left(\frac{\pi}{2}-\arcsin(h\sin\theta_H)\right)\right]+O(h_\parallel^2). \tag{26}$$

IV. NUMERICAL RESULTS

The variation of the asymmetric DW structure versus polar angle across the DW at a constant h value based on Eqs. (15) and (16) is shown in Fig. 1. Due to the presence of $h_\parallel$, the terms in the large parentheses in Eq. (16) may change sign at some large field angle θ_H in domain 2 when the field strength h increases. This makes the curves for the variation of magnetization polar angles in domain 2 reverse its proper order for $\theta_H>\pi/2$. Note that there are three curves crowded together, almost falling onto a single one, with the $\theta_H=\pi/6$ curve coming down at the bottom, and that the two curves $\theta_H=\pi/4$ and $\pi/2$ cross at $u\sim3$. Clearly, a symmetric wall will result provided only if $h_\parallel=0$.

Figure 2 shows the variation of the reduced DW width Δ/Δ_B based on Eq. (23) versus the field strength for several θ_H's. For small h values, the change in the wall width is seen to be relatively limited. At $\theta_H=90°$, we see that the wall width goes to ∞ as $h\to1$, as expected.

The DW energy function along with the new Kondorsky function are shown to depend only on $h_\parallel$ quadratically despite a linear dependence on $h_\parallel$ in the boundary conditions, Eq. (13). Numerical evaluation of the new Kondorsky function shows an appreciable improvement over the previous results[4–6] when the transverse field component gets more important, or as θ_H becomes larger than $\sim75°$. Figure 3 shows the variation of the Kondorsky function versus the field angle θ_H for several h values. The data points were taken from Ref. 4 for barium ferrite.

In summary, it is shown that the in-plane field parallel to the DW plane gives rise to asymmetric boundary conditions which asymmetrize the DW structure and modify the DW energy, and the corresponding Kondorsky function.

Susceptibility of current-carrying iron whiskers

J. -G. Lee and A. S. Arrott
Simon Fraser University, Burnaby, British Columbia Canada V5A 1S6

The magnetization pattern of an iron whisker can be altered by passing a dc current along its axis. Changes in the resistance and the ac susceptibility are used to deduce the domain structures and how they change with dc currents and/or dc magnetic fields, applied along the axis. The magnetization curls around a central core that is magnetized along the whisker axis.

We attempt to deduce magnetization patterns in iron whiskers carrying current in magnetic fields from ac susceptibility and dc magnetoresistance measurements. When a sufficient current flows along the long [001] axis of an iron crystal with {100} surfaces, the magnetization pattern changes from a structure that is primarily magnetized in $\pm$[001] to one where the magnetization circulates about that axis in the plane of the square cross section.[1] The observations of a decrease in the resistance and changes in the surface domain structures have provided strong evidence for these changes in iron whiskers.[2] Observations of flux changes also support this conclusion.[3] Representations (not data) of the field dependence of the ac susceptibility at low frequency with and without a current along the axis of a typical whisker are shown in Fig. 1. The out-phase ac response χ'' is most sensitive to changes in magnetization patterns because the losses are dominated by the eddy currents produced by moving domain walls.

There are no noticeable effects on the ac susceptibility from currents below a critical value I_c. The susceptibility for zero current shows a characteristic response that is well documented in previous studies of domain configurations, Bloch walls and magnetization processes in iron whiskers from dc to 200 kHz.[4–6] The magnetization pattern in zero field approximates, and sometimes is, the Landau structure of two long domains separated by a 180° domain wall with closure domains on each end.

If a small pickup coil is used to detect the changing flux Φ_B in the midplane of the whisker, the signal depends on the flux of magnetization Φ_M in the midplane, the applied field $H_0\hat{\mathbf{z}}$, and the demagnetizing field $\mathbf{H}_D(\mathbf{r})$. For the Landau structure, the contributions to Φ_B from $H_0\hat{\mathbf{z}}$ and $\mathbf{H}_D(\mathbf{r})$ cancel one another if the coil is tightly wound around the sample. Otherwise a correction is needed for the region between the coil and the sample. An effective susceptibility χ_{ext} is extracted from the ac voltage in the pickup coil and the ac current driving a solenoid. This is written in terms of a magnetic stiffness $\alpha(\omega)$ and a magnetic viscosity $\beta(\omega)$ as

$$\frac{1}{\chi_{\text{ext}}} = \alpha(\omega)+i\omega\beta(\omega). \tag{1}$$

In the current study, the frequency, 700 Hz, is sufficiently low that $\alpha(\omega)=\alpha(0)$ and $\beta(\omega)=\beta(0)$. The stiffness and viscosity can be calculated in the low-frequency limit for the whiskers without current. The stiffness $\alpha(0)\cong 4\pi D\equiv AH_0/\Phi_M$, where A is the midplane area and is independent of magnetization until the flux of magnetization saturates in the midplane. This happens discontinuously at the departure field H_d; see Fig. 1. H_d is very close to $4\pi DM_s\equiv H_D$, where the magnetization in the central cross section is practically uniform and saturated. For the Landau structure, labeled as such in Fig. 1, the viscosity provides information on the position of the wall:

$$\beta(0)\cong\beta_0\{\tanh[b(\pi/2)(1-\Phi_M/\Phi_s)] + \tanh[b(\pi/2)(1+\Phi_M/\Phi_s)]\},$$

where β_0 contains the conductivity and b is a numerical constant close to 1.05. The viscosity is greatest when the wall is centered in the midplane, decreasing to about one-half of the maximum just before saturation.

The various features of the ac response in the absence of current are a measure of the quality of the whisker. They are not observed if the whisker is subjected to strain. In experiments where wires are attached to measure resistance, it is necessary to be certain that the strains are less than those which would suppress the formation of the Landau structure. It was very difficult to insert a whisker, with current and potential leads attached, into the transformer, used to mea-

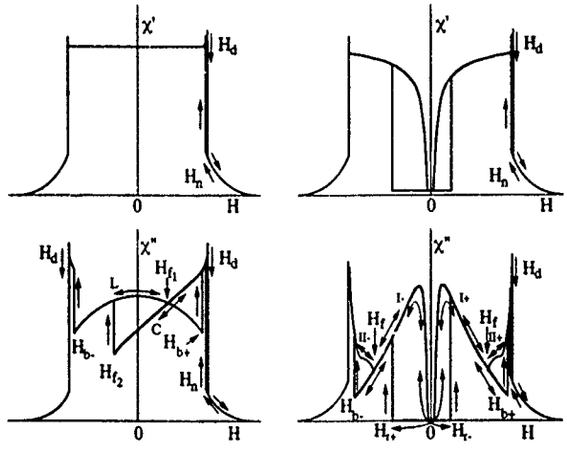

FIG. 1. Representations of the field dependence of components χ' and χ'' of the ac susceptibility for {100} iron whiskers. On the left-hand side: with no current along the axis, the responses corresponding to the Landau structure, labeled L, and to the Coleman structure labeled C, show the effects of magnetic viscosity in χ'' at low frequencies. On the right-hand side: with sufficient current to change the structure and to increase the departure field H_d by 50%, the responses corresponding to the structures of stages I and II are distinguished by differences in χ''. The magnetic viscosity increases with applied field in stage II. For stage I the magnetic response shows a low χ' for small fields. χ' increases sharply beyond an apparent threshold field for one field direction but not the other, depending on previous fields. The decrease in magnetic stiffness with field is accompanied by a decrease in magnetic viscosity.

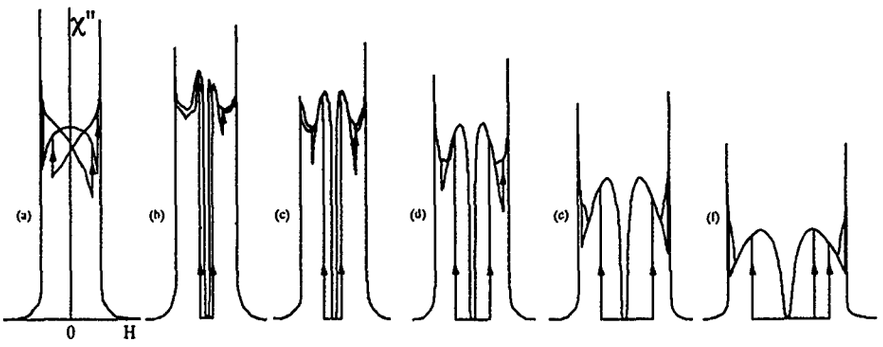

FIG. 2. Transcription of raw data for χ'' for a sequence of applied currents, I=0.02, 0.075, 0.15, 0.2, 0.4, and 0.6 A. These variations of χ'' with applied field at each current were recorded in a series of field cycles, showing the effects of hysteresis, which depend on previous maximum fields. The recorder traces have been scanned into bit maps from which this data is extracted. The response of this whisker is typical for many, but not all, of the various whiskers selected for their perfection with lengths between 2.0 and 2.5 cm and widths from 0.02 to 0.05 cm.

sure ac susceptibility, without creating such strains. It was more convenient to measure the ac susceptibility with only the current leads attached. Correspondences between the two sets of measurements provide evidence that the attachment of the potential leads did not change the dependence of magnetic structure on current and applied field.

When $I>I_c$, the field dependence of the ac susceptibility is quite different; see Fig. 1. The results are interpreted as arising from three different configurations. For $H>H_n\cong H_d$ the midplane is saturated. As H is reduced below the nucleation field, the structure called stage II^+ is nucleated. It is stable down to H_f where stage I^+ forms. Stage I^+ is stable for increasing as well as decreasing fields for all fields between H_{b+} and H_{r+}. Stage I^+ reverts to stage II^+ at H_{b+}. Stage I^- is nucleated at H_{r+}. Stage I^- and stage I^+ apparently have some similarities and some differences in their structures. One may anticipate differences because the reversal of the applied field is not accompanied by a reversal in the constant applied current.

The most striking effects occur in low fields. If the field is decreased from H_{b+} to zero, the susceptibility becomes very small and remains small for negative fields until the negative field H_{r+} is reached. $|H_{r+}|$ is much larger than the fields for which the susceptibility decreases. If H_{r+} is not reached, the response is quite reversible all the way up to H_{b+}. Similar behavior is observed if the negative field H_{r+} is exceeded to produce stage I^- which is reversible between the negative field H_{b-} and the positive field H_{r-}.

Representative recorder traces of the ac response for a typical whisker are shown in Fig. 2. To explain these data we propose that the several stages resemble the patterns shown in Fig. 3. These structures require the presence of the field from the current. This field varies almost linearly with the distance from the center, except that it reaches a higher value at the centers of the edges then it does at the corners.[7] This is the rational for the stage-II configurations a and e. The direction of the magnetization (out of the paper for the + stages) is the same in the central region and the walls, except possibly for configuration d.

An estimation of the expected behavior of a model based on these configurations requires some approximations. It is helpful to suggest that the response can be understood by considering what happens in the central cross section.[8] One can approximate the power dissipation per unit length by considering from the motion of the walls as if the whisker were infinitely long. Perhaps the energy of the whisker scales with the energy per unit length E_L of the central cross section. E_L can be broken into terms reflecting the applied field, the demagnetizing field, the field from the current, and a contribution from the wall energy. To a fair approximation

$$E_L=-H_0\Phi_M+\frac{1}{2}\frac{4\pi D}{A}\Phi_M^2+CIq^3+Wq, \tag{2}$$

where q is the side of the inner square magnetized along the axis. The demagnetizing factor $4\pi D$ depends on the dimensions of the whisker. The coefficient C for the current term can be calculated from the geometry. The coefficient W for

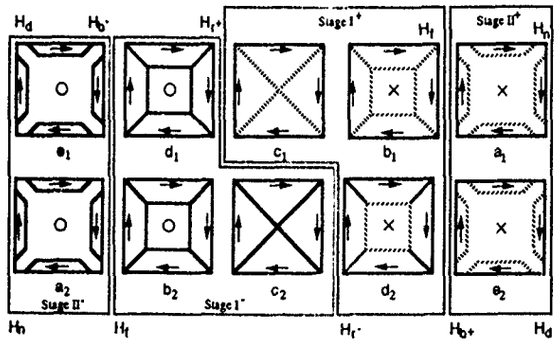

FIG. 3. Diagrams of the conjectured magnetic configurations in the midplane for stages I and II. The field is changing from H_n to H_d from right- to left-hand side for a_1 to e_1. From a_2 to e_2, the field is changing in the opposite direction. In the transformation from a_1 to b_1 the domains coalesce. The magnetization in the center is + in stage I^+ and stage II^+ and − in stage I^- and stage II^-. The transformation from c_1 to d_1 is nucleated away from the midplane. A Bloch line could cause a reversal of handedness somewhere along the diagonal wall in d_1. On going from d_1 to b_2 to c_2 in stage I^-, the handedness of that part of the diagonal wall closest to the origin is determined by the direction of the magnetization in the central core.

the wall term is calculable in the approximation that the wall energy densities σ_{110} and σ_{100} are those of walls of infinite extent:

$$W=-2\sqrt{2\sigma_{110}}+4\sigma_{100}=-0.9\sigma_{100},$$

because $\sigma_{110}=\sqrt{3\sigma_{100}}$. This favors the expansion of the core from c_1 to b_1 in Fig. 3. It is a very small effect except at zero field.

To a first approximation $\Phi_M=q^2M_s=q^2\Phi_s/A$. The negative of the derivative of the energy with respect to Φ_M/A is the average internal field acting on the moving wall. This vanishes at equilibrium. When there are moving walls, it balances the field H_e from the eddy currents. To a first approximation H_e in stage I is given by

$$H_e=-4\pi\frac{\sigma\partial\Phi_M}{c^2\ \partial t}\ \ln\left(\frac{A}{q^2}\right). \tag{3}$$

The response is found from the vanishing of the effective field

$$H_{\rm eff}=-\frac{\partial E_L}{\partial\Phi_M}+H_e=H_0-\frac{4\pi D}{A}\ \Phi_M-CI\Phi_M^{1/2}-\frac{W}{\Phi_M^{1/2}}$$

$$-4\pi\frac{\sigma}{c^2}\frac{\partial\Phi_M}{\partial t}\ \ln\left(\frac{\Phi_s}{\Phi_M}\right)=0. \tag{4}$$

From this one obtains the dependence of H_0, χ, $\alpha(0)$, and $\beta(0)$ on Φ_M:

$$\frac{H_0}{4\pi DM_s}=\frac{\Phi_M}{\Phi_s}+\frac{I}{I_1}\left(\frac{\Phi_M}{\Phi_s}\right)^{1/2}+W_1\left(\frac{\Phi_s}{\Phi_M}\right)^{1/2}, \tag{5}$$

$$\frac{1}{\chi_{\rm ext}}=\alpha(0)=4\pi D\left[1+\frac{I}{2I_1}\left(\frac{\Phi_s}{\Phi_M}\right)^{1/2}\right.$$

$$\left.-\frac{W_1}{2}\left(\frac{\Phi_s}{\Phi_M}\right)^{3/2}\right], \tag{6}$$

and

$$\omega\beta(0)=4\pi D\omega\beta_1\ \ln\left(\frac{\Phi_s}{\Phi_M}\right). \tag{7}$$

For a 0.03-cm-thick 2.3-cm-long Fe whisker at 700 Hz, the quantity $\omega\beta_1\cong1/2$. The experiments have been performed with whiskers for which $I_{\rm max}/I_1\cong1/2$. For all but the smallest fields, the terms in W_1 can be neglected. For parameters in this range, the model predicts the susceptibilities for stage I shown in Fig. 4. For stage II the model remains the same except the loss term is replaced by

$$\omega\beta(\omega)=4\pi D\omega\beta_2\ \ln[\Phi_s/(\Phi_s-\Phi_M)].$$

It would take a more detailed model for stage II than we possess to calculate β_2. Experimentally it is observed that the loss in stage II matches the loss in stage I at the transition

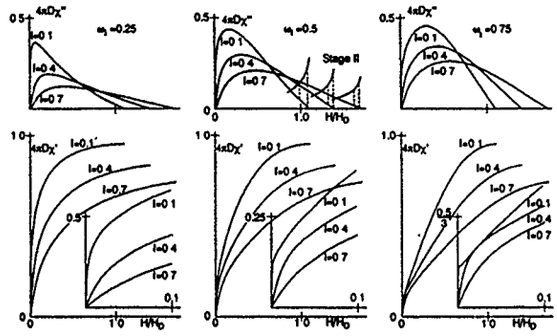

FIG. 4. Calculations of the field dependence of χ' and χ'' for three frequencies and three choices of current along the axis, including a blowup of the origin for χ'. The calculations are for the stage I. In additional, a simulation of stage II is presented in the panel for χ'' and $\omega_1=0.5$.

from stage II to stage I. This is used to pick a value for β_2 to calculate χ'' for stage II as shown for $\omega_1=0.5$ in Fig. 4.

This model accounts for much of the response in stage I^+, for example, the linear increase in the departure field H_d with current, the low susceptibility at $H=0$, the maximum in χ'', and the sharper rises in χ' and χ'' at lower currents for low fields. The model does not explain why the susceptibility stays low to a finite positive field. This effect is observed in the measurement of resistivity. The resistance remains constant for a small range of fields and then increases monotonically as Φ_M approaches Φ_s.

At present we do not know what accounts for the observations that the ac susceptibility and the resistivity remain constant for a small range of positive fields. That they remain constant for a range of negative fields is a direct consequence of the conjectured structure, whether W is positive or negative.

Except for low fields where the model appears incomplete, the behavior is well described by the first three terms in the model which come directly from Maxwell's equations and the assumption that the behavior of the whole system can be modeled by looking at the central cross section.

Magnetoacoustic emission (MAE) has been measured from a Ni bar and a mild steel bar. The magnetizing field was produced by a c-core electromagnet, which was separated from the specimen surface by a nonmagnetic spacer layer (thickness l_a). In Ni, the MAE profile contains a single peak when l_a is small. As l_a increases, a second peak appears and then a third peak, indicating that MAE is not only caused by domain wall creation and annihilation, but also by domain wall motion. In the case of the mild steel bar, only two peaks are detected, which are increasingly separated as l_a increases. The different results between the two materials can be explained by the different mobility of non-180° domain walls. The present results also indicate that the MAE profile obtained from Ni is less sensitive to l_a than that obtained from mild steel. This difference can be explained by considering the reluctance of the magnetic circuit.

I. INTRODUCTION

Magnetoacoustic emission (MAE) is under development as a technique for the nondestructive evaluation of magnetic materials. The possibilities of measuring stress[1,2] and detecting defects[3,4] using MAE have already been demonstrated. One of the practical applications of MAE is to inspect surface smoothness in metallic assemblies and components. For such applications, the specimen is usually magnetized with a c-core electromagnet placed close to its surface. In the presence of defects such as buried voids and cracks, surface perturbations such as undercutting on flat surfaces, or when the surfaces are rough and curved, the coupling between the test piece and the magnet is poor. Demagnetizing fields and stray fields are therefore induced, resulting in the modification of the MAE profile. The purpose of this paper is to report the effects of these induced fields on the MAE signals obtained from Ni and mild steel by varying the thickness of an insulating spacer layer between the magnet and the specimen surface. This study will also provide information about the physical processes involved in the generation of MAE, and may help to settle some of the current disputes about these points.[5]

II. EXPERIMENT

MAE measurements were made on a Ni and a mild steel bar of dimensions 101.6 mm by 27.0 mm by 6.5 mm, and 190.0 mm by 20.1 mm by 5.8 mm, respectively. During the measurements, a 1 Hz magnetizing field of amplitude about 40 kA m^{-1} was applied in the longitudinal direction by using a c-core electromagnet placed on the surface of the bar. The MAE signals (approximately in the range 35–200 kHz) were detected by a piezoelectric transducer, and were then amplified, rectified, and filtered. The mean signal amplitude was then plotted as a function of the applied field over half a hysteresis cycle. Ideally, the magnet and the bar should form a closed magnetic circuit with no demagnetizing field or stray flux. A practical advantage of using a c-coil magnet over a conventional air-cored coil[3] is that the magnet can be placed at any region of interest of the specimen. A similar arrangement was used in other MAE experiments.[1,2] However, a nonmagnetic spacer must be used between the magnet and the test piece in order to minimize the everpresent electrical and acoustic noises. The spacer breaks the magnetic flux path in the circuit and introduces demagnetizing fields as well as stray fields. These effects alter the MAE signals detected by the piezoelectric transducer. The measurements were repeated at different spacer thicknesses l_a, ranging from 0.12 to 0.63 mm for mild steel, and from 0.05 to 1.55 mm for Ni. The MAE profiles obtained from both Ni and mild steel are shown in Fig. 1. Plots of peak amplitudes against spacer thickness for the two specimens are shown in Fig. 2.

III. MAE PROFILES

MAE profiles obtained from Ni usually contain a single peak. The profile obtained in our experiments with $l_a = 0.05$ mm is also of this form (Fig. 1, top left). With $l_a = 0.36$ mm, an additional peak appears to the left of the main peak, and with $l_a = 1$ mm, a third peak appears to the right. (The peaks are marked with arrows.) The peak heights generally decrease with increasing spacer thickness (Fig. 2). In the case of steel, the profiles always contain two peaks (Fig. 1, right). The peak heights in any particular profile become more nearly equal after the subtraction of noise (compare Figs. 1 and 2). It has been reported that MAE profiles obtained from a toroidal polycrystalline YIG sample change drastically as a result of demagnetizing effects, and also that the emission is related purely to domain wall creation and annihilation.[5] As the results here show, if the above interpretation is correct, the peaks corresponding to the two processes would be increasingly separated as the effects of demagnetizing and field leakage increase, but there would not be a third peak in the low-field region. The existence of three peaks in the profile from Ni with larger l_a thus indi-

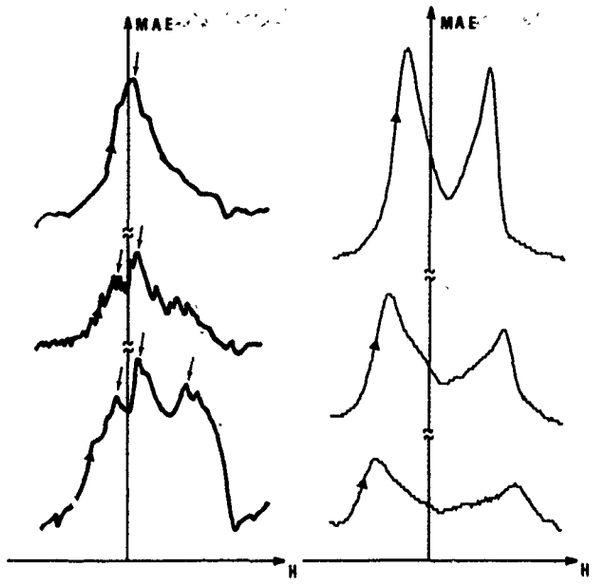

FIG. 1. MAE profiles (arbitrary units) as a function of applied field H obtained with various spacer thicknesses for Ni and mild steel. The three traces on the left were obtained from Ni with (from top to bottom) $l_a = 0.05$, 0.95, and 1.55 mm, respectively, and those on the right from mild steel with (from top to bottom) $l_a = 0.18$, 0.31, and 0.44 mm, respectively. Noise was not subtracted from these profiles. The three profiles from steel are to the same scale. The scales of the middle and bottom traces from Ni are enlarged by factors of 5 and 10, respectively, relative to the top trace.

cates that MAE is not only caused by domain wall creation and annihilation, but also by domain wall motion. The wall creation process involves the sudden release of trapped walls, the annihilation occurs when the walls abruptly collapse, and the wall motion involves the breaking away of walls from pinning centers. When the demagnetizing and flux leakage effects are small, the fields corresponding to domain wall creation and annihilation are close to the coercive field. The MAE peaks due to all three processes therefore overlap, and the profile consists of a single peak.

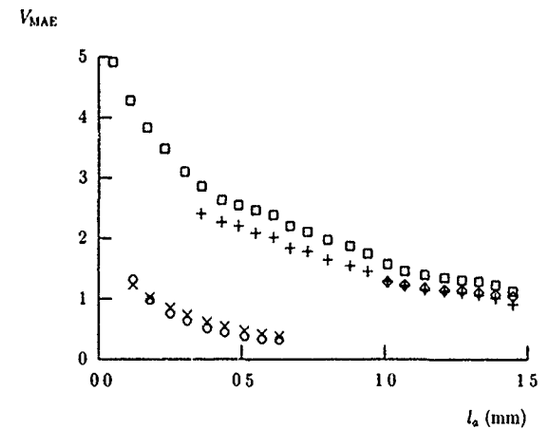

FIG. 2. Plots of peak amplitudes (V_{MAE}, arbitrary units) against l_a (mm) for Ni and mild steel. Crosses (+), squares, and diamonds correspond to the left, central, and right peaks from Ni respectively, and crosses (×) and circles correspond to the left and right peaks from steel respectively. The peak amplitudes shown were obtained after the subtraction of noise.

The fact that a central peak does not appear in the MAE profiles from steel can be explained by the difference in the mobility of non-180° domain walls in steel and Ni. Gaunt[6] has suggested that the pin restoring force f on a domain wall is given by

$$f = 2M_s A_p H_c, \tag{1}$$

where M_s is the saturation magnetization, A_p is the wall area associated with the pin, and H_c is the coercivity. Williams *et al.*[7] also reported that the velocity of the domain walls is proportional to the resistivity and inversely proportional to M_s. Therefore a material with lower M_s such as Ni tends to have a smaller f than one with a higher M_s such as steel, and the domain walls would be more mobile in Ni than in steel. The existence of a strong central MAE peak in Ni resulting from wall motion suggests that the non-180° walls in Ni are more easily unpinned than in steel, giving rise to MAE in low fields. In mild steel, some 180° walls can move in small fields, but these walls do not give rise to MAE. Non-180° walls are less mobile and require a larger field to move them. The MAE activity contributed by the motion of the latter is so close to the annihilation process that the two processes are superimposed into one peak, and therefore only two peaks appear in the MAE profile from mild steel.

IV. THE MAGNETIC RELUCTANCE

The amplitude of the MAE peaks can be estimated by considering the magnetic circuit formed by the c-core magnet, the two spacers (one for each pole), and the specimen. A coil of N turns carrying a current I around a ferromagnetic core produces a magnetomotive force (mmf) given by NI. The magnetic flux Φ is related to the magnetic reluctance $\mathfrak{R}$ and the mmf NI by

$$\Phi = \frac{NI}{\mathfrak{R}}, \tag{2}$$

where

$$\mathfrak{R} = \sum_i \frac{l_i}{\mu_i A_i}, \tag{3}$$

and l_i, μ_i, and A_i are the length of the flux path, permeability, and cross-sectional area of the different sections of the circuit in series. In our magnetic circuit the magnetic flux is therefore given by

$$\Phi = NI\left(\frac{l_m}{\mu_m A_m} + \frac{2l_a}{\mu_a A_a} + \frac{l_s}{\mu_s A_s}\right)^{-1}, \tag{4}$$

where the subscripts m, a, and s refer to the magnet, the spacers, and the part of the specimen being magnetized, respectively. The magnetic flux in the circuit is reduced when the spacers are introduced, because it requires more energy to drive the same amount of flux across the spacers than through an equal volume of iron, since the permeability of the spacers is much lower. As l_a increases, the reluctance $\mathfrak{R}$ increases and Φ decreases. This effect is further enhanced by the existence of a demagnetizing field due to the free

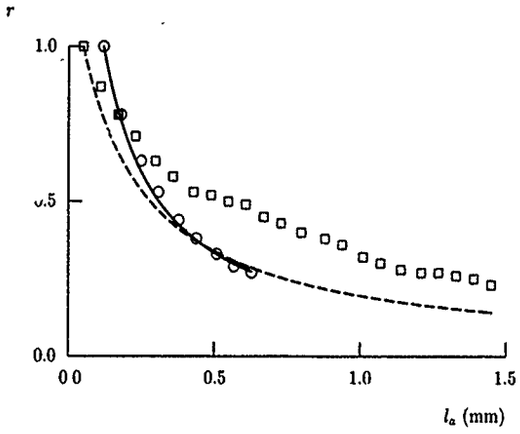

FIG. 3. Calculated $\mathfrak{R}^{-1}$ (curves) and measured peak heights (points) plotted against l_a (mm). Squares and the dashed curve refer to Ni, circles and the full curve to steel. The values have been normalized as follows: for the dashed curve, $r=\mathfrak{R}^{-1}(l_a)/\mathfrak{R}^{-1}(0.05)$, for the full curve, $r=\mathfrak{R}^{-1}(l_a)/\mathfrak{R}^{-1}(0.12)$, for the squares, $r=V_{\mathrm{MAE}}(l_a)/V_{\mathrm{MAE}}(0.05)$, and for the circles, $r=V_{\mathrm{MAE}}(l_a)/V_{\mathrm{MAE}}(0.12)$.

poles at the two ends of the magnet. However, at a given mmf, Φ is still approximately inversely proportional to $\mathfrak{R}$. In the generation of MAE, the MAE activity is proportional to the rate of change of strain, and to the change of domain volume. The former is related to the amount of magnetic flux Φ inside the test piece, thus the MAE activity is also proportional to $\mathfrak{R}^{-1}$.

The permeability μ_s of the Ni bar was measured to be about 125. Assuming that μ_s of mild steel is 1000, and that $\mu_a=1$ and $\mu_m=1000$, the values of $\mathfrak{R}$ for the magnetic circuits involving mild steel and Ni were calculated for different values of l_a. Figure 3 shows a comparison of MAE peak amplitudes with $\mathfrak{R}^{-1}$ for both specimens, as a function of l_a. For steel, the agreement is very close, so that the magnitudes of the MAE signals can be predicted for different spacer thicknesses if an initial set of data (i.e., values of l_a and observed MAE) are given. For Ni, the agreement is less close, although a similar trend is followed. The results in both Figs. 2 and 3 also show that l_a has a greater effect on the MAE in the mild steel bar. For example, in mild steel, a change of l_a from 0.12 to 0.63 mm decreases the normalized MAE signal from 1 to 0.27, while in Ni the change is from 0.87 to 0.49 when l_a changes from 0.11 to 0.61 mm. There are two reasons for this: (i) the large value of μ_s of mild steel leads to a smaller contribution of the specimen to the total reluctance $\mathfrak{R}$ of the circuit, thus a small change of l_a will significantly alter $\mathfrak{R}$ and also the observed MAE, and (ii) the value of spontaneous magnetization of mild steel is about 3.5 times of that of Ni, and the demagnetizing field created in the case of mild steel by the presence of the spacer would be 3.5 times larger than the field created in the case of Ni. Thus one would expect that the MAE signals decrease more rapidly with spacer thickness in mild steel than in Ni.

V. CONCLUSIONS

There is strong evidence that the generation of MAE is due to domain wall creation, motion, and annihilation during the process of magnetization. Movement of non-180° domain walls is involved in all three processes. The relative magnitude of the emission can be predicted by the magnetic circuit calculations.

IR spectroscopy on FeNi and FePt Invar alloys

B. Buchholz, E. F. Wassermann, W. Pepperhoff, and M. Acet
Tieftemperaturphysik (SFB 166), Universität Duisburg, 47048 Duisburg, Germany

UHV IR emission spectroscopy has been carried out at energies 9–33 mRy (wavelength 2.8–9.8 μm) in the temperature range 430–800 K on single crystals of FeNi and FePt Invar, with Curie temperatures in the respective range. The results show a drastic (up to 30%) decrease of the IR absorptivity around T_c in the energy range 23–33 mRy (2.8–4 μm), while at small energies around 9 mRy (10 μm) the absorptivity is temperature independent, as expected for $3d$ metals, and found on pure Ni. The decrease in absorptivity on the Invar alloys cannot be understood by the common temperature dependence of interband transitions; rather, it calls for the existence of moment-volume instabilities, characterized by transitions between a high-spin ground state and a temperature-induced low-spin state. Qualitative agreement of the absorptivity with respective total density-of-states calculations on Fe_3Ni is demonstrated.

I. INTRODUCTION

In recent reviews[1,2] we have shown that band calculations[3,4] provide a new ansatz to understand the broad spectrum of Invar anomalies in $3d$ alloys. Particularly, the calculations reveal that the Fe moment in ordered Fe_3Ni and Fe_3Pt is instable with respect to small changes in the atomic volume. The results call for the existence of moment-volume instabilities, characterized by a ferromagnetic high-spin-state (HS) with large atomic moment and volume (the ground state), and a low-spin-state (LS) with smaller magnetic moment and volume. Experimental evidence for the existence of these states has been given on ordered and disordered $Fe_{72}Pt_{28}$ as well as $Fe_{68.5}Ni_{31.5}$ through low-temperature Mössbauer experiments under pressure,[5] clearly revealing the HS-LS transition with increasing pressure, in quantitative agreement with the predictions from theory.

The situation at finite temperatures is less clear. Although the band calculations reveal that in the Invar concentration range the energy difference ΔE between the HS and LS states is of the order of 1–2 mRy (150–300 K), so that the LS state becomes thermally accessible, the physical nature of the excitations is still unknown. To shed more light on this situation, we carried out spin-polarized, angle-resolved photoemission on ordered $Fe_{72}Pt_{28}$.[6] The observed difference in intensity below and above the Curie temperature T_c agreed well with the calculated density-of-states (DOS) difference for fcc Fe in the HS and LS state. Since, however, other interpretations of our data have been suggested,[7,8] we think that new experiments are required to prove the correctness of our assumptions.

We have, therefore, for the first time, carried out IR emission spectroscopy in the range of wavelengths λ=2.8–9.8 μm (E=9–33 mRy) on FeNi and FePt Invar alloys in the temperature range 430–780 K, i.e., below and above the respective T_c's of the alloys. Since the HS and LS states manifest themselves in sharp peaks in the DOS, lying ~20 mRy below and above the Fermi energy, respectively, IR spectroscopy provides a suitable tool to investigate the changes in the DOS, when the sample temperature is raised through T_c. IR spectroscopy has an energy resolution of several tens of mRy, and in the range of wavelengths used the penetration depth of the radiation is some hundreds of angstroms. Both are advantageous in comparison to ultraviolet photoemission spectroscopy (UPS), where the energy resolution and the penetration depth are almost two orders of magnitude smaller.

In general, in $3d$ systems the temperature dependence of interband transitions and, therefore, the respective temperature dependence of the absorbtivity is weak. It only depends on the smearing and the changes in bandwidth due to thermal agitation and expansion, respectively. Our results on FeNi and FePt Invar cannot be understood within these arguments; rather, it calls, as we will show, for an explanation within the HS-LS transition model as earlier claimed in our UPS measurements.[6]

II. EXPERIMENT

To determine the IR absorptivity via Kirchhoff law, we have set up an IR emission spectrometer with a grid monochromator and a thermocouple radiation detector. The light intensity is measured by a lock-in technique, chopping the beam with 11 cycles/s. To increase the sensitivity, we use a relative method, i.e., the emission of a sample is measured in comparison to a standard blackbody radiator, realized by a blackened hollow Cu block with a small hole. Sample and standard are placed in direct vicinity in the sample holder, so that they can be heated simultaneously and also kept at the same constant (±30 mK) temperature. Focusing the emitted light of either sample or reference on the monochromator slit is achieved by a rotatable spherical mirror (glass, Al coated).

Although the penetration depth of the IR light in the spectral range used (2.8–9.8 μm;) is roughly 200 Å, cleanness and optical qualitiy of the sample surface are of ample

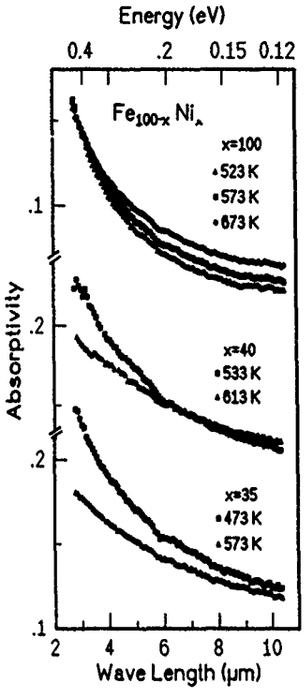

FIG. 1. Spectral absorptivity for Ni (T_c=624 K), $Fe_{60}Ni_{40}$ (T_c=620 K) and $Fe_{65}Ni_{35}$ (T_c=490 K) at constant temperatures below and above the respective Curie temperatures.

importance. The samples are therefore placed in an UHV chamber (5×10^{-9} mbar). Surface preparation involves etching and polishing before mounting. They are annealed in vacuum at 900 K for 2 h to remove possible oxide layers.

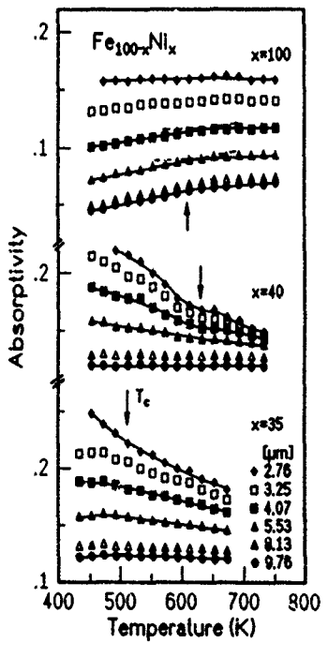

FIG. 2. Absorptivity vs temperature for Ni, $Fe_{60}Ni_{40}$, and $Fe_{65}Ni_{35}$ at constant wavelength. Note the 30% decrease in absorptivity, observed for the Invar alloys only at small wavelength. T_c's are marked by arrows.

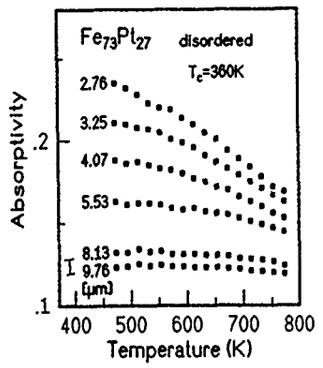

FIG. 3. Absorptivity vs temperature at constant wavelength for disordered $Fe_{73}Pt_{27}$ Invar.

III. RESULTS AND DISCUSSION

Figure 1 shows the spectral absorptivity for pure Ni and two FeNi Invar alloys at two temperatures, one above and one below the respective T_c's. Note the difference in the absorption behavior between Ni and the FeNi alloys. While for Ni the absorptivity shows only a small increase with temperature at longer wavelength, a result in accordance with earlier findings,[9] the Invar alloys exhibit opposite behavior. This is better revealed in Fig. 2, where the absorptivity is plotted as a function of temperature at constant wavelength. T_c's are marked by arrows. In Ni there are small changes in slope of the absorptivity at T_c which increase with increasing wavelength. The effect is very likely due to the decrease of the band splitting, as shown in spin- and angle-resolved UPS investigation on Ni.[10]

The behavior of Ni is contrasted by the behavior of the Invar alloys, $Fe_{59.9}Ni_{40.1}$ and $Fe_{65}Ni_{35}$ (see Fig. 2), which at large wavelength, $\lambda\simeq8-10$ μm ($E\simeq10$ mRy), show hardly any change of the absorptivity with temperature. However, at small wavelength, $\lambda\simeq2-4$ μm ($E\simeq30-40$ mRy), a drastic (30%) decrease of the absorptivity is observed, when the temperature is raised through T_c. Equal results are shown in

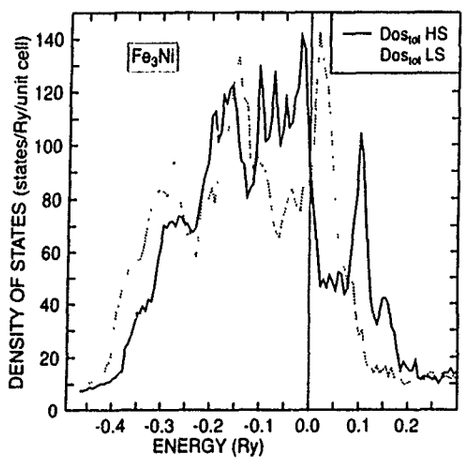

FIG. 4. Total density of states for Fe_3Ni in the HS state (r_{ws}=2.60 a.u.; solid line) and LS state (r_{ws}=2.517 a.u.; broken line).

Fig. 3, where the absorbtivity versus temperature for disordered $Fe_{73}Pt_{27}$ Invar is given. They must consequently be caused by the Invar effect.

In contrast to the behavior at longer wavelength, the observed anomalies, maximum at short wavelength, call for a decrease in the combined DOS with increasing temperature. This can be made plausible within the band-structure calculations[3,4] mentioned, i.e., within the HS-LS transition model. For this purpose we show in Fig. 4 the calculated[11] total DOS for Fe_3Ni in the HS (solid curve) and LS state (dashed curve). The HS state is characterized by the high peak in the DOS, lying about 20 mRy below E_F. For the LS state a similar feature is found. The observed reduction in the absorbtivity can thus simply be understood by temperature-induced HS-LS transitions, which cause a drastic diminution of the HS DOS in the energy range in question.

Optical spectroscopy has the drawback that it averages over the total Brillouin zone, and the combined DOS is required to understand the microscopic processes in detail. Additionally, finite temperature effects result in some "rounding" of the DOS peaks, and indirect transitions might be of importance. Our present absorption experiment—as the UPS before—gives good experimental support for the correctness of the HS-LS transition model, and the changes in electronic band structure accompanying it. Further support can result from absorption experiments at higher photon energies and lower temperature, where we expect the absorption anomaly in Invar to vanish. Experiments with a respective setup are presently under way.

Anti-Invar in Fe-Ni

M. Acet, T. Schneider, H. Zähres, E. F. Wassermann, and W. Pepperhoff
Tieftemperaturphysik (SFB 166), Universität Duisburg, 47048 Duisburg, Germany

Anti-Invar behavior in a material can be characterized by an anomalously large and a weak temperature-dependent thermal-expansion coefficient, when compared to the respective Grüneisen lattice expansion. It is just the opposite of the Invar effect, which is characterized by an anomalously small thermal-expansion coefficient. Common to Invar and anti-Invar is the fact that both posess moment-volume instabilities. Anti-Invar is observed in the paramagnetic state. It occurs in γ-Fe and in a number of $3d$ fcc binary and ternary alloys. In Fe_xNi_{100-x} alloys it is observed in the concentration range $70 \leqslant x \leqslant 100$ at. % within the fcc stability range. The effect vanishes as the Invar concentration, $x=65$ at. %, is approached. To examine the valence electron concentration dependence of the anti-Invar effect the thermal expansion has been measured in the fcc state of Fe_xNi_{100-x} for $63 \leqslant x \leqslant 100$ at. %. Using a model based on moment-volume instabilities in conjunction with a thermal activation process the size of the anti-Invar effect in these alloys has been determined. The volume enhancement is found to decrease with increasing Ni concentration from 2.8% in γ-Fe to 0% at $x=65$ at. %.

I. INTRODUCTION

$3d$ Invar alloys are an important class of materials which owe their properties to moment-volume instabilities (MVI).[1,2] Total energy calculations for Invar have shown the existence of a large-volume high-spin (HS) ground state and a small-volume low-spin (LS) state lying energetically a few mRy higher.[3] The existence of these states have also been demonstrated in FeNi and FePt Invar alloys by Mössbauer experiments under pressure.[4]

Similar to Invar alloys γ-Fe is a material which also posesses a MVI. However, in contrast to Invar total energy calculations have shown that the ground state is an antiferromagnetic (AF) LS state and the higher-lying state is a ferromagnetic (FM) HS state.[5,6] Mössbauer experiments at low temperatures on thin films of γ-Fe stabilized with different lattice constants have shown that below and above a critical lattice constant, $a_c=3.64$ Å (critical atomic volume, $V_c=12.05$ nm^3), γ-Fe is AF and FM, respectively.[7] These experiments confirmed the existence of these states in γ-Fe.

The signature of the Invar effect is a spontaneous volume magnetostriction starting near the magnetic ordering temperature and extending down to low temperatures. The anti-Invar effect, on the other hand, can be recognized by an anomalously large thermal-expansion coefficient, $\alpha(T)$, accompanied by an almost temperature-insensitive behavior at high temperatures in the PM state.[8,9] $\alpha(T)$ of $Fe_{63}Ni_{37}$ Invar and γ-Fe anti-Invar are shown in Fig. 1. The shaded areas in this figure correspond to a spontaneous volume magnetostriction in the case of $Fe_{63}Ni_{37}$ and to a volume enhancement in the case of γ-Fe.[9] An essential difference between Invar and anti-Invar is that in the former the volume effect occurs essentially in the magnetically ordered state, whereas in the latter it occurs in the magnetically disordered state.

In this work we initiate a systematic survey on the size of the anti-Invar effect as a function of valence electron concentration, e/a, in Fe-Ni alloys. With γ-Fe as a typical anti-Invar on one side and Ni a material with a "normal" thermal expansion on the other, one would expect the anti-Invar effect to disappear at some concentration of Ni when it is alloyed to Fe. At this concentration the AF-FM (LS-HS) MVI should no longer exist. For this purpose we have measured the thermal expansion of Fe_xNi_{100-x} alloys in their respective fcc stability ranges for $63 \leqslant x \leqslant 100$ at. % and examined the change in the size of the anti-Invar effect.

II. METHOD OF ANALYSIS OF $\alpha(T)$

Although the ground-state properties of the $3d$ metals and alloys can be adequately understood, a first-principles theory describing their thermal properties is not available. The problem becomes more complex in the event that a MVI exists as in the present case. In a previous study on $3d$ alloys we were able to discuss thermal properties using a two-level system based on the earlier hypothetical Weiss model.[8,10] This had given a good description of the high-temperature anomalies in the specific heat and the thermal expansion. In a recent work[9] we also used a similar model to understand the anti-Invar nature of γ-Fe, but this time with the support that a MVI in γ-Fe was a fact rather than a hypothesis. We use a similar approach here as well. The starting point is that the LS state and the HS state are separated by a small energy difference $\Delta\epsilon$, and thermal activation will lead to a mixture of these states. Although this method by no means describes the thermal evolution of the MVI, it provides a means for determining the size of the anti-Invar effect.

The observed thermal-expansion coefficient $\alpha(T)$ in anti-Invar is given by

$$\alpha(T)=\alpha_{\mathrm{lat}}^{\mathrm{LS}}(T)+\alpha_{\mathrm{ex}}(T). \tag{1}$$

The first term, $\alpha_{\mathrm{lat}}^{\mathrm{LS}}(T)$, is approximately the lattice expansion of the pure LS state. It is determined from the Grüneisen relation,

$$\alpha_{\mathrm{lat}}^{\mathrm{LS}}(T)=\frac{c_V(T)}{3Q\{1-K[E(T)/Q]^2\}^2}, \tag{2}$$

where c_V is the specific heat at constant volume, E is the internal energy, K is a constant associated with the indices of the Mie potential, and Q is a constant related to the Grün-

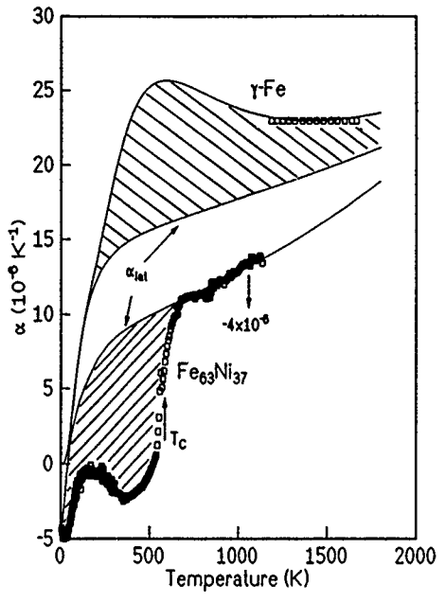

FIG. 1. The Invar in $Fe_{63}Ni_{37}$ and the anti-Invar effect in γ-Fe. Shaded areas show the associated volume magnetostriction. The ordinate for $Fe_{67}Ni_{33}$ is shifted by -4×10^{-6} 1/K. α_{lat} denotes the lattice thermal expansion.

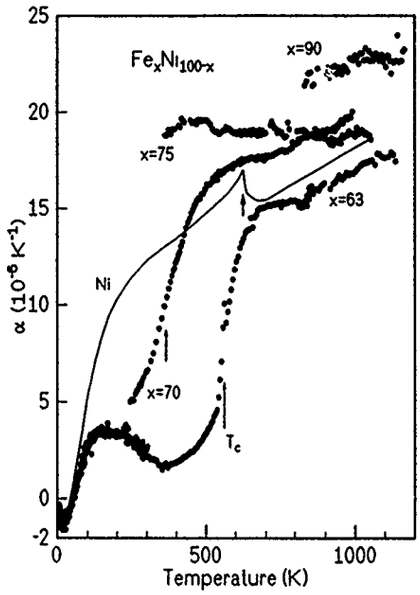

FIG. 2. $\alpha(T)$ of Fe_xNi_{100-x} for $x=0$, 63, 70, 75, and 90 at. %. Arrows point to the Curie temperatures T_C of the samples which order ferromagnetically. The data for Ni have been shifted by -1×10^{-6} K^{-1}.

eisen constant γ. The second term in Eq. (1) is the excess thermal-expansion coefficient in a two-level system and is given by

$$\alpha_{ex}(T)=\frac{\Delta V}{3V_{LS}}\frac{\Delta\epsilon}{k^2T^2}\frac{(g_{LS}/g_{HS})\exp(\Delta\epsilon/kT)}{[1+(g_{LS}/g_{HS})\exp(\Delta\epsilon/kT)]^2}. \quad (3)$$

Here $\Delta V/V_{LS}$ is the relative volume difference between LS and HS states at 0 K. $\Delta\epsilon$ is the energy difference between the two states, g_{LS}/g_{HS} is the degeneracy ratio, k is the Boltzmann constant, and T is the temperature.

III. EXPERIMENT

Samples of Fe_xNi_{100-x} with the concentrations $x=63$, 70, 75, and 90 at. % were prepared by arc melting. They were then cut to 7-mm-long cylinders with a 6 mm diameter.

The thermal expansion of FeNi alloys was measured in their respective fcc stability ranges. Two capacitive dilatometers were used, operating in the temperature ranges $4.2\leq T\leq300$ K and $300\leq T\leq1000$ K, respectively. The lower-temperature range measurements were made in a relative copper capacitance cell. The latter range was covered in a quartz push-rod-type cell. The coefficient of thermal expansion is calculated as the slope of consecutive data which were taken approximately 3 K apart in thermal equilibrium.

IV. RESULTS AND DISCUSSION

Figure 2 shows the results on $\alpha(T)$ in the fcc phases of $x=0$, 63, 70 75, and 90 at. %. The arrows mark the Curie temperatures T_C of the alloys which have FM order in the fcc state. $\alpha(T)$ of Ni was measured in order to demonstrate that the data for the alloys show no experimental artifact arising from experimental procedures. The data in the PM temperature range of the $x=63$ at. % sample and Ni can be described by Eq. (2). For $x\geq70$ at. % $\alpha(T)$ in the PM range becomes more temperature insensitive with increasing Fe concentration, thus reflecting the anti-Invar effect. Therefore, one can conclude from this data that as the Invar concentration ($x=65$ at. %) is approached from Fe-richer concentrations the anti-Invar effect disappears.

Attempting to analyze $\alpha(T)$ of alloys with $x\geq70$ at. % only with Eq. (2) leads to unrealistic values of K and Q, hence to an unrealistic Grüneisen constant. Therefore, to ana-

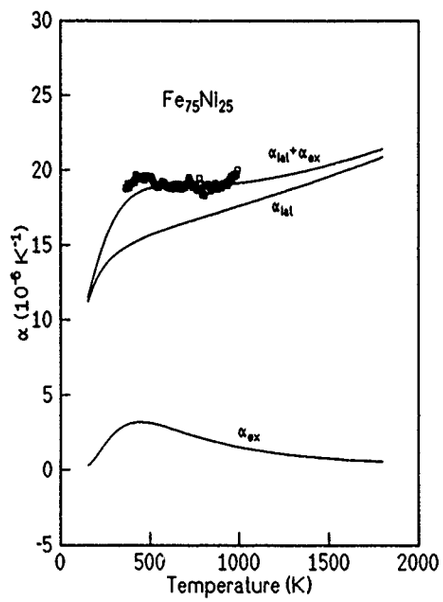

FIG. 3. The analysis of the excess and the lattice thermal expansions for the $x=75$ at. % sample. The shaded area is the anti-Invar effect, which amounts to 0.77%. (Compare to γ-Fe in Fig. 1.)

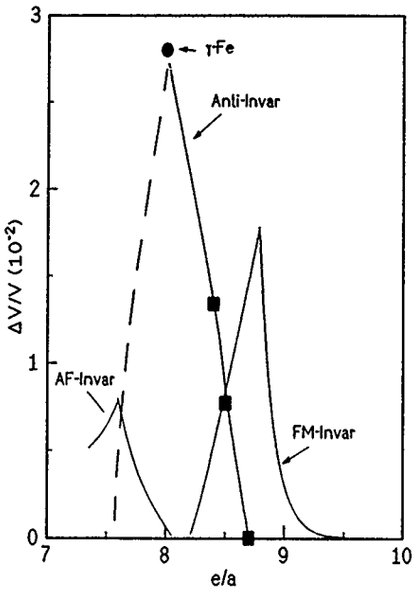

FIG. 4. Volume magnetostriction in AF Invar, FM Invar, and anti-Invar. The broken line is the anticipated behavior of anti-Invar on the AF side. The solid squares are the present data. The point for γ-Fe is from Ref. 9.

lyze the data for $x \geq 70$ at. % we first determine $\alpha_{cx}(T)$. This calculation is presented here for the $x=75$ at. % sample. We estimate the values of g_{LS}/g_{HS} and $\Delta\epsilon$, appearing in Eq. (3) from the e/a dependence of these quantities, determined from specific-heat measurements on fcc $3d$ alloys.[8,9] $\Delta V/V_{LS}$ is estimated by interpolating between the value for γ-Fe, 0.7, and $x=65$ at. %, where this quantity should vanish along with the disappearence of anti-Invar. There are therefore no adjustable parameters in Eq. (3). $\alpha_{lat}(T)$ is next determined to give the best fit to the data. Figure 3 shows the result of such an analysis. The curves in this figure are extended up to 1800 K which is near the melting point. The lack of data at these temperatures hinders a more accurate analysis, but nevertheless it allows for an estimation of the size of the anti-Invar effect. In this particular alloy the total volume enhancement amounts to 0.77%. A similar analysis for an alloy with $x=80$ at. %, for which the data of an earlier measurement was used,[8] yields 1.34 at. %. For $x=65$ or 63 at. % there is no volume enhancement in the paramagnetic state.

The total volume enhancement in $3d$ systems as a function of e/a is plotted in Fig. 4. The curves for AF and FM Invar are adapted from Refs. 1 and 11. The broken line for $e/a<8$ shows the anticipated behavior of anti-Invar on the AF side. The figure clearly demonstrates that the volume effects associated with anti-Invar can be larger than that in Invar.

ACKNOWLEDGMENTS

We are grateful to H. Bach for preparing the samples. Work was supported by Deutsche Forschungsgemeinschaft (SFB 166).

X-ray-absorption fine structure of selected R_2Fe_{17} nitrides

T. W. Capehart, R. K. Mishra, and F. E. Pinkerton
Physics Department, General Motors Research & Development Center, 30500 Mound Road, Warren, Michigan 48090-9055

X-ray-absorption fine structure from the rare-earth L_3 edges in $R_2Fe_{17}N_{3-x}$ (R=Sm, Pr, or Nd), $x\sim0.2$, establishes that these nitrides have 2.6±0.6 nitrogen atoms bonded 2.54–2.57 Å from the rare-earth site. The observed enhancement of the nitrogen backscattering from magnetically oriented powders of $Sm_2Fe_{17}N_{3-x}$ establishes that between 80% and 100% of the nitrogen atoms occupy $9(e)$ sites of the $Sm_2Fe_{17}N_{3-x}$. No evidence is found for partial nitrogen occupancy of the $18(g)$ sites in $Sm_2Fe_{17}N_{3-x}$.

Compounds with the stoichiometry R_2Fe_{17} (R denotes rare earth) form for all the lanthanides, except lanthanum.[1] The structure of these compounds is a variant of the $CaCu_6$ structure with pairs of Fe atoms replacing one-third of the rare-earth atoms. Coey and Sun[2] discovered that interstitial nitrides can be prepared from the R_2Fe_{17} series, and that nitriding produces a remarkable increase in Curie temperatures.[3,4] In general, the Curie temperatures for the resulting nitrides are approximately 700 K with only a weak dependence on the identity of the rare earth. The resulting nitrides have either the rhombohedral Th_2Zn_{17} or the hexagonal Th_2Ni_{17} structure depending on whether the rare earth is from the beginning or end of the lanthanide series. All the nitrides, except $Sm_2Fe_{17}N_{3-x}$, have basal-plane magnetocrystalline anisotropy.

X-ray-absorption fine structure (XAFS) investigations on randomly oriented powders of $Sm_2Fe_{17}N_{3-x}$ have been previously reported.[5,6] While these studies concluded that N occupied the $9(e)$ sites in the Th_2Zn_{17} structure, they do not exclude the possibility of partial occupancy of other sites 2.54–2.56 Å from the rare-earth site. Neutron-diffraction studies on $Y_2Fe_{17}N_{3-x}$ and $Nd_2Fe_{17}N_{3-x}$ have also been reported.[7] For Y nitride, neutron diffraction finds nitrogen occupies only the $9(e)$ sites. For $Nd_2Fe_{17}N_{3-x}$, however, the nitrogen is found to occupy both the $9(e)$ and $18(g)$ sites with maximal occupancies of 1.8 and 0.72 nitrogen atoms, respectively. Such a large dependence of the nitrogen site occupancy on the rare-earth site identity is unexpected; for example, the related $Nd_2Fe_{14}B$ structures are isomorphic, i.e., the structural parameters of these compounds are independent of the rare-earth species.

The existence of a second occupied nitrogen site in $Nd_2Fe_{17}N_{3-x}$ found by neutron diffraction prompted us to extend our previous EXAFS and x-ray appearance near-edge structure (XANES) studies on the technologically most interesting of the R_2Fe_{17} nitrides, $Sm_2Fe_{17}N_{3-x}$. In this work, we report measurements on magnetically oriented samples of $Sm_2Fe_{17}N_{3-x}$ to determine if there is significant partial occupancy of the $18(g)$ site in the Sm nitride. The EXAFS measurements on oriented samples provide a direct method to identify the plane(s) containing the N atoms, and a greater sensitivity to any partial N occupancy of the $18(g)$ sites in these systems. In addition, EXAFS and XANES measurements were made on unaligned samples of $Pr_2Fe_{17}N_{3-x}$ and $Nd_2Fe_{17}N_{3-x}$.

Polycrystalline powders of $R_2Fe_{17}N_{3-x}$ (R=Pr,Nd,Sm) for this work were prepared following a procedure similar to that of Coey and Sun.[2] Details of our sample preparation of the Sm compounds have been given earlier.[5] The ground powders had single-phase x-ray-diffraction patterns of the rhombohedral Th_2Zn_{17} structure (space group $R\bar{3}m$), with the lattice parameters given in Table I. Subsequently, a portion of each of the R_2Fe_{17} powders was heated in N_2 at 700–800 K for 16 h. The x-ray-diffraction peaks of these nitrided powders were shifted relative to those of the corresponding R_2Fe_{17} parent compound, consistent with the previous Th_2Zn_{17} structure, but with expanded lattice parameters. Also, a small amount of α-Fe was evident in the diffraction patterns. The parameters, given in Table I, are close to those previously reported by Buschow *et al.* for these nitrides.[4] Samples for the measurements on aligned powders were made by suspending finely ground powders (−500 mesh) in paraffin. These samples were then placed in the field of an electromagnet to align the basal planes of these compounds in the same direction. Well-aligned samples were obtained by suspending these powders in melted paraffin and reversing the polarity of a ~15 kOe field several times.

X-ray-absorption spectra were measured initially on beamline A3 at the Cornell High Energy Synchrotron Source (CHESS), and repeated on beamline X11 at the National Synchrotron Light Source (NSLS) using Si(111) double-crystal monochromators. The L_3-edge spectra from R_2Fe_{17} and $R_2Fe_{17}N_{3-x}$ are all dominated by a single peak near the absorption threshold similar to the spectra for the corresponding trivalent reference compounds. There were, however, small consistent differences in the L_3-edge spectra between the parent R_2Fe_{17} compounds and their nitrides. First, the white line is higher and narrower in the nitrides. Second, the leading edge of the absorption spectrum for each nitride is shifted ~1 eV higher than its parent. The edge shifts produced by nitriding are analogous to the edge shifts caused by

TABLE I. Th_2Zn_{17} structure lattice parameters.

Compound	a (Å)	c (Å)
Pr_2Fe_{17}	8.5781	12.4509
$Pr_2Fe_{17}N_{3-x}$	8.7796	12.6237
Nd_2Fe_{17}	8.5638	12.4470
$Nd_2Fe_{17}N_{3-x}$	8.7635	12.6345
Sm_2Fe_{17}	8.5476	12.4354
$Sm_2Fe_{17}N_{3-x}$	8.7307	12.6300

oxidation, but are much smaller in magnitude.

The Fe K-edge XANES of these compounds also reflects an alteration of the Fe environment produced by nitriding. The near-edge threshold for R_2Fe_{17} is 0.4 ± 0.1 eV lower than the threshold for α-Fe. This suggests that, relative to α-Fe, there is a net electron transfer to the Fe. Assigning an approximate valence to Fe based on this shift is difficult. This is the result of the considerable variability in the rate with which $3d$ transition-metal edges shift with valence.[8] Nominally, the threshold shifts for the $3d$ K edges are ~1 eV per unit valence,[9] which suggests the average valence of the Fe sites in R_2Fe_{17} is anionically shifted by ~0.4 with respect to α-Fe. Indeed, this is qualitatively consistent with the valence of $-6/17$ that is anticipated from the formal rare-earth valence and the compound stoichiometry. The absorption thresholds of $R_2Fe_{17}N_{3-x}$ are shifted ~0.2 eV relative to their parents toward the α-Fe absorption thresholds. From this shift of the edge, it appears that Fe environment in the nitride is intermediate between its anionic state in R_2Fe_{17} and covalent state in α-Fe. We also note that the intensity of the pre-edge peak in α-Fe, $R_2Fe_{17}N_x$, and R_2Fe_{17} increases as the average volume of the Fe site decreases.

These XANES results imply a small negative charge transfer to the nitrogen for all three nitrides. These shifts imply that nitrogen is slightly anionic. While nitrogen cations are small, the covalent radius of nitrogen is 0.75 Å, and the anion is even larger. This steric consideration strongly suggests that for the R_2Fe_{17} lattice only the $9(e)$ and $18(g)$ sites are large enough to accommodate an interstitial nitrogen.

In the simplest approximation[10] the EXAFS oscillations are given by

$$\chi=\sum_j \frac{N_j}{kr_j^2} F_j(k)\theta^{-\sigma^2 r_j^2-2r_j/\lambda}\sin(2kr_j+2\theta_c+\theta_b), \quad (1)$$

where the summation extends over the coordination shells of the probed atom. For the jth component, N_j is the number of atoms in the shell, $F_j(k)$ the atomic backscattering amplitude, σ^2 the mean-square relative displacement[11] of the effective radius r_j, and $\theta_b(k)$ is the backscattering phase shift. The other factors determining $\chi(k)$ are the central atom phase shift $\theta_c(k)$ and the inelastic mean free path of the photoelectron λ. Due to the dependence of EXAFS on the chemical state of the atom, the most reliable determinations of bond distances and coordination numbers are made when the backscattering phase and amplitude functions are obtained from a chemically and structurally similar compound. In general, if the same atomic species occupies inequivalent lattice sites then the sum in Eq. (1) must be performed for each inequivalent site and averaged according to site multiplicity. In the Th_2Zn_{17} structure the rare earths occupy only one inequivalent lattice site [the $6(c)$] while there are four inequivalent Fe sites. As a consequence, analysis of the rare-earth EXAFS is simpler and more direct than the Fe EXAFS.

Because of the close relationship between the parent compounds and these nitrides, the parent compounds are excellent models for the rare-earth backscattering shells in the nitrides. It is possible to isolate the R-N shell in $R_2Fe_{17}N_{3-x}$

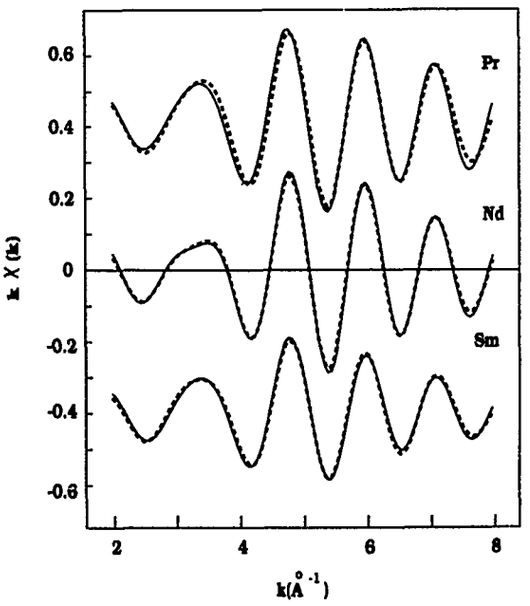

FIG. 1. Analysis of the filtered $\chi(k)$ EXAFS data from the first shell of randomly oriented powders of $R_2Fe_{17}N_{3-x}$ (R=Pr, Nd, Sm), using phase and backscattering amplitude functions from the parent compound for the R-Fe shell, and the rare-earth nitride for the R-N shell. The filtered data are given by the dotted lines, and the two shell fits are shown by the solid lines.

simply from the differences in the EXAFS oscillations in the following way: Since $f(k)$, $\theta_c(k)$, and $\theta_b(k)$ vary slowly with k, the phase difference in $\chi(k)$ due to a small (1%–2%) uniform lattice expansion, $r_j\rightarrow(1+\epsilon)r_j$, can be accounted for by k rescaling $k\rightarrow k/(1+\epsilon)$. By plotting $k^2\chi(k)$ for $k>5$ Å, which accentuates the Fe and rare-earth backscattering, and matching phases, an "average" expansion of the lattice can be readily determined. For the three sets of compounds we find that the lattice expansion determined by this procedure is very close to the average of the o- and a-axis expansions determined from x-ray diffraction.

We have analyzed the EXAFS data from the first shell of randomly oriented powders of $R_2Fe_{17}N_{3-x}$ using the phase and backscattering amplitude functions from the parent compound for the R-Fe shell, and the rare-earth nitride for the R-N shell. Since the central atom phase shifts of Pr and Nd are very similar, the Nd-N shell from NdN was used for analyzing the Pr compound. The R-N shell is not resolved from the first R-Fe shell in these nitrides, making it necessary to fit the Fourier-filtered data to a two-shell model. In general, both the parent compounds and the nitrides were Fourier filtered between 1.7 and 3.4 Å. Since the nitrogen backscattering contributes to the EXAFS only below 6 $Å^{-1}$, the uncertainties in this analysis are modestly large. We estimate the uncertainty in rare-earth–nitrogen shell radius and coordination number to be ±0.02 Å and ±1.0, respectively. The fits to the filtered data are shown in Fig. 1, and the rare-earth–nitrogen shell radii and coordination numbers are reported in Table II.

A comparison of the Pr and Nd results to the earlier work on Sm shows only minor differences between the three systems: a small (0.03 Å) contraction of the rare-earth–

TABLE II. $R_2Fe_{17}N_x$ EXAFS results.

$R_2Fe_{17}N_{3-x}$	$r_{R\text{-}N}$ (Å)	x
$Pr_2Fe_{17}N_{3-x}$	2.57±0.02	0.5±1.0
$Nd_2Fe_{17}N_{3-x}$	2.56±0.02	0.5±1.0
$Sm_2Fe_{17}N_{3-x}$	2.54±0.02	0.2±1.0

nitrogen shell between Pr and Sm, and a slight difference in the phase of the nitrogen backscattering (due to differences in the central atom phase shift).

Using oriented samples and utilizing the linear polarization of synchrotron radiation, we can further constrain the occupancy of the nitrogen site(s). To first order, the outgoing photoelectrons produced by the x ray follow a $\cos^2\Theta$ distribution, where Θ is the angle between the polarization vector and the exit angle of the photoelectron. By using this cone as a "flashlight" to see an enhancement in backscattering from a particular species, it is possible to identify bond directions.

The (Fourier-filtered) difference in the EXAFS oscillations from magnetically aligned powders of the Sm_2Fe_{17} and $Sm_2Fe_{17}N_{3-x}$ oriented in the x-ray beam so the x-ray polarization was parallel to their basal planes is shown in Fig. 2. There is an enhancement of the intensity of the nitrogen backscattering, which is clearly evident in the difference $\chi(k)$ shown in Fig. 2. The backscattering for the oriented powder is enhanced by a factor of 1.6±0.2 with respect to the randomly oriented powders. If all the nitrogen atoms are in the basal plane, i.e., in the 9(e) sites, the enhancement factor should be 1.5. For all nitrogen atoms in 18(g) sites the nitrogen backscattering should be diminished by a factor ~0.75. Using the estimated uncertainty of the enhancement factor of ±0.15, the measured enhancement requires that >80% of the nitrogen atoms are in the basal planes containing the rare earth sites in these compounds, the 9(e) site. This is quite different from the neutron-diffraction results for the Nd compound where ~40% of the nitrogen was found in the 18(g) sites.

In summary, the small shifts observed in the rare-earth L_3-edge and iron K-edge absorption thresholds between the parent R_2Fe_{17} compounds and their nitrides imply that nitrogen is nearly covalent in the nitrides. Based on the steric requirements of nearly covalent N, the only sites large enough to accommodate nitrogen are those of 9(e) and 18(g) symmetry. For $R_2Fe_{17}N_{3-x}$ the R-N shell radii range from 2.57 to 2.54 Å for R=Pr, Nd, or Sm. A composite estimate of the nitrogen occupancy from the three nitrides gives a R-N coordination of 2.6±0.6. The observed enhancement of the nitrogen backscattering from the oriented $Sm_2Fe_{17}N_{3-x}$ requires that >80% of the nitrogen occupies the 9(e) sites, though it is fully compatible with 100% occupancy of the 9(e) site. This is consistent with the structure found by neutron diffraction for the Y homologue of this series.

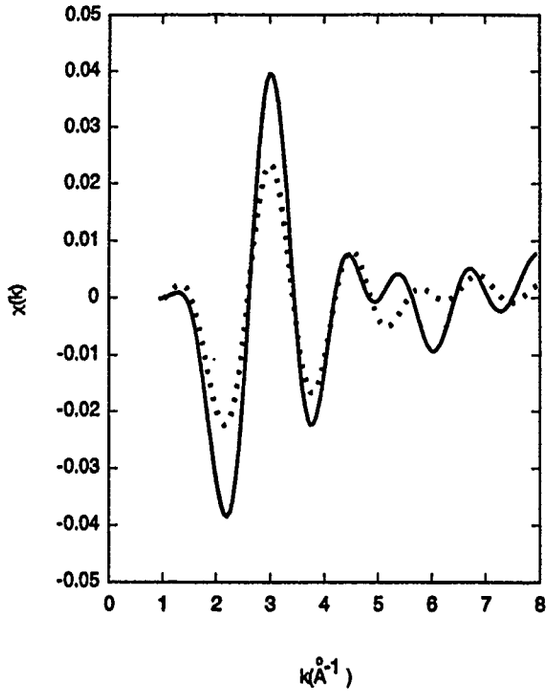

FIG. 2. A comparison of the Fourier-filtered difference between $Sm_2Fe_{17}N_{3-x}$ and the Sm_2Fe_{17} EXAFS oscillations $\chi(k)$ for magnetically aligned powders (solid line) and unaligned (dotted line).

We thank CHESS and NSLS for the use of their facilities during these experiments. This research was carried out (in part) at the National Synchrotron Light Source, Brookhaven National Laboratory, which is supported by the U.S. Department of Energy, Division of Materials Science and Division of Chemical Sciences (D.O.E. Contract No. DE-AC02-76CH00016).

Exchange stiffness and magnetic anisotropies in bcc $Fe_{1-x}Co_x$ alloys

X. Liu and R. Sooryakumar
Department of Physics, The Ohio State University, Columbus, Ohio 43210

C. J. Gutierrez and G. A. Prinz
Naval Research Laboratory, Washington, DC 20375

Brillouin scattering measurements from several bcc $Fe_{1-x}Co_x$ epitaxial films are reported. The magnetic-field dependence of the spin-wave spectrum as well as the in-plane directional dependence of the surface magnon are determined. The saturation magnetization of the alloys was measured independently through superconducting quantum interference device magnetometry. Self-consistent fitting of the magnon dispersions determined from the separate Brillouin experiments provide values for the concentration dependence of the exchange stiffness D, the fourth-order crystalline cubic anisotropy K_1, and surface anisotropies K_s and $K_{s,p}$. In agreement with ferromagnetic resonance data, K_1 is found to change sign for x beyond about 35 at. % while D steadily increases with cobalt concentration up to $x\sim0.5$ and subsequently decreases in two Co-rich samples.

Despite tremendous recent progress, itinerant ferromagnets such as the $3d$ metals continue to provide challenges in understanding their electronic properties. The central problem remains that of electron correlations and their influence on various magnetic properties. On the one hand, magnetotransport[1] and existence of a Fermi surface[2] show that these electrons have a delocalized band-state character and display extended moment features. On the other, the Curie-type high-temperature magnetic susceptibility[3] argues for localized atomlike behavior. It is important to recognize that these mutually opposite extremes are connected continuously by varying the relative strength of the electron-electron interaction U/W, where U and W are the intra-atomic Coulomb energy and bandwidth, respectively.

The recent successful growth of epitaxial bcc $Fe_{1-x}Co_x$ films,[4] that include elemental bcc Co (Ref. 5) and bcc Fe as end members, offers a unique opportunity to address some of the important issues relating to itinerant ferromagnets. The possibility to systematically vary a few critical parameters that influence the renormalization of bare interaction parameters and the occupation numbers in k space, allows for a study of their effects on the spin dynamics. Located toward the end of the $3d$ series, it is believed that the hcp phase of cobalt is more strongly correlated than bcc Fe.[6,7] The bandwidth W of metastable bcc Co (Refs. 8 and 9) is approximately 1.5 eV smaller than that of hcp Co making this phase of Co one of the most strongly correlated $3d$ ferromagnets. Thus, in moving across the alloy series the strength of the correlation is directly varied from the strongly correlated bcc Co limit to the weak ferromagnet bcc Fe.

It is special that all $Fe_{1-x}Co_x$ films ($0\leq x\leq1$) are grown in registry with the same substrate and stabilized in the bcc phase.[4] Hence, the series is characterized by one crystal structure and essentially uniform lattice parameters. This feature thus allows for direct comparison of the magnetic properties of different alloys, without modeling the uncertain effects of lattice spacings and crystal structures.

A correct description of dynamical spin fluctuations in the intermediate regime between local and itinerant magnetism is essential to a unified theory, and thus the spin susceptibility $X(q,\omega)$ is a key parameter.[10] The imaginary part of $X(q,\omega)$ is observed by light scattering from spin waves where the energy of long-wave magnons is given by $\hbar\omega=Dq^2$. For small q and ω, D can be calculated rigorously and its sign and magnitude are a direct measure of the stability of the ferromagnetic state.[11] D is also of interest, since the variation of the Curie temperature with composition seems to be largely controlled by the low-temperature value of D.[12] Magnetic anisotropies, both surface and volume contributions, also play a crucial role in the stabilization of long-range ferromagnetic order in laminar geometries.

In this article we report on Brillouin scattering measurements from thermal magnons in five $Fe_{1-x}Co_x$ films (Table I). The magnetic-field dependence and anisotropies of the spin-wave characteristics relative to the crystalline axes are utilized to determine $D(x)$ and the anisotropy constants K_1 (volume magnetocrystalline), $K_{s,p}$ (surface in plane) and K_s (surface out of plane). With increasing Co concentration ($0.3\leq x\leq0.47$) D is found to increase from 470 to 800 meV Å^2 and then decrease in two samples for $x>0.6$. We also determine that K_1 changes sign from being positive to negative at $x\sim0.35$, a result consistent with ferromagnetic resonance measurements.[4]

The $Fe_{1-x}Co_x$ (001) films several hundred angstroms thick were fabricated by molecular-beam epitaxy on ZnSe (001)-epilayered GaAs (001) substrates. The films were characterized by electron diffraction, Auger spectroscopy, and the final alloy composition measured by x-ray fluorescence.[4] The average magnetic moments of the films were determined at room temperature with a superconducting quantum interference device (SQUID) magnetometer.

The Brillouin measurements were performed at room temperature utilizing up to 100 mW of p-polarized $\lambda=514.5$ nm laser light.[13] Two independent Brillouin experiments were carried out on each film. In one, the field dependence of the bulk ω_B and surface ω_s magnon frequencies was measured, since their response is particularly sensitive to D. In a second series of measurements, H was rotated in finite steps

away from the [100] axis by an angle ϕ_H and the magnon frequencies determined. These experiments provide for the magnetic anisotropies. Results for the spin-wave stiffness previously determined[13] from pure bcc (110) Co films grown directly on to GaAs substrates are also included in the following section. Thus comparing its surface anisotropies with those of other samples should be done with caution.

Figure 1 shows a series of Brillouin spectra from $Fe_{0.53}Co_{0.47}$ in different applied magnetic fields. The strongest feature S in the spectra is the surface mode ω_s. With increasing H, ω_s increases steadily. The weaker peak at higher frequency shifts is the first bulk magnon ω_{B_1}. The corresponding spin-wave frequencies are plotted as a function of H in the inset to Fig. 1. The solid lines are a fit to the field dependence data based on the analysis discussed below. Figure 2 shows spectra of the surface mode from $Fe_{0.53}Co_{0.47}$ as a function of ϕ_H at $H=2$ kG. Reflecting magnetic anisotropies in the films, ω_s displays an oscillatory behavior with ϕ_H that is summarized in the inset to Fig. 2. The solid curve is the result of calculations presented below. Similar Brillouin spectra with comparable quality of fits were obtained from the other samples. The results for M, the saturation magnetization, as determined from SQUID magnetometry, are summarized in Table I.

The Brillouin data for the H and ϕ_H dependence are utilized self-consistently to determine the important spin-wave parameters in $Fe_{1-x}Co_x$. The field-dependent data were analyzed as detailed in our previous studies.[13] Briefly, we utilize Maxwell's equations and the equation of motion of M. Boundary conditions related to the continuity of the normal and in-plane magnetic fields at the film interfaces as well as the general exchange boundary conditions[13] $\mathbf{M}\times(\nabla_{\mathbf{M}}E_{\text{surf}} - D\partial\mathbf{M}/\partial\mathbf{n})$ where E_{surf} is the surface anisotropy energy density and $\mathbf{n}$ the unit vector normal to the film are enforced. The resulting set of homogeneous equations yield nontrivial solutions only if the corresponding determinant is zero. The

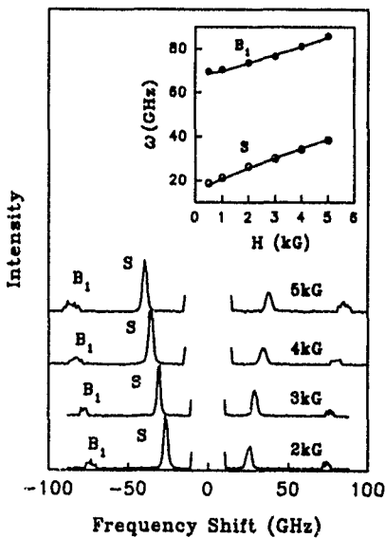

FIG. 1. Brillouin spectra of $Fe_{0.53}Co_{0.47}$. The magnetic field H was directed along [100]. The angle of incidence was 21°. The inset shows the surface ω_s and first bulk ω_B spin-wave frequencies as a function of H. The solid lines are a fit using our model.

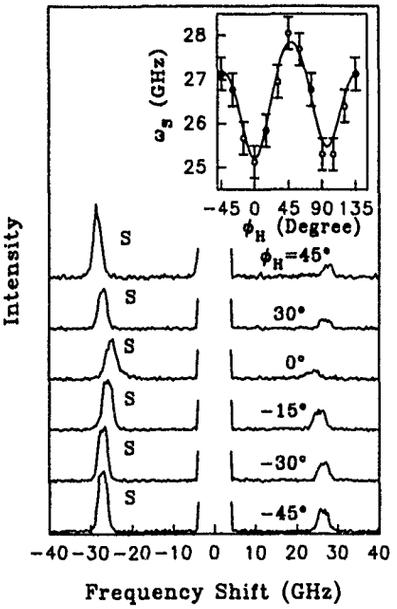

FIG. 2. Brillouin spectra of $Fe_{0.53}Co_{0.47}$ as a function of ϕ_H, the angle of the magnetization direction with respect to [100]. The measurement was done at $H=2$ kG and the angle of incidence was 21°. The inset summarizes the oscillatory behavior of $\omega_s(\phi_H)$. The solid line is a fit to the data.

determinant is employed in an iterative scheme where D, γ, K_1, $K_{s,p}$, and K_s are varied to satisfy the condition of a vanishing determinant. The field dependence of ω_B and ω_s is most sensitive to D and γ.

The anisotropy constants have a strong influence on $\omega_s(\phi_H)$ and the ϕ_H dependence can be derived from the free-energy density to yield, for $qd \ll 1$, the expression[15]

$$\omega_s^2=\frac{\gamma^2}{M^2}\, f_{\theta\theta}f_{\phi\phi} + 2\pi\gamma^2 \frac{f_{\theta\theta}+f_{\phi\phi}[1+2/(qd)]+4\pi M^2}{1+1/(qd)}, \qquad (1)$$

where, for (001) growth,

$$f_{\theta\theta}=MH\cos(\phi-\phi_H)+K_1(4\sin^4\phi-4\sin^2\phi+2) + \frac{4}{d}\,[K_s-K_{s,p}\cos^2(\phi-\phi_0)],$$

$$f_{\phi\phi}=MH\cos(\phi-\phi_H)+K_1(16\sin^4\phi-16\sin^2\phi+2) + \frac{4}{d}\,\{K_s-K_{s,p}\cos[2(\phi-\phi_0)]\}.$$

$f_{\theta\theta}$ and $f_{\phi\phi}$ are second derivatives of the free-energy density with respect to θ and ϕ, evaluated at the equilibrum angles. θ is the polar angle of M with respect to [001] and ϕ the azimuth angle with respect to [100]. ϕ_0 is the tilting angle of $K_{s,p}$ with respect to [100], q the in-plane magnon wave vector, and d the film thickness.

Dispersion of the $\omega(H)$ magnon branches is obtained from the numerical iteration scheme and provides excellent fit to the data. For example, calculations for $Fe_{0.53}Co_{0.47}$ are shown as solid lines in the inset to Fig. 1. Similarly data for $\omega_s(\phi_H)$ are fitted utilizing Eq. (1). The parameters K_1, K_s, $K_{s,p}$, and ϕ_0 were used iteratively to provide the best fit to the $\omega_s(\phi_H)$ data. The anisotropy constants thus deduced agreed, within the error bars, with those values determined from the $\omega(H)$ behavior. A typical fit for $\omega_s(\phi_H)$ is shown in Fig. 2. The resulting parameters are listed in Table I.

Although elemental bcc Fe is ferromagnetic, fcc Fe is antiferromagnetic as is the neighboring element Mn. Thus, Fe is on the boundary between ferromagnetism and antiferromagnetism. The increasing values for D determined in the Fe-rich $Fe_{1-x}Co_x$ alloys indicate an intrinsic stability of ferromagnetism in these alloys. The variation of D with composition in bulk alloys of Fe with a limited Co concentration ($x \leq 0.50$) was measured by neutron scattering in 1965.[16] While our values for D are generally consistent with these measurements for high Fe concentrations, D for the $x \sim 0.5$ sample deduced from the present study is about 60% larger. The reason for this deviation is unclear, and may be related to differences in sample quality; no details of structural or magnetic characteristics of the alloys utilized in Ref. 16 are available. The decrease in D we find for the $x=0.68$ and $x=1$ films suggest that, if the Curie temperature is largely determined by spin-wave excitations, T_c is decreasing in this Co concentration regime.

Model band calculations by Edwards and Muniz[11] yield an explicit formula for D for an alloy with varying electron concentrations. The theory has been applied[17] to $Fe_{1-x}Co_x$ and predicts an increase in D of over 50% from the pure Fe value to that in $Fe_{0.5}Co_{0.5}$ and thus is qualitatively in agreement with our measurements. However, reasons for the decreasing trend in the measured magnitude of D for the two Co-rich films ($Fe_{0.32}Co_{0.68}$ and bcc Co), which is similar to reports on the dependence of D on x from bulk $Fe_{1-x}Cr_x$ alloys,[16] are not readily apparent. Qualitative differences as $x \to 1$ in the local minority and majority density of states from which the local moments are derived are particularly relevant. Moreover, what effect do the strong electron correlations expected in bcc Co play in the spin-wave stiffness D? Such questions have been addressed by Callaway and Wang,[10] who considered the effect of electron correlations on D using spin-dependent local exchange plus correlation potential of a ferromagnetic electron gas. It is shown that in this simple, though unrealistic, model correlations do lead to a substantial reduction in D. In real correlated metals such as bcc cobalt, the reductions should continue to be present, but their magnitude is unknown.

In summary, Brillouin measurements on $Fe_{1-x}Co_x$ alloys have provided the composition dependence of the exchange stiffness, the cubic and surface anisotropy constants. $D(x)$ increases steadily until $x \sim 0.5$ beyond which it is found to decrease. The composition dependence of K_1 is strong and changes sign around $x \sim 0.35$. These measurements of $D(x)$ and $K_1(x)$ in well-characterized $Fe_{1-x}Co_x$ alloys should enable testing current first-principle calculations on spin fluctuations in the regime between local and itinerant magnetism and magnetic anisotropies without being burdened by extraneous issues such as structural and lattice constant modifications.

Approach to the electronic structure of antiferromagnets

J. Callaway, D. G. Kanhere,[a] and A. Kolchin
Department of Physics and Astronomy, Louisiana State University, Baton Rouge, Louisiana 70803-4001

A study of a simple band model of a commensurate, two-dimensional antiferromagnet is briefly described. A self-consistent calculation shows a transition from a paramagnetic to a metallic antiferromagnetic state when an interaction is stronger than a critical value. The transition is accompanied by a change in size (large to small) of the Fermi surface. An insulating state may be obtained if there is exactly one electron per site.

I. INTRODUCTION

Although density functional theory is expected to give an exact description of the ground state of a system of electrons, calculations based on the local spin density approximation (LSDA) frequently give quite unsatisfactory results for antiferromagnetic insulating, transition-metal compounds.[1,2] In some cases (CoO, La_2CuO_4, for example), the materials are predicted to be metallic, contrary to fact. In other cases (MnO, NiO) which are predicted to be insulating at $T=0$, the gap is too small, and the magnitude of the local moment is too small. Several different procedures have been advocated to avoid these difficulties: One can employ a model Hamiltonian approach which contains parameters representing LSD bands combined with other terms of the Hubbard type to represent short-range electron interactions. The methods of many-body theory can then be employed to obtain a more satisfactory description of the electronic structure.[3] The self-consistent inclusion of a self-interaction correction has been proposed as a method for modifying the LSDA itself.[4] However, the bands resulting from these calculations do not appear to agree well with results of photoemission measurements. Another approach modifies the LSDA energy functional by the addition of two Hubbard-like, orbital-dependent terms.[5]

Here we propose another procedure, similar to that of Anisimov and co-workers,[5] but intended to retain what we consider to be an important feature of the LSDA, independence of an orbital basis. Specifically, we add to the exchange correlation potential of the standard LSDA, a "magnetic pseudopotential" which is determined from the spin density in the magnetic state. The pseudopotential contains an arbitrary constant which is intended to be adjusted so that some important calculated property, such as a spin moment, or an energy gap, agrees with experiment. Since the pseudopotential involves the spin density, a self-consistent calculation is required.

In this article we report the application of this procedure to a simple model, reserving the question of its utility in quantitative investigations of real materials to a subsequent publication.

II. MODEL

We discuss a simple two-dimensional (square) antiferromagnet in a two-sublattice approximation. Spiral, incommensurate, and disordered systems are not considered. We use for the ordinary potential of the chemical lattice

$$V(\cos 2\pi x/a+\cos 2\pi y/a), \tag{1}$$

where a is the chemical lattice constant. We investigate the possible establishment of an antiferron agnetic state by an interaction (the magnetic pseudopotential),

$$4U\rho_{-\sigma}(K_1)\cos \pi x/a \cos \pi y/a. \tag{2}$$

This term is added to the Schrödinger equation for electrons of spin σ; a corresponding term which is, however, proportional to $\rho_{\sigma}(K_1)$ is added to the corresponding equation for spin $-\sigma$. The quantity K_1 is the magnitude of the smallest reciprocal lattice vector of the magnetic structure. A consequence of introducing the potential (2) is to add a term to the energy (i.e., to the exchange correlation functional),

$$N(K_1)U\rho_{\sigma}^2(K_1), \tag{3}$$

where $N(K_1)$ is the number of wave vectors in the star of K_1 (4 in the present example).

The calculation of the band structure with the use of Eq. (2) has to be made self-consistently, since it involves $\rho_{-\sigma}(K_1)$, which has to be obtained from the wave functions. Two features which result from the self-consistency requirement deserve comment as follows.

(i) The model obeys the theorem of Kohn and Nettel.[6] In general, an antiferromagnetic solution can arise self-consistently in systems of two and three dimensions only for U greater than some minimum value. This does not apply in one dimension, and these are exceptions for band structures with special features, such as perfect nesting. In this respect, the present model differs significantly from the usual nearest-neighbor tight binding band often employed in the study of high-T_c superconductors, for which any repulsive Hubbard interaction, no matter how weak, leads to an antiferromagnetic state.

(ii) The model is not equivalent to the imposition of a staggered magnetic field, a device which has already been employed in some LSDA calculations[7] and can also lead to antiferromagnetism. In the present case, the interaction involves a Fourier coefficient of the spin density. This Fourier coefficient depends on both the angular and the radial variation of the spin density. In contrast, a magnetic field couples only to the net spin excess on the site. We believe our approach is more flexible and capable of extension in that additional pseudopotential parameters may be introduced if desired. It is also more complicated because self-consistency is

required. Whether these differences in principle will lead to significantly different results remains to be determined by calculations for physical materials.

III. RESULTS

We summarize the essential results of our calculations on the two-dimensional model below. It is hoped to publish a more complete account elsewhere.[8] First, we consider the half-filled band case, one electron per site.

In this case, as U is increased from zero, nothing happens until a critical value U_c is reached. At this point, antiferromagnetism develops but the system remains metallic. A gap develops around the point $(\pi/2,\pi/2)$ in the two-dimensional Brillouin zone which gradually diminishes along the diagonal line to $(\pi,0)$. The lowest state at $(\pi,0)$ is doubly degenerate. There is a pocket of holes around $(\pi,0)$ and an electron pocket in the second band around $(\pi/2,\pi/2)$. As U is increased further, the system becomes insulating. The transition between antiferromagnetic metal and antiferromagnetic insulator occurs when a nondegenerate state in the third band falls below the doubly degenerate state. This causes a reconnection of the band structure. The lowest band is cut off from the others and is completely occupied. As U is further increased, the width of the occupied band decreases rapidly. Although the model is a band model, it is natural to describe the large U system as localized.

It is convenient, in presenting quantitative results, to remove the lattice constant from the problem by modifying the usual Rydberg atomic units so that the unit of energy is $(4\pi^2/a^2)$Ry, a being the lattice constant in Bohr units. One may observe that $2\pi/a$ is not very far from unity for many physical systems, so that for qualitative purposes, energies are roughly Rydbergs. The values we quote for U and V below are in these units.

Now we consider occupancies n_e per site different from 1. For small values of n_e the system is nonmagnetic. As n_e increases, there is a transition to an antiferromagnetic but still metallic state. In this state, the Fermi surface, which is shown in Fig. 1, comes into contact with the boundary of the Brillouin zone. The portion of the Fermi surface in contact with the zone boundary effectively disappears since there is an antiferromagnetic gap on the boundary. The Fermi surface consists of pockets of holes around the zone corners, which fill in as $n_e \to 1$. The value of the hole doping $\delta = 1 - n_e$ at which the transition between antiferromagnetic and paramagnetic states occurs depends on both U and V [the strength of the ordinary potential Eq. (1)]. In the case shown in Fig. 1, the transition occurs at about $n_e = 0.73$.

A diagram showing the critical value U_c as a function of n_e is presented in Fig. 2. This has been computed for a relatively small value of V (0.15). We see that U_c is rather flat as n_e decreases from 1. The curve turns up at about $n_e = 0.8$, which is close to the value $\pi/4$ at which a free-electron Fermi circle would come into contact with the (magnetic) zone boundary. For n_e smaller than this, U_c rises rapidly because large distortion of the free-electron Fermi circle is required to establish an antiferromagnetic state.

The value of the "hole" concentration required cause a transition to a nonmagnetic state in this example (≥ 0.2) is much larger than that for which it occurs in some cuprate superconductors; however, alternative parameters can readily be found for which the critical value of $\delta(\delta_c)$ is much smaller. As examples, we note that for $V=0.5$ and $U=1.6$, it occurs for $\delta_c \sim 0.07$, while for $V=0.5$ and $U=1.5$, $\delta_c = 0.01$. In general, when V increases, the curve of U_c vs n_e becomes steeper.

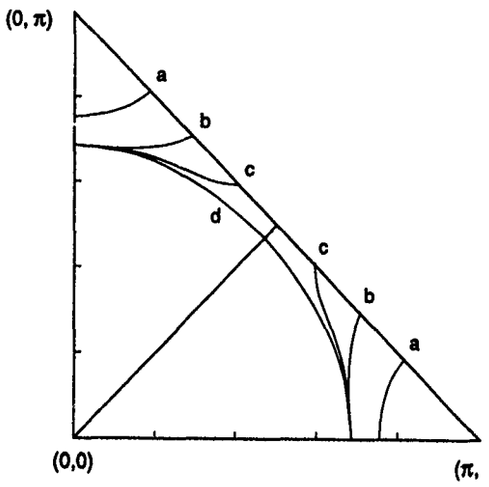

FIG. 1. Fermi "surfaces." Two irreducible wedges are combined to show symmetry. Curves: (a) $n_e=0.90$; (b) $n_e=0.80$; (c) $n_e=0.75$; (d) $n_e=0.72$. Parameters: $V=0.15$, $U=0.55$.

Luttinger's theorem[9] asserts that the volume enclosed by the Fermi surface in an interacting system is the same as the volume enclosed by the Fermi surface in a noninteracting system of the same n_e. However, this theorem does not apply when there is a change in the spatial periodicity. This does change when antiferromagnetism disappears.

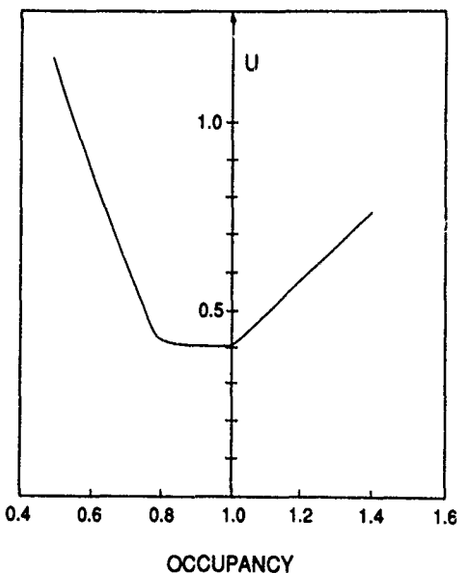

FIG. 2. The critical potential strength for a transition from a paramagnetic to a metallic antiferromagnetic state as a function of occupancy n_e. This diagram was calculated for $V=0.15$. The antiferromagnetic insulating phase occurs only for $n_e=1$ and $U>0.46$.

An n_e increases beyond 1, qualitatively similar but quantitatively different behavior occurs. Elliptical electron pockets in the second band are formed around the point $(\pi/2,\pi/2)$. These expand toward X. Utlimately, the pockets reach X, antiferromagnetism disappears, and a large Fermi surface reappears. As n_e increases still further toward 2, the Fermi surface changes to holelike, corresponding to a nearly full band.

In summary, we have explored a simple, self-consistent band model which exhibits a transition between a paramagnetic and an antiferromagnetic state when an interaction is stronger than a critical value. The transition is accompanied by a change in size (large to small) of the Fermi surface. If there is exactly one electron per site, an insulating state may be formed. We believe this approach may be readily generalized to apply to realistic electronic structure calculations. Obviously, the utility of our approach in realistic calculations will depend on whether it is possible to obtain agreement with experiment with the use of a small number (one or two) magnetic pseudopotential parameters. This remains to be tested.

Magnetization density in URu_2Si_2 and URh_2Si_2

Alessandra Continenza and Patrizia Monachesi
Dipartimento di Fisica, Universitá dell'Aquila, I-67100 L'Aquila, Italy

The magnetic properties of the isostructural compounds URu_2Si_2 and URh_2Si_2 are compared in order to ascertain the different role played by Ru vs Rh. The total magnetic moment, obtained by spin-polarized electronic calculations with the full potential augmented plane-wave method within local spin-density approximation, agrees quite satisfactorily with the measured one in URh_2Si_2, whereas it is orders of magnitude too big in URu_2Si_2. However, important differences are found among the two compounds: These are the substantial contribution to the total magnetic moment of negative d spin polarization and the larger radial extention and asphericity of the magnetization density (in two crystal planes) in the Ru compound compared to the Rh compound. Also, the f positive spin-polarization density on U differs in the two compounds. This should result in different magnetic form factors in diffraction experiments.

URu_2Si_2 and URh_2Si_2 form in the tetragonal $ThCr_2Si_2$ structure whose atomic coordination is shown in Fig. 1. Both compounds order with a simple antiferromagnetic (AFM)[1-3] stacking along the c axis and their effective magnetic moment at high temperature is close to that of the U^{4+} ion. However, besides the structural similarities in the paramagnetic and ordered phases, the two compounds show dramatically different behavior below T_N.

The measured magnetic moment is $\simeq 0.03\mu_B$/f.u. and $1.96\mu_B$/f.u. below $T_N = 17.3$ and 138 K in URu_2Si_2 (Ref. 2) and URh_2Si_2,[3] respectively. Moreover, URu_2Si_2 is a heavy-fermion antiferromagnet (specific-heat coefficient $\gamma = 180$ mJ/mol K^2), becomes a superconductor[2,4] below $T_c \simeq 1.2$ K, and shows several other peculiarities in the specific heat, thermal expansion,[5] magnetic excitations,[1] and susceptibility.[6]

Tentative explanations for the phenomenology of URu_2Si_2 have been given in terms of crystal field[7] or quadrupolar order,[6,8] but none is thoroughly consistent with all the experimental observations at the time. On the other hand, none of the anomalies found in URu_2Si_2 has been observed in URh_2Si_2, whose low-temperature behavior fits in the trend of other isostructural compounds.[3]

Presently, we undertake *ab initio* electronic structure calculations for the two compounds to investigate the different role played by Ru compared to Rh in the paramagnetic and ordered phases. Electronic effects due to the valence configuration of the metallic ion seem to be of extreme importance as suggested by magnetization measurements[9] on polycrystals of $URu_{1-x}Rh_xSi_2$. In the ternary compound the behavior of T_N versus concentration changes drastically for values of x that do not affect the volume considerably. This behavior reminds us of the transition from a magnetic to a moment-reduced Kondo state [e.g., CeAg (Ref. 10)], due to the increase[11] of the Anderson hybridization.

The self-consistent calculations are made with a full potential augmented plane-wave (FLAPW) method[12] within the local spin-density approximation[13] (LSDA). We use for both compounds the lattice constants[2] of URu_2Si_2, $a = 4.124$ Å and $c = 9.582$ Å, the actual volume difference among the two compounds amounting to $\simeq 1\%$.

Numerical results in the paramagnetic state yield, at E_F, a dominant density of states (DOS) n_l with f character on U and d character on the transition-metal ion, in both compounds (n_f is of the order of 4 states/eV U ce other l states as well as Si states contribute negligibly at E_F in both cases. The integrated density of occupied states amounts to about 2.8, 2.7 el/U for f states and 6.5 el/Ru, 7.5 el/Rh for d states in URu_2Si_2 and URh_2Si_2, respectively. The Stoner factor in the paramagnetic phase is found to be equal to 1.0 in URh_2Si_2 and to 0.88 in URu_2Si_2.

There are differences among the two compounds in the f and d density of states close to E_F. Worthy of notice in URu_2Si_2 is the occurrence of a partial splitting of the f DOS in a higher peak above and a lower peak below E_F. The latter has a $\simeq$1-eV-wide resonance below E_F with a high peak of $d$states from Ru.

The spin-polarized calculations are done in the ferromagnetic configuration for both compounds. Although not the ground state, the ferromagnetic phase is obtained in the presence of an external field.[14] We focus on the ferromagnetic phase since we believe that the effects on the magnetic properties of the different valence configuration of Ru and Rh are qualitative the same as in the antiferromagnetic phase. Results of spin-polarized calculations are summarized in Table I.

In URh_2Si_2 the total moment agrees satisfactorly with

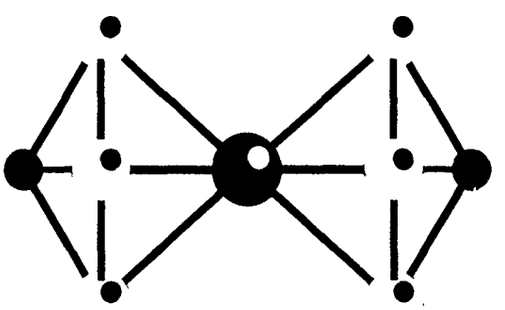

FIG. 1. Atomic coordination of the tetrahedral structure of URu_2Si_2 and URh_2Si_2. The c axis passes through the U (black/white dot) atom and two Si (black) atoms The plane (010) contains one U, four Ru/Rh, and two Si atoms. The basal plane (001) contains four Ru/Rh atoms (white/black dot).

TABLE I. Total magnetic moment and most relevant l partial components from different atoms (in parentheses) in UX_2Si_2 (where X=Ru, Rh) obtained from spin-polarized calculations in the ferromagnetic configuration.

Type	μ_T (μ_B/f.u.)	μ_f (μ_B/U)	μ_d (μ_B/U)	μ_d (μ_B/X_2)
URu_2Si_2	1.37	1.41	0.07	−0.22
URh_2Si_2	1.83	1.75	0.07	−0.08

the experimental one: The f component contributes ≈96% to the total magnetic moment. In URu_2Si_2 the LSDA total moment is lower due to a conspicuous antiparallel contribution from the d states on Ru (lacking on the Rh compound) and to a lower f polarization. μ_T is, however, in very bad agreement with the measured value in URu_2Si_2, as also found in previous[15] electronic structure calculations for the antiferromagnetic phase. These results support *a posteriori* the idea that the type of magnetic order is not crucial to understand the different behavior of the two materials.

In Figs. 2 and 3 we report the most relevant partial DOS for the spin-polarized case in the two compounds. The splitting found in the paramagnetic f DOS of URu_2Si_2 is enhanced by the exchange field but only for the majority spin component. This fact, along with the different spin polarization of the d electrons in Ru and Rh, brings us to look at the spatial distribution of the magnetization density.

We plot in Figs. 4 and 5 the net spin polarization in two crystal planes parallel and perpendicular to the c axis (see Fig. 1). It can be seen that in the plane (010) the symmetry of

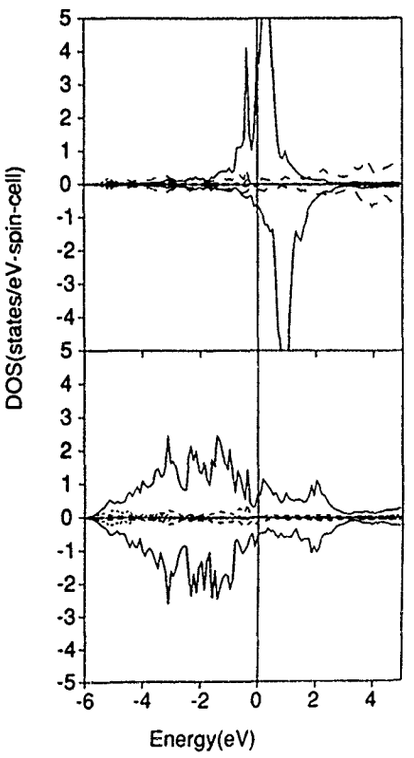

FIG. 2. Minority and majority spin DOS of URu_2Si_2 on U (top) and on Ru (bottom). The solid line refers to f states on U and d on Ru. Minor l components are also indicated by dotted lines.

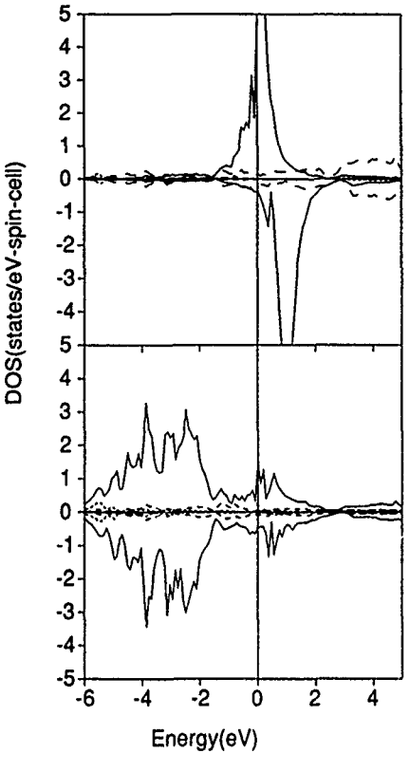

FIG. 3. Same as in Fig. 2, for URh_2Si_2.

the majority spin density on U, essentially f-like, as well as the minority spin density of essentially the d states on the metallic ion, is different in the two compounds. Also, in the basal plane (001), the negative spin density on Rh is quite

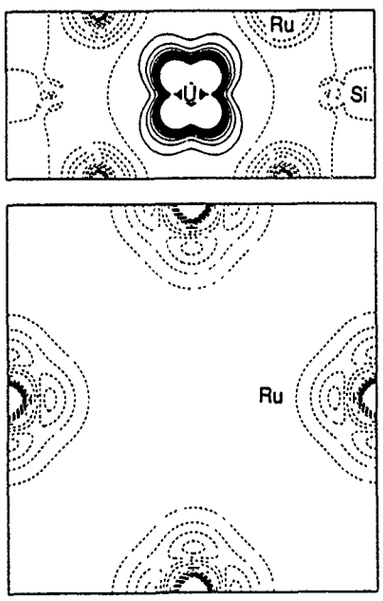

FIG. 4. Magnetization density in the crystal plane (010) (upper panel) and (001) (lower panel) of URu_2Si_2. Continuous and dotted lines indicate the contours of positive and negative spin density, respectively. Contours are equally spaced by 1.0 el/cell.

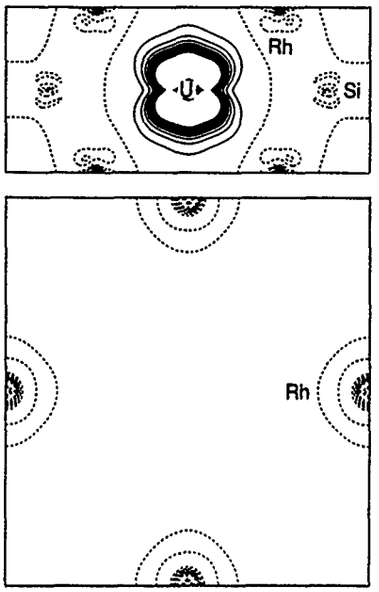

FIG. 5. Same as in Fig. 4, for URh_2Si_2.

different from Ru, with a larger asphericity and inhomogeneity on the latter ion.

The results obtained so far suggest the following major conclusions.

There are two main differences found presently among URh_2Si_2 and URu_2Si_2 and must stem only from the outermost configuration of Ru compared to Rh and not from volume effects, as follows.

(i) The *d* minority spin polarization on Ru is about three times larger than on Rh. This substantial spin polarization has not been found in previous calculations[15] in the AFM configuration nor pointed out explicitly in any experimental measurement. Worthy of notice is that the *d* spin polarization on Ru and Rh is not proportional to the U *f* moment (see Table I).

(ii) The spatial distribution of the magnetization density calculated in the two planes (001), (010) has a different profile and magnitude in the two compounds. As a consequence, one would expect substantially different magnetic form factors in the two compounds, especially in the (001) plane since the contribution from the Ru minority spin density has a radial extension twice as large as Rh. The different magnetization density patterns, both on U and Ru/Rh atoms, suggest that the magnetic coupling in the two planes shown in Figs. 4 and 5 may differ considerably in the two compounds. From the analysis of the total valence-charge density in the same planes we find that in URu_2Si_2 the charge density on Ru near the nucleus is higher in the (001) than in the (010) plane. In the latter case the interstitial charge density is substiantially nonuniform. In URh_2Si_2 the role of the two planes is reversed and the interstitial charge density in the plane (010) is roughly half that of URu_2Si_2. This raises the question of the validity of the point-charge model in the determination of the crystal-field parameters in URu_2Si_2 and the role of the crystal field in determining the superconducting pairing in heavy-fermion compounds.[16]

As found in several compounds of Ce with moderate or strong correlation, the strength of the hybridization, increased[11] by pressure or composition, may drive a transition from a (anti)ferromagnetic to a spin-compensated Kondo ground state. Since this behavior is actually shown by $URu_{1-x}Rh_xSi_2$ for $x>0.3$, calculations of the hybridization in the two compounds is in progress. Worth noticing is that in URu_2Si_2 a strong hybridization is expected between the U *f*, the Ru *d* states, and, possibly, Si *p* states. If this is the case, one would be in the presence of Anderson hybridization due to metallic superexchange. This might render the spin-spin coupling strongly dependent on the crystal-field state.

In $TbPO_4$, an antiferromagnetic-phase transition is accompanied by a cooperative Jahn–Teller effect involving a Tb ion-lattice coupling that induces a tetragonal-to-monoclinic distortion of the crystal lattice and an associated readjustment of the Tb electronic states as required by the lowering of the rare-earth-site symmetry. The laser-excitation and emission spectra of $TbPO_4$ and 0.1% Tb-doped YPO_4 single crystals were studied at temperatures below and above the phase transitions. The line shapes of transitions in the stoichiometric compound are unusually broad and asymmetric while those observed for the dilute compound are relatively sharp. In addition, the $TbPO_4$ spectra show an anomalous temperature dependence near the phase transition, indicating strong interactions of the rare-earth ions with their local environments. In the present work, a comparison of the optical results with the results of new neutron-scattering measurements is made.

I. INTRODUCTION

Rare-earth orthophosphates, RPO_4 (R=Tb–Lu), crystallize in the tetragonal zircon structure (space group $I4_1/amd$) in which four equivalent rare-earth ions in a unit cell occupy sites of D_{2d} symmetry. The low-temperature magnetic properties of these compounds are strongly influenced by the symmetry of the rare-earth low-lying states that are split by crystal-field effects. The Tb, Dy, and Ho compounds have doublet ground states dominated by $|J \pm J_M\rangle$ components of large J_M, while the Er, Tm, and Yb compounds have ground states that are either energetically isolated singlets or Kramers doublets with a highly isotropic spin-magnetization density. Consequently, long-range antiferromagnetic ordering has been observed only in the former compounds with Néel temperatures T_N=2.28, 3.4, and 1.39 K for $TbPO_4$, $DyPO_4$, and $HoPO_4$, respectively.[1–3] The antiferromagnetic phase has a simple "two-sublattice" structure with the direction of the rare-earth magnetic moment lying parallel/antiparallel to the crystallographic c axis. Many magnetothermal properties, such as the magnetic susceptibility and heat capacity of these materials, can be adequately described by either a three-dimensional Ising model[4,5] or by a molecular-field theory.[6]

$TbPO_4$ differs from the $DyPO_4$ and $HoPO_4$ antiferromagnets in the occurrence of an additional Jahn–Teller transition at 2.15 K where the Tb ion-lattice coupling induces a distortion of the tetragonal lattice to a monoclinic structure with a corresponding tilting of the Tb moments away from the tetragonal c axis in the (110) plane.[7–9] A number of investigations, both experimental and theoretical, have previously been undertaken in attempts to understand the intriguing properties of $TbPO_4$. In particular, the interpretation of the optical-absorption and emission spectra (as well as electronic Raman-scattering data) of $TbPO_4$ are complicated by unusually broad transitions and asymmetric line shapes. Since the excited states of Tb^{3+} ions in a variety of materials are known to participate in various energy-transfer processes involving excitonic fluorescence, relaxation, and dispersion induced by magnetic-exchange interactions,[10–13] we have performed optical-absorption and emission as well as neutron-scattering experiments on both single-crystal and powder samples of $Tb_xY_{1-x}PO_4$ in an attempt to clarify the nature of the Tb-Tb interactions at low temperatures. This article presents results which provide new insight into the properties of the magnetic transitions within the Tb^{3+} $^7F_6$ ground multiplet and electronic transitions between the $^7F_6$ and $^5D_4$ multiplets in both the paramagnetic and antiferromagnetic phases of the $Tb_xY_{1-x}PO_4$ (x=0.01 and 1) compounds.

II. EXPERIMENTAL DETAILS

Single crystals of $TbPO_4$ and 0.1% Tb:YPO_4 were grown by dissolving and reacting the appropriate rare-earth oxides in molten lead pyrophosphate at high temperature[14] followed by subsequent slow cooling. Polycrystalline powders of $TbPO_4$ were prepared by the technique of precipitation from molten urea.[15] The resulting samples were examined by x-ray and neutron diffraction and were found to have the appropriate zircon structure. A tunable dye laser pumped by a pulsed Nd:YAG laser was used in the optical-absorption and fluorescence experiments. The laser linewidth was 0.4 cm^{-1}. Fluorescence emission from the lowest component of the $^5D_4$ multiplet was dispersed by a monochromator and detected by a cooled photomultiplier. Signals from the photomultiplier were averaged using a DEC minicomputer. The optogalvanic effect in a uranium-argon hollow-cathode lamp was used for wavelength calibration of the excitation spectra. The single-crystal samples were mounted in an optical cryostat with the c axis perpendicular to the incident laser beam. Low-temperature measurements ($T \leq 4.2$ K) were performed with the samples immersed in liquid helium, and the helium vapor was pumped in order to reduce the temperature to below the λ point.

Inelastic neutron-scattering measurements were performed using the QENS spectrometer at the Argonne spallation neutron source IPNS. The energy resolution of the QENS spectrometer varies smoothly from about 0.12 meV (0.96 cm^{-1}) at the elastic position to ≈0.45 meV (3.6 cm^{-1}) at an energy transfer of 10 meV. A sample consisting of

approximately 30 g of polycrystalline $TbPO_4$ was cooled in a conventional helium cryostat and used in the neutron-scattering experiments.

III. RESULTS AND DISCUSSION

The $^7F_6 \rightarrow {}^5D_4$ excitation spectra of 0.1% Tb^{3+}:YPO_4 at 8 K obtained with both the σ (photon electric field $\mathbf{E} \perp$ the crystallographic c axis) and π ($\mathbf{E} \| c$ axis) polarization are shown in Fig. 1. Under the D_{2d} point-group symmetry, the Tb^{3+} $^7F_6$ ground multiplet is split by the crystal field into seven singlets, $2\Gamma_1+\Gamma_2+2\Gamma_3+2\Gamma_4$, and three doublets, $3\Gamma_5$, and the excited $^5D_4$ multiplet is split into five singlets, $2\Gamma_1+\Gamma_2+\Gamma_3+\Gamma_4$, and two doublets, $2\Gamma_5$. The Γ_5 doublet ground state has been previously identified by neutron and optical studies.[16–18] The seven observed peaks shown in Fig. 1(a) can be interpreted as excitations from the Γ_5 ground state to the seven crystal-field-split states in $^5D_4$. The selection rules for electric-dipole transitions allow only $\Gamma_5 \leftrightarrow \Gamma_5$ and $\Gamma_3 \leftrightarrow \Gamma_4$ transitions in the π-polarization and $\Gamma_5 \leftrightarrow \Gamma_{1,2,3,4}$ transitions in the σ-polarization configuration; however, some of the formally forbidden transitions were observed—probably due to imperfect polarization conditions. The energies and linewidths of the transitions, determined by nonlinear fits of the data to the reference uranium and argon lines, are listed in Table I. It can be seen that all of the optical transitions of the Tb^{3+} ions in the dilute sample are very sharp (Fig. 1) with measured linewidths between 0.4 and 0.5 cm^{-1}. Given that the laser-line resolution is 0.4 cm^{-1}, inhomogeneous line broadening in this sample cannot exceed 0.3 cm^{-1}. In addition, intrinsic broadening of the lines due to Tb-Tb interactions and zero-field hyperfine splitting are negligibly small.

In the case of the observed optical and neutron spectra of the stoichiometric compound $TbPO_4$, the optical transitions in the 2.2–80 K temperature range are unusually broad and the lines are asymmetric. Figure 2(a) shows a typical excitation spectra of $TbPO_4$ observed at approximately 4.2 K in the π-polarization configuration. The transitions from the ground state to the two Γ_5 and the Γ_3 states of the $^5D_4$ multiplet are

[a]All the linewidths are less than 0.3 cm^{-1}.

broadened into three bands with linewidths of more than 10 cm^{-1}. At the lower temperature of 1.5 K, we observed that these bands remained broad, and new weak narrow lines appeared [see Fig. 2(b)]. The assigned transition energies and the estimated linewidths for $TbPO_4$ are given in Table I. The small difference in the energies of the levels between the 0.1% Tb:YPO_4 and the stoichiometric $TbPO_4$ samples reflects the somewhat different crystal-field environments in these two materials.

The crystal-field excitations from the ground state to the next four higher states within the $^7F_6$ ground multiplet, as measured by neutron scattering at 1.5 and 4.2 K, are shown in Fig. 3. The observed transitions at both 4.2 and 1.5 K are significantly broader than the instrumental resolution. This indicates that the peaks are intrinsically broadened by interactions of the Tb magnetic moments with the environment. In fact, at 4.2 K the first three states at 0, 3.8, and 7.8 cm^{-1}, determined by a detailed inelastic neutron-scattering study,[16] are merged into a band exhibiting an asymmetric profile. The strong peak evident at zero energy in the T=4.2 K spectrum originates from magnetic elastic scattering within the doubly degenerate Γ_5 ground state. At 1.5 K, the degeneracy is lifted by the reduction of site symmetry due to the tetragonal-to-monoclinic distortion of the lattice. As a result, the elastic

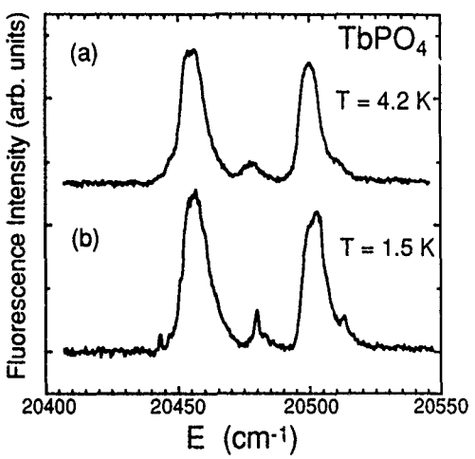

FIG. 2. Laser-excitation spectra of the $^7F_6 \rightarrow {}^5D_4$ transitions of Tb^{3+} in $TbPO_4$ in π polarization: (a) T=4.2 K and (b) T=1.5 K.

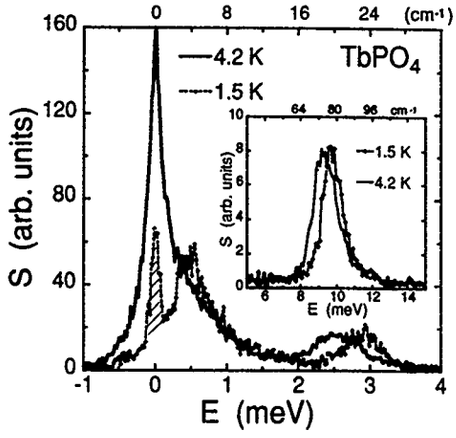

FIG. 3. The low-energy excitation spectra of $TbPO_4$ obtained by neutron scattering at 4.2 and 1.5 K. The energy resolution of the spectrometer varies smoothly from about 0.12 meV (0.96 cm^{-1}) at the elastic position to ≈0.45 meV (3.6 cm^{-1}) at $E=10$ meV. Both spectra contain a residual nuclear elastic-scattering component (shaded area) arising from the sample and container.

intensity diminishes and the spectrum shifts to higher energies by approximately 4 cm^{-1}. Long-range magnetic ordering has set in, and the neutron spectrum represents a measure of the magnon density of states. The energy-level scheme, as determined by neutron measurements, agrees well with that obtained from the optical emission spectra of the $^5D_4\,\Gamma_1$ state to the $^7F_6$ ground multiplet.

The present optical and neutron-scattering measurements have provided new information regarding crystal-field effects and magnetic interactions in the $Tb_xY_{1-x}PO_4$ system at low temperatures. In the dilute limit of 0.1% Tb in YPO_4, the Tb-Tb interactions are determined to be negligible and single-ion crystal-field transitions give rise to sharp peaks which are observed in the optical spectra at all temperatures. The narrow linewidths of these excitations indicate that the effects of defect-induced inhomogeneous broadening, zero-field hyperfine splitting due to the nuclear spins, and the relaxations of the Tb^{3+} excited states are small. As the Tb concentration increases, the probability for interactions between a pair of Tb^{3+} excited states is enhanced under selective excitation by the laser field in an optical experiment. Such exciton-exciton interactions were, in fact, observed for $Tb_xY_{1-x}PO_4$ through luminescence studies reported by Hirano and Shionoya[10] and by Diggle and co-workers.[11]

The present optical and neutron-scattering experiments on $TbPO_4$ have emphasized the study of superexchange interactions between the Tb^{3+} magnetic moments at low temperatures. Such interactions eventually lead to long-range antiferromagnetic ordering of the Tb^{3+} moments at 2.28 K and to a Tb ion-lattice coupling at 2.15 K. The exchange interaction, however, must intensify significantly at temperatures near the phase transitions, as manifested by the broadened transitions present in the optical and neutron spectra at 4.2 K. The effect of inhomogeneous broadening can be ruled out as the cause of this effect due to the appearance of additional narrow peaks at 1.5 K, in the optical spectra. The significance of exchange interactions between the Tb ions at $T<50$ K is also supported by the systematic deviation of the experimentally obtained values for the paramagnetic susceptibility $\chi_\parallel$ (i.e., with the applied field parallel to the crystallographic c axis), from the calculated values that are based solely on single-ion crystal-field effects.[16] At 4.2 K, strong exchange interactions induce spin fluctuations that dynamically broaden the otherwise sharp crystal-field levels and reduce the lifetimes of the excitations. Consequently, the transition lines are broad and asymmetric. At 1.5 K, the Tb^{3+} wave functions are determined by the diagonalization of a Hamiltonian that includes the effects of crystal fields and long-range magnetic interactions. In general, the wave functions contain a number of components of $|JJ_M\rangle$ and they vary depending on the spin-wave propagation directions. The broad bands seen in the spectra at 1.5 K may be interpreted as magnon-to-optical exciton-band transitions. Such transitions have been found[12,19] previously for the case of $Tb(OH)_3$ and $GdCl_3$ and give rise to broad, asymmetric spectra. The magnon wave functions will also modify the selection rules for electric-dipole transitions. The additional narrow peaks in the 1.5 K spectra probably reflect such an enhancement of some transition intensities as favored by the selection rules.

Magnetic structures of itinerant electron systems (abstract)

J. Kübler, L. Sandratskii, and M. Uhl
Institut für Festkörperphysik, Technische Hochschule Darmstadt, Germany

Under well-defined conditions itinerant electrons conspire to form magnetic moments that can show a variety of order phenomena in and near the ground state. We describe these quantitatively using energy-band theory which supplies a powerful conceptual and computational tool. Both the density functional and methodological bases are briefly reviewed and results are presented not only for noncollinear antiferromagnetic moment arrangements, but also for states having incommensurate helical order characterized by some wave vector q. In particular, we discuss the static nonuniform, exchange-enhanced magnetic susceptibility obtained for a selected set of transition metals.[1] The observed temperature variation of the electron density of states of bcc iron can be explained just as that of the $5d$ states of gadolinium. For fcc-iron precipitates we find an incommensurate antiferromagnet ground state[2] as observed by neutron-diffraction experiments. For other frustrated antiferromagnets, like the hexagonal Laves phase $ThMn_2$, we obtain an incommensurate ground state, again in agreement with neutron diffraction experiments. Concerning the INVAR problem we add transverse magnetic fluctuations to the longitudinal fluctuations that recently have been quite successful in explaining magneto-volume anomalies of INVAR. Finally, we discuss the magnetization reversal in magnetic multilayers subject to an applied magnetic field.

Electronic structure and spin-density distribution in Y_2Fe_{17} (abstract)

Ming-Zhu Huang and W. Y. Ching
Department of Physics, University of Missouri, Kansas City, Missouri 64110

We have calculated the spin-polarized band structure of the Y_2Fe_{17} compound in the rhombohedral structure using the first-principles self-consistent orthogonalized linear combination of atomic orbitals method in the local spin-density approximation. Using a real space integration scheme, we have obtained the site-decomposed magnetic moments as follows: $-0.28\mu_B$ on Y-6(c), $2.54\mu_B$ on Fe-6(c), $2.08\mu_B$ on Fe-9(d), $2.28\mu_B$ on Fe-18(f), and 2.10 on Fe-18(h). Similar values are obtained when the more traditional Mulliken scheme is used. The calculated spin magnetic moments are in good agreement with Mössbauer data but are somewhat larger than these obtained by Coehoorn using the linear muffin-tin orbitals (LMTO) method.[1] The calculated density of states are similar to that of Coehoorn's. In order to have a better insight on the magnetic structure of Y_2Fe_{17}, the real space spin density distributions are plotted and it is shown that the negative spin density on the Y site extends to a fairly large region. We will extend our calculation to Nd_2Fe_{17} crystal and to cases in which the Fe atoms are selectively substituted by Al, Si, and Ga, as well as the effect of the N addition. Previous OLCAO calculations[2,3] on $Nd_2Fe_{17}N$ systems were nonself-consistent and therefore less reliable.

Energetics of bcc-fcc lattice in Fe-Co-Ni compounds (abstract)

E. G. Moroni
Department of Theoretical Physics, Royal Institute of Technology, S-10044 Stockholm, Sweden

T. Jarlborg
Department of Condensed Matter Physics, University of Geneva, CH-1211 Geneva 4, Switzerland

The linear muffin tin orbital method is applied to compute the energy properties of several ordered binary Fe-Ni, Fe-Co, and ternary Fe-Ni-Co compounds near the bcc-fcc transition, from first principles. The calculations use the local spin density and the Perdew–Wang gradient corrected approximation to treat exchange and correlation. We address the importance of the gradient corrected approximation for the calculation of the fcc-bcc energetics for these 3D Fe-based systems near the Fe rich region. By adding Co to the Fe-Ni alloy it is possible to reduce the volume expansion accompanying the fcc to bcc transition. To study these effects we have considered the energetics in several ordered ternary systems with a fcc and bcc lattice. When increasing the e/a ratio from 8.5 (Fe_3Ni) to 8.75 ($NiFe_2Co$) and to 9 (Co or FeNi) one finds increased stability of the FM fcc phase compared to the bcc phase. We observe also that by increasing the e/a ratio the magnetic moment of the fcc lattice becomes more stable; this induces an augmentation of the spontaneous magnetostriction and a decrease of the volume change accompanying the fcc-bcc transition. A comparison of the different computed magnetic and ground-state properties with experimental data is provided.

Prediction of pressure-induced changes in magnetic ordering of correlated-electron uranium systems (invited)

Q. G. Sheng and Bernard R. Cooper
Department of Physics, West Virginia University, Morgantown, West Virginia 26506-6315

Experimentally, hydrostatic pressure experiments provide a very sensitive way to probe the development of magnetic ordering in correlated-electron systems. We have now developed and applied theory allowing us to understand and quantitatively predict the variation of ordering temperature with pressure in uranium-based correlated-electron materials on a wholly predictive calculated basis, i.e., without using any experimental data as input in the calculation. The theory physically captures the changes in the *f* spectral density distribution in space and time that are driven by pressure-induced increased band-*f* hybridization. As a test case, we have predicted behavior in good agreement with experiment for UTe where experimentally (Link *et al.*) T_c increases from 104 K to a maximum of 181 K at 7.5 GPa and then decreases to 156 K at 17.5 GPa. Our calculations: (1) using full-potential total-energy calculations match the experimental lattice parameter change with pressure within 2% and provide the decrease in average $5f$-electron number; (2) extract information from the electronic structure calculation on the hybridization-induced changes and insert this into many-body theory to calculate the increase in two-ion coupling with pressure (from increased *f* spectral admixture into the bands) giving the initial increase in T_c; (3) calculate the decrease in ordering temperature (in terms of coupling) with decreased $5f$ number (localized spectral density) which gives the ultimate decrease in T_c.

In correlated-electron uranium-based materials like UTe[1,2] and UPt_3,[3] the change in magnetic ordering in response to hydrostatic pressure has interesting characteristics: the ordering temperature rises with, or at least is insensitive to, pressure initially, while the low temperature ordered moment m_o decreases or indeed plunges dramatically. In the case of the weakly correlated ferromagnet UTe, in the measurements of Link *et al.*[2] T_c increases from 104 K at ambient pressure to a maximum of 181 K at 7.5 GPa and then decreases to 156 K at 17.5 GPa; while the decrease of m_o with the initial pressure in the measurements of Bartholin *et al.*,[1] while substantial, is not drastic in comparison to the results of Hayden *et al.*[3] for the heavy-fermion antiferromagnet UPt_3.[3] For UPt_3,[3] the application of 2.05-kbar pressure causes no observable change in T_N; while m_o is drastically reduced by 50%. If, as in the mean field theory, the ordering temperature T_{order} scales with the two-ion coupling J and the low temperature ordered moment m_o: $T_{\text{order}} \propto J m_o(m_o+1)$, then, in both UTe and UPt_3, J increases and m_o decreases with pressure.

In order to understand this behavior, we consider the following effects: (i) the effect of pressure on the *f* spectral weight distribution in real space; (ii) the effect of this real space *f* spectral weight distribution on hybridization; (iii) the effect of hybridization on the *f* spectral weight distribution in energy space; and finally, the consequences of the effects in (i)–(iii) on magnetic ordering. These effects are described as follows.

(i) Localized $5f$ spectral loss in real space: When pressure increases, the system responds with the following reactions: the atomic distance decreases, → the volume of the core region reduces, → the core potential becomes less attractive, → the *f* states diffuse more of their waves outside the core region. This can be described by band structure calculations. In such calculations, the core regions are represented by muffin-tin spheres, supposing neighboring muffin-tin spheres touch, but do not overlap, with each other. The *f* waves(partial waves with orbital quantum number $l=3$ within a muffin-tin sphere) are singled out and filled up to the Fermi level, thus obtaining the real space localized *f*-electron number n_f. Table I shows the results of such calculations for UTe, from which one can see the decrease of n_f with pressure. As a result of crystalization, the *f* waves as a whole can no longer accommodate 14 electrons per atom, as a free atom can. The reason is that the parts of the *f* wave function at large radial distances (or, outside the muffin-tin spheres in band structure calculation) are distorted by the crystal field and lose the *f* characteristic, thus being excluded from the *f* waves. Such $5f$-shell spectral loss in the real space is stronger when the atoms are closer to each other in a crystal. A consequence of this real space $5f$-shell spectral loss is the reduction of the localized *f* moment. Notice that the n_f calculated from band structure theory is a time average.

(ii) Increase of hybridization: Hybridization V depends on the integral between the *f* state $\phi_f(r)$ and extended band state $\psi_{\text{band}}(r)$: $V=\langle\psi_{\text{band}}(r)|H|\phi_f(r)\rangle$, where $\phi_f(r)$ consists of both $l=3$ orbital wave function contained within the muffin-tin sphere and crystal-symmetry-dominated wave function diffusing outside the muffin-tin sphere. The more $\phi_f(r)$ is diffused in space, the more it overlaps with $\psi_{\text{band}}(r)$, thus the larger the V. As described in (i), pressure causes $\phi_f(r)$ to be more diffused, thus V grows with pressure. As a

TABLE I. Renormalized lattice volume V/V_0, and $5f$ electron number n_f at different pressures P calculated for UTe from the LMTO band structure calculation.

P (GPa)	atmos	0.98	2.9	5.4	8.3	11.7	15.5	19.7
V/V_0	1.0	0.979	0.952	0.927	0.901	0.877	0.852	0.828
n_f	2.73	2.71	2.69	2.67	2.64	2.62	2.60	2.58

consequence, the hybridization-induced two-ion coupling also grows with pressure.

(iii) Localized $5f$ spectral loss in energy space: Without hybridization, the $5f$ states form a narrow f peak in energy space. When hybridization is turned on, parts of the f waves are stripped off from the narrow f peak and go to the extended regions in the energy space. This is schematically shown in Fig. 1. The parts of the f waves in the extended regions still keep the f characteristic; however, being extended states, they do not belong to a single atom, but to the whole crystal. In real space, electrons of these parts of the f waves hop around among neighboring atoms; and during their stay on a certain atom, they are contained within a muffin-tin sphere and are f-like in nature. The hopping is via non-f-extended bands, a result of hybridization. Thus, the f waves can be viewed as consisting of two parts: one in the narrow f peak, (these f waves are stable on a single atom, and therefore form the localized f waves); the other in the extended regions, (these f waves hop among neighboring atoms, and therefore form itinerant f waves). The division of these two parts is not clear cut. The addition of these two parts of the f waves on a certain atom, after time averaging, gives the f spectral weight in real space. The n_f calculated from the band structure calculation is such a time average: it is an accumulation of all the f waves, in the f peak as well as in the extended regions, up to the Fermi level. As a consequence, not all of n_f contributes to the stable local f moment; instead, parts of n_f, belonging to the extended states and being itinerant, do not always follow the magnetic polarization of the local moment. Since this effect is hybridization-induced, it also grows with the pressure.

We can see in the foregoing that as pressure increases, effects in (i) lead to effects in (ii), which further leads to effects in (iii). In other words, the f spectral loss in real space enhances hybridization; and hybridization enhances the f spectral loss in energy space. The f spectral loss in real space reduces the local moment by turning f waves into non-f-waves [described in (i)]; the f spectral loss in energy space reduces the local moment by turning localized f waves into itinerant f waves [described in (iii)]. Both effects in (i) and (iii) weaken the magnetic ordering. On the other hand, through increasing the two-ion coupling, hybridization strengthens the magnetic ordering [described in (ii)], thus competes with effects in (i) and (iii).

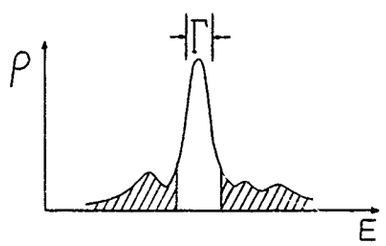

FIG. 1. f spectrum in energy space. The narrow peak, the localized f spectral weight, has a width Γ. The presence of f waves in the extended region is indicated by hatching.

The varying magnetic ordering with pressure can be explained by the competing effects described above. The initial increase of T_c can be explained as the initial winning effect of the mechanism which strengthens magnetic ordering; the ultimate decrease of T_c can be explained as the eventual changeover of winning and losing effects. Whether it wins initially or not, ultimately the second, moment-reduction, mechanism discussed above wins.

In the following, we quantify this theory using techniques based on the theoretical framework we have developed.[4] This involves the following procedures. (1) Using full-potential total-energy calculations, match the experimental lattice parameter change with pressure and provide the decrease in time averaged f-electron number in real space. This part of the calculation is of concern with regard to effects in (i) as mentioned above. (2) Extract information from the electronic structure calculation on the hybridization-induced changes and insert this into many-body model Hamiltonian to calculate the increase in two-ion coupling with pressure. This part of the calculation is of concern with regard to the effects in (ii). (3) Using Ising model to simulate the effect of the decrease in ordering temperature (in term of coupling) with decreased f spectral weight. This part of the calculation is of concern with regard to the effects in (iii). As a test case, this calculation is done for UTe.

(1) We perform a sequence of band structure calculations with a series of different lattice constants. We use a full-potential linearized muffin-tin orbital (LMTO) band structure (self-consistent relativistic LDA) calculation. The curve of the total energy versus unit cell volume is calculated. It has a minimum corresponding to the ambient pressure lattice constant, which is smaller than experiment by 3%. The result can be improved by including the orbital and spin polarization into the calculation (performed by S. P. Lim), and the error of lattice constant is reduced to less than 2%. The derivative of the total energy with regard to the unit cell volume is pressure. The lattice volume change with pressure and the f electron number (in the real space) n_f change with pressure are shown in Table I and Fig. 2. (The experimental results in Fig. 2 are from Gerward *et al.*, Ref. 5.) n_f changes from 2.73 at ambient pressure to 2.58 at 20 GPa, a loss of 0.15 electron per atom.

Figure 3 shows the results of the density of states (DOS) at three lattice constants. The DOS spectra have two peaks

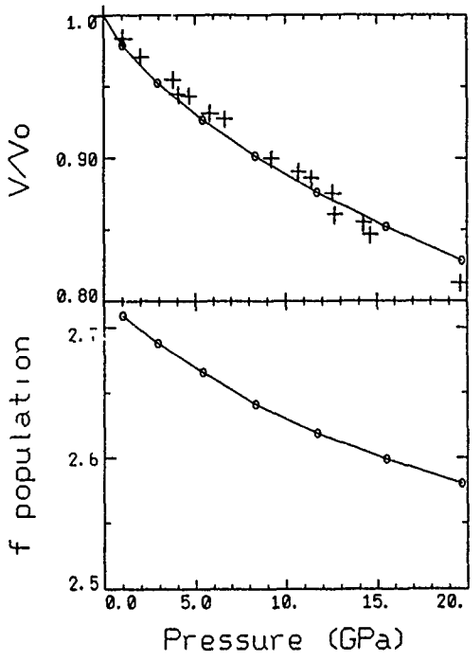

FIG. 2. Top: normalized lattice volume V/V_0 vs pressure. Bottom: $5f$ electron number n_f vs pressure. The open circles are points calculated from the LMTO band structure calculation. The crosses are experimental volume data from Gerward *et al.* (Ref. 5).

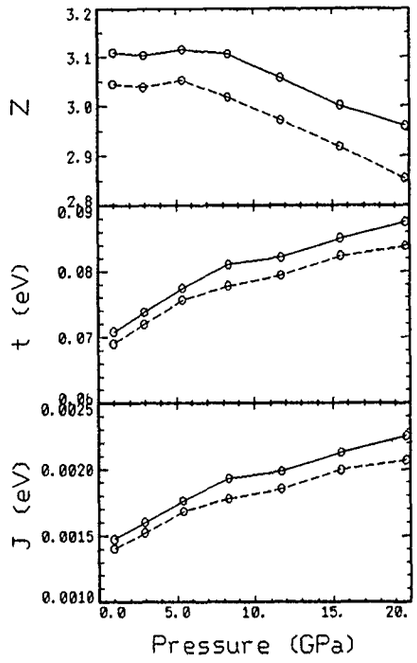

FIG. 4. Top: localized (corresponding to area of density of states peak) f spectral weight Z vs pressure. Middle: t vs pressure. Bottom: J vs pressure. The solid line is calculated for $\rho_{\text{cutoff}}=20\%\rho_{\text{max}}$; the dashed line for $\rho_{\text{cutoff}}=25\%\rho_{\text{max}}$.

originating from the f states and split by spin-orbit coupling. The peak on the higher energy ($j=7/2$) side is empty. The other ($j=5/2$) peak contains electrons, and the physics of interest occurs there.

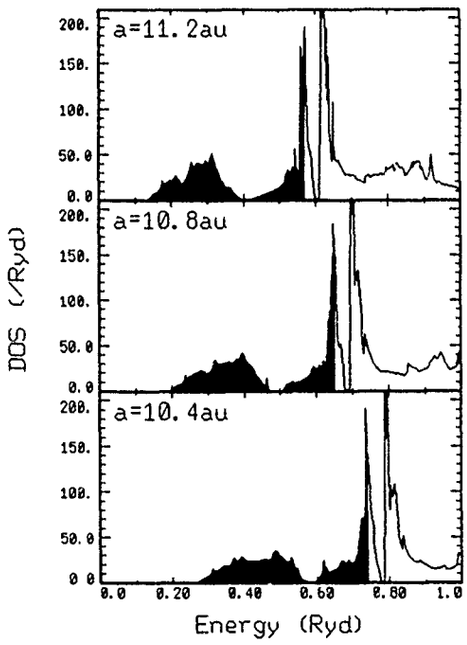

FIG. 3. Density of states of UTe, calculated with three lattice constants: $a=11.2$ a.u. (top); $a=10.8$ a.u. (middle); $a=10.4$ a.u. (bottom). The states below the Fermi level are indicated by shading.

(2) Comparing the three DOS spectra in Fig. 3, one can see that the ($j=5/2$) f peak becomes wider when the lattice constant is smaller. We define the width Γ for the f peak

$$\Gamma=\frac{[\int_{\rho>\rho_{\text{cutoff}}}(E-E_{\text{max}})^2\rho(E)dE]^{1/2}}{\int_{\rho>\rho_{\text{cutoff}}}\rho(E)dE}, \tag{1}$$

where ρ is the density of states, E_{max} is the energy at the peak ρ_{max}. ρ_{cutoff} has to be chosen in the calculation, since, as mentioned above, the division of the localized f waves and itinerant f waves is not clear cut. In the following calculation, we choose ρ_{cutoff} to be 15%, 20%, 25%, and 28% of the peak value ρ_{max}, and results from different ρ_{cutoff} will be compared.

Since a bandwidth can be attributed to the interatomic interaction, Γ indicates the coupling of f states localized on neighboring atoms. Suppose such coupling only occurs for the first nearest neighbor; then Γ can be related to the two-ion coupling J in the following way. Consider the Hubbard model

$$H_H=\left(-t\sum_{\substack{in\\mm'}}c^{+}_{im}c_{i+n,m'}+\text{h.c.}\right)+U\sum_{i,m\neq m'}n_{im}n_{im'}, \tag{2}$$

where t is the interatomic interaction, U the on-site Coulomb repulsion, m the magnetic quantum number, i an atomic site, $i+n$ the first neighbors of site i. A tight binding band results from using H_H

$$E_k=E_0-t\sum_n \exp(-ikR_n). \tag{3}$$

For a fcc lattice, this band has a width $\Gamma = 1.04t$. This is obtained by projecting E_k onto the energy space using the tetrahedral technique.[6] Thus, calculating Γ from the DOS spectra using Eq. (1) for a real system gives t. The middle panel of Fig. 4 shows the so calculated t vs pressure. t increases with pressure as expected.

If $U \gg t$, H_H can be converted into the following model:[7]

$$H = \left(-t \sum_{\substack{in \\ mm'}} c_{im}^{+} c_{i+n,m'} + \text{h.c.} \right) - J \sum_{in} \mathbf{S}_i \cdot \mathbf{S}_{i+n}, \qquad (4)$$

where $J = t^2/U$. In going from Eq. (3) to Eq. (4), the approximation has been made that the quantum number of S_i^Z can only be $m = \pm 1$. Clearly J is the two-ion coupling. U can be calculated from a supercell scheme.[4] This gives $U = 3.4$ eV at ambient pressure, and U changes very little (less than 0.3 eV) with pressure up to 20 GPa. We take $U = 3.4$ eV for all the pressures. With t obtained as above, we can calculate $J = t^2/U$. J vs pressure is shown in the bottom panel of Fig. 4. J also increases with pressure as expected.

(3) The J interaction supposedly occurs between stable local moments. However, as mentioned above, in effect (iii), only the f waves in the narrow f peak in the energy space are localized. The rest of the f waves are itinerant and do not participate in the local magnetization. Define the localized f spectral weight Z:

$$Z = \int_{\rho > \rho_{\text{cutoff}}} \rho(E)\, dE, \qquad (5)$$

where the choice of ρ_{cutoff} is taken according to that used in the definition of the width Γ of the f peak. From the DOS spectra, we calculate the Z change using Eq. (5). The results of Z vs pressure are shown in the top panel of Fig. 4.

U in UTe is close to an f^3 configuration. Suppose that the two-ion coupling occurs between the f^3 atoms. When an f^3 atom loses one unit of f spectral weight and reduces to an f^2 configuration, one unit of charge is moved into the extended band states located in a region surrounding this atom, and hence can screen this atom from magnetic interaction with its neighbors. Bearing in mind that the two-ion coupling in UTe is band mediated, such screening can be quite effective. Consequently, the magnetic coupling of an f^2 atom with its neighbors is much weaker, and f^2 atoms can be approximated as magnetically "empty" sites.

Define a baseline Z_0 as the localized f spectral weight corresponding to the situation that the system is in the f^2 configuration. Then $Z - Z_0$ gives the fraction of atoms which are in the f^3 configuration. Actually we do not know the local configuration for UTe at any pressure. However, since our purpose is to see the change with pressure, we artificially suppose that UTe is in the f^3 configuration at ambient pressure. This requires us to set the baseline Z_0 at the value so that $Z - Z_0 = 1$ at ambient pressure. With this setting of Z_0, the fraction of f^3 atoms changes from 1 at ambient pressure to 0.8–0.85 at 20 GPa, depending on the choice of ρ_{cutoff}. We see that due to the localized f spectral loss, the fraction of magnetically empty sites increases with pressure.

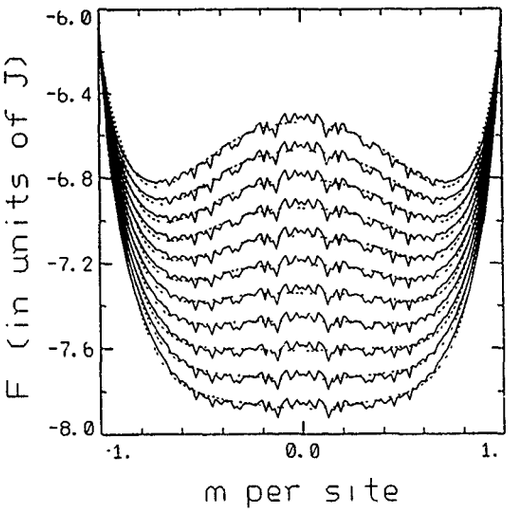

FIG. 5. Free energy F vs magnetization m at temperatures below and above T_c calculated from a computer simulation with an 8×8×8 fcc Ising lattice for the case of no holes. The free energy (per site) is in units of coupling J. The solid lines are raw data from simulation; the dashed lines are results of the least square fitting to smooth out the noise. The curve on the top is for $T = 9.0J$, each of the curves below is for a temperature increment of $0.2J$ from the temperature corresponding to the curve above it. With increasing temperature, the double minimum disappears and m becomes zero at $T_c = 10.5J$.

The influence of localized f spectral loss on magnetic ordering can be simulated by an Ising model with holes. We use an Ising model in order to capture the very anisotropic nature of the two-ion hybridization-mediated interaction[4] in a simple way; in future work we plan to treat this anisotropy more realistically as has already been done at ambient pressure.[4] In this model, each lattice site fluctuates between being occupied by a moment or empty; the ratio of the average number of empty sites (holes) to the number of total sites is the fraction of magnetically empty sites in UTe as mentioned above; all the occupied sites are coupled to their nearest neighbors by an Ising interaction J, provided that neighbor is also occupied, while the holes do not couple to any sites.

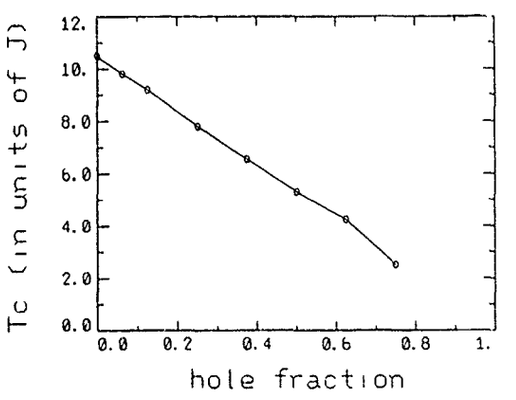

FIG. 6. T_c (in terms of two-ion coupling J) vs hole fraction. Calculated from a computer simulation with an 8×8×8 fcc Ising lattice.

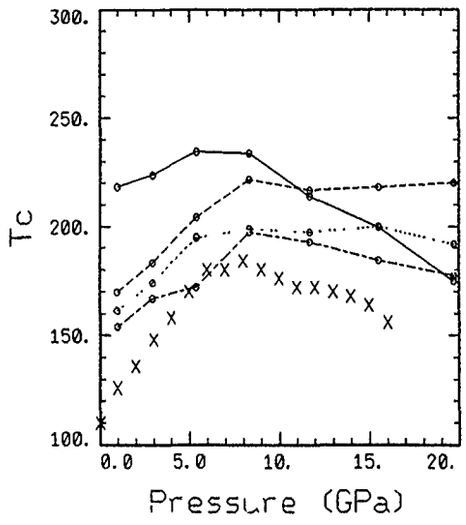

FIG. 7. T_c vs pressure for UTe. The solid line is calculated for $\rho_{\text{cutoff}}=15\%\rho_{\text{max}}$; the long dashed line for $\rho_{\text{cutoff}}=20\%\rho_{\text{max}}$; the short dashed line for $\rho_{\text{cutoff}}=25\%\rho_{\text{max}}$; the long–short-dashed line for $\rho_{\text{cutoff}}=28\%\rho_{\text{max}}$. The crosses are experimental data from Link *et al.* (Ref. 2).

Computer simulation calculates the curve of free energy versus total moment m of the Ising lattice at different temperatures. When the temperature is below T_c, the curves have double minima where $m\neq 0$; above T_c, the curves have a single minimum at $m=0$. (see Fig. 5.) This provides the method of calculating T_c. By putting different numbers of holes in the Ising lattice, one can calculate the dependence of T_c on the hole fraction. In Fig. 6, we show the result for the dependence of T_c on the hole fraction calculated from a simulation using an 8×8×8 fcc Ising lattice.

With the two-ion coupling J, the localized f spectral weight Z and their relation to the ordering temperature T_c obtained as discussed in the sequence numbered (1)–(3) above, we calculate T_c vs pressure. The results are shown in Fig. 7. Comparing with experiment, the initial increase of T_c is well predicted. Above 7.5 GPa, the calculated curves flatten, and do not go down as drastically as experiment. We believe that these results reflect the competing effects of hybridization as described at the beginning of this paper. But there are still some effects missing in the calculation: the transition from the increasing T_c to decreasing T_c region is more abrupt in experiment. We are in the process of looking for the reasons for this behavior.

In conclusion, we have performed TB-MTO band structure calculations for UTe at various pressures. The results match the lattice volume reduction with pressure. They also give the reduction of the real space $5f$-electron number and the widening of the localized f spectral peak in energy space with pressure. We use a model Hamiltonian to relate to the localized f spectral peak in energy space, and then extract the effective two-ion interaction J from the width Γ of the localized f spectral peak. Bearing in mind that the $5f$ configuration fluctuates, we relate the area of this peak to the fraction of atoms which are in a configuration magnetically coupled to their neighbors. We use an Ising model with holes to simulate how the change of this fraction determines the change of T_c. All the calculations are completely first principle based. A few artificial factors are involved, such as ρ_{cutoff} and Z_0. This is legitimate since we are primarily interested in the change with pressure rather than the absolute scales of the calculated results.

The calculations capture the competing effects probed by pressure. These effects, namely the f spectral loss in real space and energy space and their interplay with hybridization, hold the key to understanding the correlated-electron systems. By probing these effects by pressure and calculating them from first principle, we are on the way to understanding these effects on a quantitative basis.

The behavior of UPt_3,[3] a heavy-fermion antiferromagnet referred to in Sec. I, represents an especially interesting challenge for the theory discussed here. The scales of ordered moment and of pressures used are very different ($\sim 0.02\mu_B$/U atom and a few kbar) from those of UTe; and this is also true for the nature of the response, little change in T_N and a strong decrease in ordered moment. From the point of view of the theory described here, the behavior of UPt_3 would represent the extreme nonlinear limit of the magnetic ordering response under the combined effects of hybridization and band-f coulomb exchange prior to the "wash-out" of moment[8] on entering the heavy-fermion regime. It would be interesting to see how the present theory fares once the anisotropy is treated more realistically under pressure as is already done at ambient pressure.[4] Our educated guess is that in contrast to band theory[9] which gives no magnetic ordering, our theory will give an overly large ordered moment. It would then be especially interesting to see the response to applied pressure. This would provide an important clue as to whether the non-Kondo on-site correlation effects included in our theory contain the essential ingredients for understanding heavy-fermion magnetic ordering or whether other omitted correlation effects are essential.

ACKNOWLEDGMENTS

This research was supported through the National Science Foundation under Grant No. DMR91-20333 and a grant from the European Institute for Transuranium Elements. Supercomputer time was provided by the San Diego Supercomputing Center. We have greatly benefited from discussions of the experimental situation with U. Benedict, P. Link, and G. H. Lander of the European Institute for Transuranium Elements. S. P. Lim performed the band theory total energy calculation which included polarization, as used in calculating the lattice constant.

We perform exact diagonalization studies of the one-dimensional lattice Anderson model for various clusters. The ground state energy and spin–spin correlation functions are calculated as functions of Hubbard U, hybridization V, and f level occupancies. For the symmetric case, we compare our results with weak and strong coupling perturbation theory.

We study the lattice Anderson model on finite, one-dimensional (1D), lattices in this paper. The model is defined by the Hamiltonian

$$H=-t\sum_{i\sigma}(c^{\dagger}_{i\sigma}c_{i+1\sigma}+hc)+E_f\sum_{i\sigma}n_{fi\sigma}+U\sum_{i}n_{fi\uparrow}n_{fi\downarrow}$$

$$+V\sum_{i\sigma}(c^{\dagger}_{i\sigma}f_{i\sigma}+hc)\,, \tag{1}$$

where $c^{\dagger}_{i\sigma}(c_{i\sigma})$ and $f^{\dagger}_{i\sigma}(f_{i\sigma})$ are creation (annihilation) operators for electrons in d and f orbitals on site i with spin σ, and $n_{fi\sigma}=f^{\dagger}_{i\sigma}f_{i\sigma}$. The d electrons hop with amplitude t, thus forming a conduction band e_k. The f electrons hybridize with d electrons with amplitude V, and have the usual Hubbard interaction U between spin up and down f electrons on the same site. The site energy E_f defines the relative position of f states with respect to the Fermi energy of the d electrons. An important special case is the so-called symmetric Anderson model in which $E_f=-U/2$.

When $U=0$, one can diagonalize Eq. (1) easily. Two bands are obtained with energies

$$E^{\pm}_k=\tfrac{1}{2}[e_k+E_f\pm\sqrt{(e_k-E_f)^2+4V^2}]\,, \tag{2}$$

in which $e_k=-2t\cos(k)$ is the d electron band energy. A characteristic quantity in the Anderson lattice model is the gap Δ that separates the two bands. This is given for $U=0$ by $2\Delta=E^{+}_{k=0}-E^{-}_{k=\pi}=\sqrt{4t^2+4V^2}-2t$. The magnitude of the ratio U/Δ defines weak and strong coupling regions.

This model has been studied for many years in connection with valence fluctuation problems and an extensive literature exists.[1–3] Several approximation techniques have been applied to deal with many-body aspects of this model including renormalization group analysis,[4] the Gutzwiller variational approach,[5–7] the large-orbital-degeneracy $1/N$ expansion,[8,9] and perturbation theory.[10,11] Numerical calculations have also been carried out.[11–19]

In this paper we use an exact diagonalization method to study the ground state properties of model of Eq. (1) for lattices with $N=2$, 4, 6, and 8. We are restricted by computer memories so that we are unable to go beyond $N=8$. In order to obtain reliable answers in the thermodynamic limit, finite size extrapolation is needed and one may wonder if these lattices are large enough. As we will show in the following, fortunately, we are able to achieve accurate extrapolation based on our finite lattice results.

One can show, without much difficulty, that, for a 1D tight binding band, the ground state energy per site on an N site lattice with total electron number $N_e=4n$ is

$$\frac{E_{4n}}{N}=\frac{2}{N}\sum_{k}e(k)=-\frac{2t}{\pi}\sin\left(\frac{2n\pi}{N}\right)\frac{\pi/N}{\tan(\pi/N)}\,, \tag{3}$$

while for the infinite system with density N_e/N it is

$$\frac{E_{\infty}}{N}=-\frac{2t}{\pi}\sin k_f=-\frac{2t}{\pi}\sin\left(\frac{2n\pi}{N}\right)\,, \tag{4}$$

where $k_f=(\pi/2)(N_e/N)$ is the Fermi wave number. Thus, finite lattice results for $N_e=4n$ give an upper bound.

With total electron number $N_e=4n+2$, the ground state energy per site is

$$\frac{E_{4n+2}}{N}=\frac{2}{N}\sum_{k}e(k)$$

$$=-\frac{2t}{\pi}\sin\left(\frac{2n\pi}{N}+\frac{\pi}{N}\right)\frac{\pi/N}{\sin(\pi/N)}\,, \tag{5}$$

while for the infinite system with density N_e/N it is

$$\frac{E_{\infty}}{N}=-\frac{2t}{\pi}\sin\left(\frac{2n\pi}{N}+\frac{\pi}{N}\right)\,. \tag{6}$$

Thus finite lattice results for $N_e=4n+2$ give a lower bound.

For the symmetric Anderson lattice model, the oscillation between lattice size $N=4n$ and $N=4n+2$ is still present, as we found numerically. Therefore, we can use data obtained from $N=4n$ and $4n+2$ to set up upper and lower bounds for infinite system results. This approach can also be applied to other quantities to be discussed below. Hence we are able to obtain results for infinite systems with reasonable accuracy. We also tried other extrapolation schemes by assuming asymptotic forms of calculated quantities.

We have performed exact diagonalization calculations for the symmetric case with $t=1.0$, $V=0.5$ (hence $\Delta=0.12$), and U varying from 0 to 4, i.e., from weak coupling to strong coupling, in the 1/2-filled sector. Our results for the ground state energy per site are shown in Fig. 1. The estimated errors in extrapolations are within the size of the symbol.

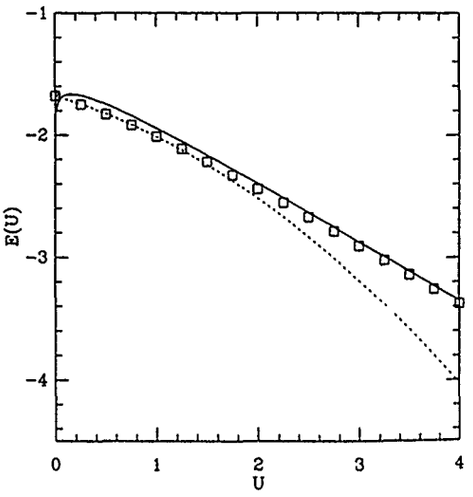

FIG. 1. The ground state energy per site as function of U for the symmetric Anderson lattice model with $t=1$, $V=0.5$. The dashed line is the weak coupling perturbation result from Eq. (7), and the solid line is the strong coupling perturbation result from Eq. (9). The squares are the exact diagonalization results and the uncertainties in the infinite system extrapolation are within the size of the symbol.

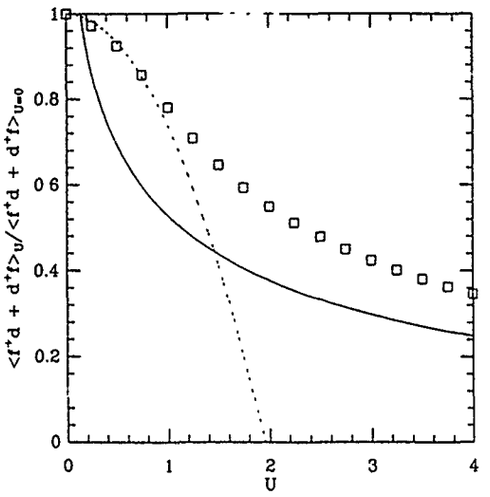

FIG. 2. Square of the f orbital local moment as function of U for the same case as in Fig. 1.

According to perturbation t[11] for the symmetric case in the weak coupling limit where U/Δ is small, the ground state energy per site is

$$E(U)=\frac{2}{N}\sum_k E_k^- - \frac{U}{4} - \frac{U^2}{N^3}\sum_{pkq}\frac{v_p^2u_{p+q}^2v_{k+q}^2u_k^2}{E_{k+q}^+ + E_p^+ - E_k^- - E_{p+q}^-} \quad (7)$$

with

$$u_p^2=\tfrac{1}{2}[1+e_p^2/(e_p^2+4V^2)^{1/2}]\,, \quad (8)$$

$$v_p^2=\tfrac{1}{2}[1-e_p^2/(e_p^2+4V^2)^{1/2}]\,. \quad (9)$$

In the strong coupling limit where U/Δ is large, the ground state energy per site is

$$E(U)=-\frac{U}{2}+\frac{2}{N}\sum_k e_k f(e_k) - \frac{2V^2}{N}\sum_k \frac{1-f(e_k)}{U/2+e_k}\,, \quad (10)$$

with $f(e_k)$ being the zero temperature Fermi factor.

We show weak coupling results as the dashed line and strong coupling results as the solid line in Fig. 1. Note that there is a singularity in strong coupling limit as $U\to 0$ [roughly $\ln(U)$] but it is hard to see from Fig. 1.

As U increases from 0 to ∞, electrons tend to localize in the f orbitals and form local moments. We measure these moments by m_{fz}^2, defined by

$$m_{fz}^2=\langle(n_{f\uparrow}-n_{f\downarrow})^2\rangle\,, \quad (11)$$

which varies from $\frac{1}{2}$ when $U=0$, to 1 when $U=\infty$. For weak coupling we have

$$m_{fz}^2=\frac{1}{2}+\frac{4U}{N^3}\sum_{pkq}\frac{v_p^2u_{p+q}^2v_{k+q}^2u_k^2}{E_{k+q}^+ + E_p^+ - E_k^- - E_{p+q}^-}\,, \quad (12)$$

while for strong coupling we have

$$m_{fz}^2=1-\frac{2V^2}{N}\sum_k\frac{1-f(e_k)}{(U/2+e_k)^2}\,. \quad (13)$$

We show these results as the dashed line and solid line in Fig. 2, along with data points obtained from our exact diagonalization studies. Again, estimated errors in extrapolations are within the size of the symbol.

From Fig. 2, it is evident that weak coupling perturbation is invalid for $U/\Delta>8$ and strong coupling perturbation gives bad answers for $U/\Delta<20$. One may note that for energy calculations, both perturbation resuits are quite good over a much wider range of U/Δ. This behavior occurs in many highly correlated systems and our results show that a good ground state energy is not a sufficient criterion for the validity of an approximation scheme.

As U increases from zero, the effective hybridization is expected to be reduced due to correlations. To measure this reduction we calculate the matrix element $\langle c_{i\sigma}^\dagger f_{i\sigma}+hc\rangle$ and plot the ratio with respect to its $U=0$ value in Fig. 3. The weak and strong coupling results can be obtained from $\frac{1}{2}\partial E/\partial V$. We see that weak coupling perturbation is pretty good for $U/\Delta<8$ again, but strong coupling perturbation is not good although qualitatively reasonable. This can be understood by observing that in weak coupling the perturbation was carried out to second order in U, while in strong coupling the perturbation was only carried out to first order in $1/U$.

Now we consider the nonsymmetric case in which $E_f\neq -U/2$. As E_f varies, one enters different physical regions. Basically, there are five regions.[14] (1) Maximally occupied f states, where the f orbitals are doubly occupied ($n_f\sim 2$, $n_c\sim 0$). This region is characterized roughly by $E_f<-U-2t$. (2) The first mixed valence region, $-U-2t<E_f<-U-t$. The f occupation in this region

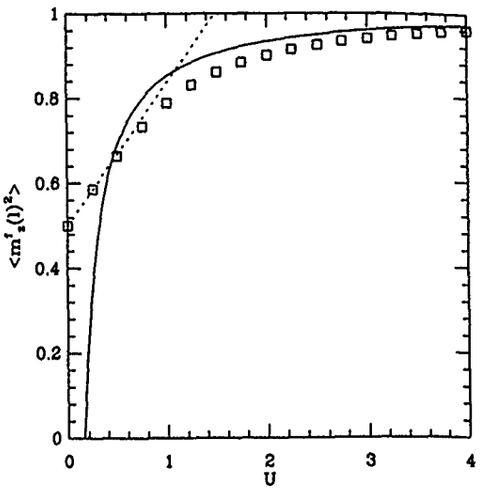

FIG. 3. The ratio of the hybridization matrix element $\langle c^{\dagger}_{l\sigma} f_{l\sigma} + hc \rangle$ to its $U=0$ value as a function of U for the same case as in Fig. 1.

changes between 1 and 2. (3) The Kondo region, in which one has $n_f \sim 1$, $n_c \sim 1$. Its range is roughly $-U-t<E_f<t$. (4) The second mixed valence region, $t<E_f<2t$. The f occupation in this region changes between 1 and 0. (5) The region of empty f levels ($n_f \sim 0$), $E_f>2t$. Figure 4 shows f and c electron occupations and clearly demonstrates these five regions.

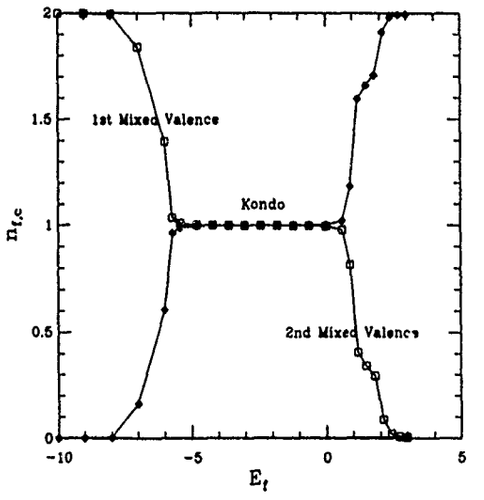

FIG. 4. The electron occupation of f orbitals (squares) and c orbitals (diamonds) as a function of E_f for $U=5.0$, $t=1.0$, and $V=0.1$.

In summary, we have studied some ground state properties of the one-dimensional Anderson lattice model by an exact diagonalization technique. We have performed finite size analysis and estimated results for infinite systems. Comparison with perturbation theory for the symmetric Anderson lattice model showed that weak coupling calculations are quite accurate for $U/\Delta<8$ and strong coupling calculations are reasonably satisfactory for $U/\Delta>20$. For the nonsymmetric case, we found that five distinct regions exist depending on the site energy E_f. The different types of physical behavior illustrated in Fig. 4 have been found in small system calculations for other geometries,[14] and are presumably characteristic of the strong interaction-weak hybridization sector of the model generally, independent of the restriction of the present calculations to one dimension. Within the Kondo regime where n_c and n_f are close to 1, our finding that the energy and other physical quantities vary smoothly between weak and strong coupling limits is probably also independent of dimensionality.

Some of the computations were performed at the National Center for Supercomputing Applications, University of Illinois at Urbana-Champaign, and at National Energy Research Supercomputer Center, Lawrence Livermore National Laboratory. We are grateful for their support. The portion of the work performed at LSU was supported by the National Science Foundation under Grant No. DMR 91-20166.

Effects of doping in Kondo insulators (invited)

P. Schlottmann
Department of Physics, Florida State University, Tallahassee, Florida 32306

Kondo insulators like $Ce_3Bi_4Pt_3$ and CeNiSn are compounds with small-gap semiconductor properties. Nonmagnetic impurities, so-called Kondo holes, break the translational invariance and hence the coherence of the ground state. Impurity states can be introduced by (i) substituting the rare earth (actinide) ion or (ii) by replacing (or adding, removing) one of the ligand atoms. Isolated impurities usually give rise to bound states in the gap. Depending on the nature of the impurity (charge neutral or a dopand) the Fermi level is pinned by the impurity level or lies in the gap. In the former case the Kondo hole has magnetic properties (Curie susceptibility and Schottky anomaly in the specific heat), while in the latter situation the properties are nonmagnetic. For a finite concentration of Kondo holes the situations (i) and (ii) are qualitatively different. In (i) it gives rise to an impurity band inside the gap of the semiconductor. The height and width of the impurity band in the f-electron density of states are proportional to $c^{1/2}$ for small concentrations. If the impurities are charge neutral the Fermi level lies in the impurity band giving rise to a specific heat proportional to T and a Pauli-like susceptibility. If the impurities dope the bands the properties remain semiconducting with a strongly reduced gap. For ligand impurities [case (ii)] tails of impurity states develop close to the gap edges, suppressing in this way the gap. The system remains a semiconductor if the impurities are charge neutral, but $C \propto T$ and χ is finite if they are dopands.

I. INTRODUCTION

The effects of coherence in heavy-fermion systems are most pronounced in so-called Kondo insulators, which have small-gap semiconductor properties due to the hybridization gap at the Fermi level. The Kondo insulators SmS, SmB_6, and TmSe were already an exciting topic more than ten years ago.[1] The more recent discovery of several Ce, Yb, and U based Kondo insulators (e.g., CeNiSn,[2] $Ce_3Bi_4Pt_3$,[3] YbB_{12},[4] and UNiSn)[5] has renewed the interest in this subject. All systems seem to be nonmagnetic at low T, except TmSe and UNiSn for which antiferromagnetic long-range order (for UNiSn accompanied by an insulator-metal transition) has been reported. In view of the small energy gaps involved the properties of these compounds strongly depend on strains in the crystal and impurities. Adding impurities, in particular small amounts of nonmagnetic impurities (Kondo holes), breaks the translational invariance of the lattice and gradually destroys the coherence of the heavy-fermion ground-state. Kondo holes are experimentally[6] realized by substituting, e.g., Ce or U ions in a stoichiometric lattice by La or Th impurities, or by replacing, adding, or removing a ligand atom. Depending on the characteristics of the impurity (e.g., charge neutral or dopand) the properties of the Kondo hole can be magnetic or nonmagnetic. In this paper we discuss several possible situations that may arise, extending in this way our previous results.[7,8]

In earlier publications[9,10] we reported a microscopic theory of the Kondo hole, for both the metallic and insulating situations. The Kondo hole is a missing f electron at a given site, which is introduced by a very large local f level energy, preventing the occupation of the f level. Correlations within the f band are introduced via a self-energy, evaluated to second order in U. We studied the scattering off the Kondo hole in the local density of f states (DOS) in the neighborhood of the nonmagnetic impurity. The f DOS at the Kondo hole is zero. In a Kondo insulator a bound state develops in the energy gap, whose spectral weight decreases rapidly with increasing distance from the impurity. These states only appear in the coherent phase. In this paper we generalize these results by including a potential scattering of the conduction electrons. If the Fermi level is pinned by the bound state the properties of the Kondo hole are magnetic; on the other hand, if the Fermi level lies in the gap (doping) the impurity is nonmagnetic. We furthermore consider here a defect causing a local change in the hybridization (e.g., missing or substituted ligand atom).

When the concentration of Kondo holes (locally missing f electrons) is increased an impurity band forms, gradually smearing the hybridization gap of the Kondo insulator. For a low density of impurities, c, the width and the height of this band depend nonanalytically on c.[7] If the impurities are charge neutral (e.g., La replacing Ce) the Fermi level is pinned within this band and there is a small low T regime with the specific heat proportional to T with a strongly enhanced γ and a Curie–Weiss-like susceptibility. If the impurities dope the system with electrons or holes (e.g., Th replacing Ce) the Fermi level lies in the reduced gap and excitations have to overcome the gap (nonmagnetic semiconductor). Finally, if the impurity is a ligand defect (local perturbation of the hybridization) the band edges of the hybridization gap are strongly reduced. If the impurities are charge neutral the Fermi level lies in the gap, while doping converts it into a metal.

The remainder of this paper is organized as follows. In Sec. II we introduce the equations leading to the Kondo hole bound state and the impurity band in the case of a finite concentration. Properties of isolated Kondo holes are discussed in Sec. III, while in Sec. IV we present our results for finite c. Concluding remarks follow in Sec. V.

II. THE MODEL AND THE f DENSITY OF STATES

We consider the Anderson lattice without orbital degeneracy

 0021-8979/94/75(10)/7044/6/$6.00 © 1994 American Institute of Physics

$$H_0=\sum_{\mathbf{k}\sigma}\epsilon_{\mathbf{k}}c^{\dagger}_{\mathbf{k}\sigma}c_{\mathbf{k}\sigma}+\epsilon_f\sum_{i\sigma}f^{\dagger}_{i\sigma}f_{i\sigma}+U\sum_i n_{i\uparrow}n_{i\downarrow}$$

$$+V\sum_{\mathbf{k}\sigma}(c^{\dagger}_{\mathbf{k}\sigma}f_{\mathbf{k}\sigma}+f^{\dagger}_{\mathbf{k}\sigma}c_{\mathbf{k}\sigma}), \tag{2.1}$$

where V is the on-site hybridization, ϵ_f is the f level energy, U is the Coulomb repulsion in the f shell, $n_{i\sigma}=f^{\dagger}_{i\sigma}f_{i\sigma}$, $c^{\dagger}_{\mathbf{k}\sigma}$ ($f^{\dagger}_{\mathbf{k}\sigma}$) creates a conduction electron (f electron) with momentum $\mathbf{k}$ and spin σ, and $f^{\dagger}_{i\sigma}$ is the Wannier state at the site $\mathbf{R}_i$. An isolated Kondo hole at the site $\mathbf{R}$ can be introduced by the following Hamiltonian:

$$H_1=\frac{1}{N}\sum_{\mathbf{k}\mathbf{k}'\sigma}\exp[-i(\mathbf{k}-\mathbf{k}')\mathbf{R}][\Delta\epsilon_f f^{\dagger}_{\mathbf{k}\sigma}f_{\mathbf{k}'\sigma}$$

$$+Wc^{\dagger}_{\mathbf{k}\sigma}c_{\mathbf{k}'\sigma}+\Delta V(f^{\dagger}_{\mathbf{k}\sigma}c_{\mathbf{k}'\sigma}+c^{\dagger}_{\mathbf{k}\sigma}f_{\mathbf{k}'\sigma})], \tag{2.2}$$

where N is the number of sites, and $\Delta\epsilon_f$, W, and ΔV are the scattering potentials experienced by the electrons. In earlier publications[7,9] we only considered the scattering of the f electrons in the limit $\Delta\epsilon_f\to\infty$ and $W=\Delta V=0$. $\Delta\epsilon_f\to\infty$ corresponds to a missing f electron at the site $\mathbf{R}$. In this paper we first solve the general scattering problem and discuss then special limits.

Since the impurity potential is factorizable, the $U=0$ scattering problem can be solved exactly.[9] It is convenient to introduce the matrix Green's function

$$\hat{G}_{\mathbf{k},\mathbf{k}'}(z)=\begin{pmatrix}\langle\langle f_{\mathbf{k}};f^{\dagger}_{\mathbf{k}'}\rangle\rangle_z & \langle\langle f_{\mathbf{k}};c^{\dagger}_{\mathbf{k}'}\rangle\rangle_z\\ \langle\langle c_{\mathbf{k}};f^{\dagger}_{\mathbf{k}'}\rangle\rangle_z & \langle\langle c_{\mathbf{k}};c^{\dagger}_{\mathbf{k}'}\rangle\rangle_z\end{pmatrix}, \tag{2.3}$$

where we dropped the spin index, since for $U=0$ up and down spins decouple. Using the equation of motion for $\hat{G}$ we obtain after some algebra

$$\hat{G}_{\mathbf{k},\mathbf{k}'}(z)=\hat{G}^0_{\mathbf{k}}(z)\delta_{\mathbf{k},\mathbf{k}'}+\hat{G}^0_{\mathbf{k}}(z)\hat{T}_{\mathbf{k},\mathbf{k}'}(z)\hat{G}^0_{\mathbf{k}'}(z) \tag{2.4a}$$

with the t matrix given by

$$\hat{T}_{\mathbf{k},\mathbf{k}'}(z)=(1/N)e^{-i\mathbf{k}\mathbf{R}}\hat{M}\left(\hat{I}-(1/N)\sum_{\mathbf{k}''}\hat{G}^0_{\mathbf{k}''}(z)\hat{M}\right)^{-1}e^{i\mathbf{k}'\mathbf{R}}, \tag{2.4b}$$

where $\hat{I}$ is the identity, and

$$\hat{M}=\begin{pmatrix}\Delta\epsilon_f & \Delta V\\ \Delta V & W\end{pmatrix}. \tag{2.4c}$$

Here $\hat{G}^0_{\mathbf{k}}(z)$ is the Green's function without impurity. The bound states in the gap of the Kondo insulator are given by the poles of the t matrix. The components of the quantity $\hat{G}^0(z)=(1/N)\Sigma_{\mathbf{k}}\hat{G}^0_{\mathbf{k}}(z)$ are related to the DOS of the conduction electrons. Assuming an elliptic DOS of half-width D [$g(z)=1/(z-\epsilon_f)$],

$$F(z)=\frac{1}{N}\sum_{\mathbf{k}}\frac{1}{z-\epsilon_{\mathbf{k}}}=\frac{2}{D^2}(z-\sqrt{z^2-D^2}), \tag{2.5}$$

$$G^0_{ff}(z)=g(z)+V^2g(z)^2F[z-V^2g(z)],$$

$$G^0_{cf}(z)=G^0_{fc}(z)=Vg(z)F[z-V^2g(z)], \tag{2.6}$$

$$G^0_{cc}(z)=F[z-V^2g(z)].$$

The imaginary part of these quantities vanishes inside the gap, and depending on the scattering parameters the real part of the t matrix may diverge, giving rise to a bound state. Equations (2.4)–(2.6) then completely determine the f electron Green's function for one Kondo hole in the absence of Coulomb repulsion.

The main effect of the Coulomb repulsion is to introduce an f electron self-energy. For heavy electrons the momentum dependence of the self-energy is much less important than its energy dependence. We limit ourselves to a self-energy to second order in U about the Hartree–Fock solution.[11] Schweitzer and Czycholl[12] developed a systematic approach based on a $1/d$ expansion (d is the dimension)[13] to overcome the tedious $\mathbf{k}$ integrations for the periodic Anderson lattice. The calculation is greatly simplified in leading order ($d\to\infty$), which corresponds to the local approximation (momentum independent) and already contains the most relevant correlations. The $\mathbf{k}$ dependence, introduced by the $1/d$ corrections,[12] is weak for $d=3$.

The self-energy to order U^2 and within the local approximation ($d\to\infty$) has the correct analytic properties and qualitatively the expected physical features. The correlations are momentum independent and incorporated into the $U=0$ solution for the Kondo hole by renormalizing the bare f level energy according to $\epsilon_f\to\epsilon_f+(1/2)Un_f+\Sigma_U(z)$, where n_f is the f level occupation. The self-energy is not calculated self-consistently[14] with dressed Green's functions, i.e., propagators with a self-energy, since a renormalized vertex would also be needed to avoid violations of Ward identities. Similarly, we do not self-consistently incorporate the effects of the Kondo hole into $\Sigma_U(z)$. The impurity breaks the translational invariance; this affects the f electron propagator giving rise to an additional $\mathbf{k}$ dependence in the self-energy, which is neglected here.

To second order in U and within the local approximation we have[7,15]

$$\Sigma_U(z)=U^2(-i)\int d\lambda e^{i\lambda z}[A(\lambda)^2B(-\lambda)+B(\lambda)^2A(-\lambda)], \tag{2.7a}$$

$$A(\lambda)=\int_{-\infty}^{\mu}d\omega\, e^{-i\lambda\omega}\rho(\omega),\quad B(\lambda)=\int_{\mu}^{\infty}d\omega\, e^{-i\lambda\omega}\rho(\omega), \tag{2.7b}$$

where μ is the chemical potential, and $\rho(\omega)=-(1/\pi)\mathrm{Im}\,G^0_{ff}(z)$ with $z=\omega+i0$ and ϵ_f containing the Hartree–Fock shift due to the Coulomb interaction.

For the (electron-hole) symmetric case, i.e., $\epsilon_f=0$ and exactly two electrons per site, the system is an insulator and the chemical potential lies in the gap, $\mu=0$. The imaginary part of the self-energy has a gap of about three times the gap of the bare DOS (convolution of three propagators). The real and imaginary parts of $\Sigma_U(z)$ for this case as a function of ω are shown in Fig. (1). For the purpose of studying Kondo

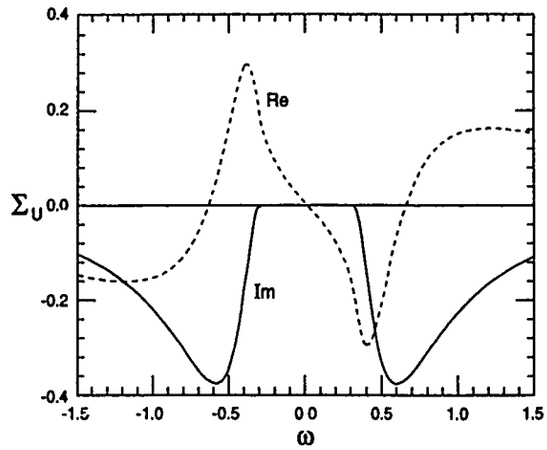

FIG. 1. Real (dotted) and imaginary (full line) parts of the Coulomb self-energy to second order in U as a function of ω for $V=1$, $D=10$, $\epsilon_f=0$ (Hartree–Fock shifted), $U=1$ and two electrons per site As expected for an insulator the imaginary part vanishes in the interval $-3V^2/D<\omega<3V^2/D$ and the slope of the real part is negative.

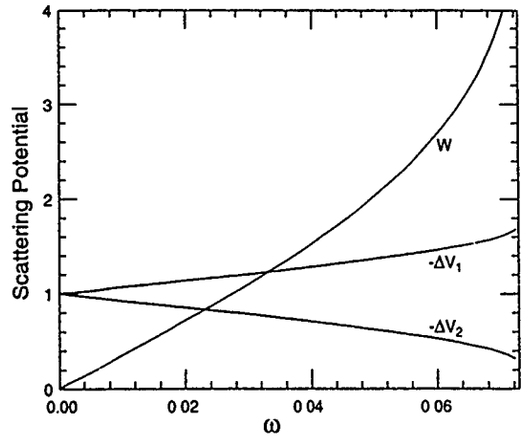

FIG. 2. Position of the bound state(s) in the hybridization gap for the symmetric Kondo insulator with $\epsilon_f=0$, $V=1$, $U=1$, $D=10$ and two electrons per site as a function of the scattering potential. The curve W refers to $\Delta\epsilon_f=\infty$, so that the only relevant scattering parameter is W. The energy of the boundstate is an odd function of W. The curves denoted with ΔV correspond to the ligand defect with $\Delta\epsilon_f=W=0$. There are two resonances for negative values of ΔV. $\Delta V(\omega)$ is an even function. Note that boundstates do not exist for all values scattering potentials.

hole bound states in the gap of a Kondo *insulator*, the self-energy is then real over the range of interest of ω. Note that the real part of $\Sigma_U(z)$ has a negative slope, leading to the well-known Kondo mass enhancement also relevant for impurity bands (see below), and to a narrowing of the gap (reduction of the hybridization, Kondo temperature). A discussion of the insulating asymmetric and the metallic situations can be found in Refs. 8 and 9.

To generalize the above to a finite concentration of impurities, c, we rewrite the perturbed Green's function as a Dyson equation with an impurity self-energy $\hat{\Sigma}_{\text{imp}}(z,\epsilon_f,V)=cN\hat{T}_{\mathbf{kk}}(z)$. This matrix self-energy renormalizes the frequency, the f level energy and the hybridization; a self-consistent treatment of this self-energy leads to

$$\tilde{z}=z-\Sigma_{cc}(\tilde{z},\tilde{\epsilon}_f,\tilde{V}), \tag{2.8a}$$

$$\tilde{\epsilon}_f=\epsilon_f+\Sigma_{ff}(\tilde{z},\tilde{\epsilon}_f,\tilde{V})-\Sigma_{cc}(\tilde{z},\tilde{\epsilon}_f,\tilde{V})+\Sigma_U(z), \tag{2.8b}$$

$$\tilde{V}=|V+\Sigma_{fc}(\tilde{z},\tilde{\epsilon}_f,\tilde{V})|, \tag{2.8c}$$

where the bare ϵ_f contains the Hartree–Fock shift $Un_f/2$, and we take the absolute value of the hybridization to keep it real (this corresponds to a gauge transformation, which has no effect on the f DOS). Equations (2.8) are equivalent to the sum of all diagrams with noncrossing impurity lines. They lead to a complex f level energy and finite imaginary part of $\tilde{z}$, which broaden the δ function of the Kondo hole bound state giving rise to an impurity band of finite width. Note that Σ_U is not renormalized; its effect on the Kondo hole band is more quantitative than qualitative.

III. RESULTS FOR ISOLATED KONDO HOLES

We have to distinguish the situations of a missing f electron (e.g., a La ion replacing a Ce atom) and a ligand defect. We first treat the missing f electron case, which corresponds to the limit $\Delta\epsilon_f\to\infty$. Carrying out the matrix products in Eq. (2.4) we obtain

$$\hat{\Sigma}_{\text{imp}}(z,\epsilon_f V)=-c\{G^0_{ff}(z)-W[G^0_{ff}(z)G^0_{cc}(z)-G^0_{cf}(z)G^0_{fc}(z)]\}^{-1}\times\begin{pmatrix}1-WG^0_{cc}(z) & WG^0_{fc}(z)\\ WG^0_{cf}(z) & -WG^0_{ff}(z)\end{pmatrix}. \tag{3.1}$$

This self-energy does not depend on ΔV, since the large $\Delta\epsilon_f$ potential inhibits the occupation of the f level. For $W=0$ we recover the results of Refs. 7 and 8. If W does not exceed a critical value, a δ-function-like bound state develops in the gap of the insulator. For the symmetric Kondo insulator ($\epsilon_f=0$ and two electrons per site) and $U=1$ Fig. 2 shows the position of the pole as a function of W, which moves from one band edge to the other. For larger values of W no bound state is formed. On a lattice the spectral weight of this bound state in the local f DOS falls off rapidly with the distance from the impurity,[9,10] so that the bound state is almost completely localized on the nearest neighbor sites to the Kondo hole. Since there are no f electrons at the site of the Kondo hole, its local f DOS is zero. Both the size of the gap and the spectral weight of the bound state decrease with U via the self-energy as a consequence of the reduction of charge fluctuations. This bound state also appears in the d electron DOS.

The properties of the Kondo hole bound state depend on the nature of the impurity; for instance, if a trivalent Ce ion is replaced by La there is no change in valence and the Fermi level is pinned at the impurity boundstate. On the other hand, if Ce is substituted by Th, which is tetravalent, there is an additional conduction electron and the bound state will be filled. The Fermi level in this case lies in the gap between the bound state and the empty band edge and the properties remain those of a nonmagnetic insulator. In the former case, however, when the Fermi level is pinned by the impurity, the Kondo hole is magnetic: Despite the fact it originated from a

missing f electron its zero-field susceptibility follows a Curie law. A small magnetic field polarizes the localized state at $T=0$ and induces a Schottky anomaly in the specific heat in analogy to a spin 1/2. This effective spin could in principle be experimentally detected by electron paramagnetic resonance. In practice, however, the inhomogeneous broadening of this line will make its observation difficult. Due to slightly different surroundings the resonance energies of the defects have a distribution, whose width has to be of the order of 0.1 K or smaller to be observable. Kondo holes affect the low frequency infrared absorption in Kondo insulators. Large magnetic fields would still polarize Kondo holes with a distribution of bound state energies, but would also modify the bulk properties of the Kondo insulator, e.g., reduce its gap.[16]

In a metallic environment, on the other hand, low energy electron-hole excitations are allowed and the imaginary part of the self-energy $\Sigma_U(z)$ is nonzero everywhere except at the Fermi level. The hybridization gap is smeared to a pseudogap, i.e., the f DOS is nonzero everywhere over the entire range of interest. The Kondo hole now forms a pseudo-bound-state of finite width,[10] which is small if we have very heavy fermions. The energy of the bound state lies in the pseudogap, i.e., not at the Fermi level, but its spectral weight is still located in the neighboring cells to the impurity. The magnetic and thermal properties of this pseudo-bound-state are those of a resonant level off-resonance with the Fermi level, i.e., a Curie–Weiss law and a Schottky-like specific heat with the Weiss temperature and the position of the maximum of C given by the energy of the resonance.

We now treat the ligand defect. In principle, all three scattering amplitudes in Eq. (2.2) could be nonzero, but the most relevant one now is ΔV. For simplicity we then consider $W=\Delta\epsilon_f=0$. Carrying out the matrix products in Eq. (2.4) we obtain

$$\begin{aligned}\hat{\Sigma}_{\rm imp}(z,\epsilon_f,V)&=c\{[1-\Delta V G^0_{fc}(z)][1-\Delta V G^0_{cf}(z)]\\&\quad-(\Delta V)^2 G^0_{ff}(z)G^0_{cc}(z)\}^{-1}\\&\quad\times\begin{pmatrix}(\Delta V)^2G^0_{cc}(z) & \Delta V-(\Delta V)^2G^0_{fc}(z)\\ \Delta V-(\Delta V)^2G^0_{cf}(z) & (\Delta V)^2G^0_{ff}(z)\end{pmatrix}.\end{aligned}\tag{3.2}$$

The zeroes in the denominator of Eq. (3.2) determine the positions of the δ-function-like bound state. There are in principle two poles (quadratic equation in ΔV) both corresponding to negative values of ΔV. In general, it requires a threshold value of ΔV for a bound state to develop and ΔV should not exceed a critical value. The positions of the poles for the symmetric Kondo insulator ($\epsilon_f=0$ and two electrons per site) are displayed in Fig. 2.

The properties of the ligand defect again depend on the characteristics of the impurity. If the defect is a donor or acceptor the Fermi level will be pinned at one of the bound states and the impurity is magnetic as discussed above. If the defect is charge neutral, on the other hand, it does not pin the Fermi level and its properties are nonmagnetic.

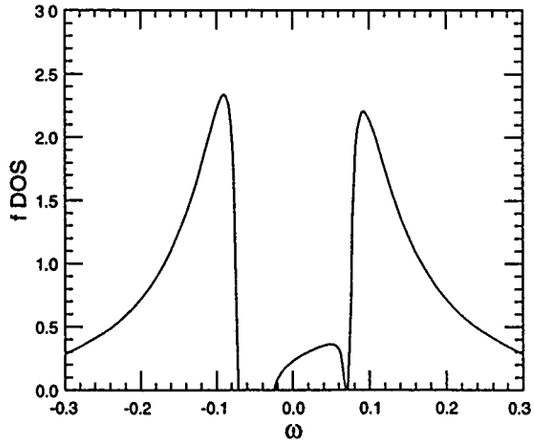

FIG. 3. f DOS for $V=1$, $U=1$, $D=10$, $\epsilon_f=0$ (Hartree–Fock corrected), $c=0.03$, $\Delta\epsilon_f=\infty$, $\Delta V=0$, and $W=1$. The structure inside the hybridization gap is the impurity band, which is separated by two gaps from the continuum of the Kondo insulator. The asymmetry arises from $W\neq 0$.

IV. IMPURITY BANDS

Finite concentrations of Kondo holes can give rise to impurity bands in the gap of the Kondo insulator. To gain insight we first analyze the symmetric situation ($\epsilon_f=\mu=0$) with $U=W=\Delta V=0$ in the limit $\Delta\epsilon_f\to\infty$. Since $W=0$ only ϵ_f is renormalized but not V and z when $\hat{\Sigma}_{\rm imp}(z)$ is treated self-consistently. Due to the impurity self-energy the dressed f level energy acquires an imaginary part for small frequencies. In particular, for $\omega=0$ $\tilde{\epsilon}_f$ is purely imaginary and for small c we obtain $\tilde{\epsilon}_f=-2ic^{1/2}V^2/D$. Hence, the height of the band is not analytic in c. A similar analysis with $\omega\neq 0$ yields an impurity bandwidth of the order of $\tilde{\epsilon}_f$, so that the impurity band is approximately semielliptic with both height and width proportional to c for small c. Due to the nonanalytic dependence on $c^{1/2}$ the self-consistency condition Eq. (2.8b) and the limit $c\to 0$ cannot be interchanged. For $W\neq 0$ the impurity band becomes asymmetric, but the properties are otherwise similar.

To obtain more quantitative results we have to incorporate the Coulomb self-energy $\Sigma_U(z)$. As an example we show in Fig. 3 the f DOS for the symmetric host with $U=1$, $W=1$, $\Delta\epsilon_f=\infty$, and $c=0.03$. The asymmetry is due to the nonzero value of W. The f DOS does not show the van Hove saddle point singularities discussed in Refs. 9 and 10, since we consider a simple elliptic DOS for the conduction electrons. As discussed above the main effect of U is to narrow the gap of the Kondo insulator and to increase the height of (and to narrow) the peaks in the f DOS. The impurity band is separated from the continuum of the Kondo lattice by two gaps. The position of the band edges limiting the gap for $W=0$ (only one is shown, the other one is symmetric) and three values of U are displayed in Fig. 4(a). The gap is given by the region between the shown boundaries. The gap narrows with increasing U and increasing concentration of impurities, but within the range of validity of our approximations (noncrossing impurity lines in the self-energy) the gap never closes. For small c the $c^{1/2}$ dependence of the impurity

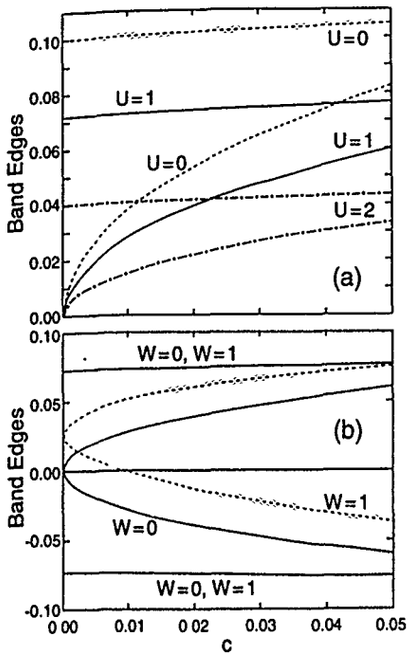

FIG. 4. Band edges of the hybridization gap and the impurity band for $V=1$, $D=10$, $\epsilon_f=0$ (Hartree–Fock corrected), and $\Delta\epsilon_f=\infty$ as a function of c. (a) $W=0$ and three values of U; the dashed line refers to $U=0$, the solid curve to $U=1$ and the dash-dotted one to $U=2$. (b) $U=1$ and $W=0$ (solid curve) and $W=1$ (dashed line). Note that the gap narrows with U and the edges are symmetric only if $W=0$. The impurity band is always separated by a gap from the continuum of the insulator. Note the $c^{1/2}$ dependence for very low c.

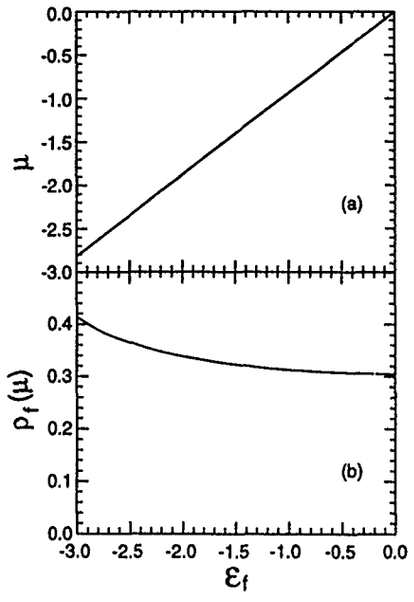

FIG. 5. (a) Chemical potential, μ, and (b) f DOS at the Fermi level, ρ_f, as a function of the (Hartree-Fock corrected) f level energy for $V=1$, $U=1$, $D=10$, $W=0$, $\Delta\epsilon_f=\infty$, and $c=0.04$ (see Ref. 7).

band is observed. The band edge of the continuum of the Kondo insulator only increases slightly with c.

In Fig. 4(b) we show the four band edges for the symmetric Kondo insulator with $U=1$ for the cases $W=0$ and $W=1$. The $W=0$ case is the same as the solid curve in Fig. 4(a). The band edge of the Kondo lattice depends only very weakly on W. The impurity band for $W=1$ is strongly asymmetric and still has the $c^{1/2}$ dependence for small c. Consequently one gap is smaller than the other, but neither gap is closed within the range of validity of the theory.

The properties of the impure Kondo insulator once more depend on the characteristics of the impurities. We distinguish among dopands (e.g., Th replacing Ce) and charge neutral impurities (e.g., La substituting Ce). In the former case the Fermi level lies in one of the gaps discussed above and the system behaves like a nonmagnetic insulator. In the latter case the Fermi level lies in the impurity band. The chemical potential μ is determined self-consistently via $\mu=\mathrm{Re}\,[\tilde{\epsilon}_f(\mu)]$ and is displayed in Fig. 5(a) as a function of ϵ_f for $W=0$ and $c=0.04$ ($\Delta\epsilon_f\to\infty$). Note that $\mu(\epsilon_f)$ is a linear function of ϵ_f with a slope that is only slightly smaller than one. The corresponding f electron DOS at the Fermi level is shown in Fig. 5(b). There is only a small increase of $\rho_f(\mu)$ with the asymmetry. On the other hand, $\rho_f(\mu)$ strongly depends on the concentration of Kondo holes; it grows monotonically with c, being proportional to $c^{1/2}$ for small c. The finite f DOS at the Fermi level gives rise to a specific heat contribution proportional to T. The range of this linear T dependence is of the order of the width of the impurity band. The γ coefficient[7,8] is proportional to $\rho_f(\mu)$ and tracks the same weak ϵ_f dependence. The effective mass associated with γ for the parameters of Fig. 5 is about 15–20 times the mass of the conduction electrons. The susceptibility also follows the same trends.

For sufficiently small c all states in the impurity band are localized (charge neutral impurities), but an insulator-metal transition is expected as a function of c. When c is increased the bound states (located at the nearest neighbor sites to the impurity) start to overlap and electrons may percolate giving rise to conductivity and affecting the infrared optical properties. Magnetic order of the spin-glass-type is also possible.

Finally, we briefly address the situation $\Delta V\neq 0$ and $\Delta\epsilon_f=W=0$ by showing in Fig. 6 the f DOS for $\Delta V=-0.4$ and $c=0.05$ as compared to the pure symmetric Kondo insulator (dotted curve). The height of the main peaks decreases and impurity tails protude into the gap. If the ligand defects are charge neutral the Fermi level remains within the gap and the system is a nonmagnetic insulator with a reduced gap. If the ligand impurity dopes the crystal the Fermi level lies in the continuum; hence $C\propto T$ at very low T and depending on the position of the mobility edge the system will be a metal or an insulator.

V. CONCLUDING REMARKS

We presented a summary of our results for various types of impurity states in a Kondo insulator. The formation of a Kondo insulator is perhaps the most dramatic implication of "coherent scattering." Kondo holes destroy the translational invariance and hence the coherence. We considered isolated Kondo holes, typically leading to a bound state in the hybridization gap, and finite concentrations of impurities, giving rise to impurity bands.

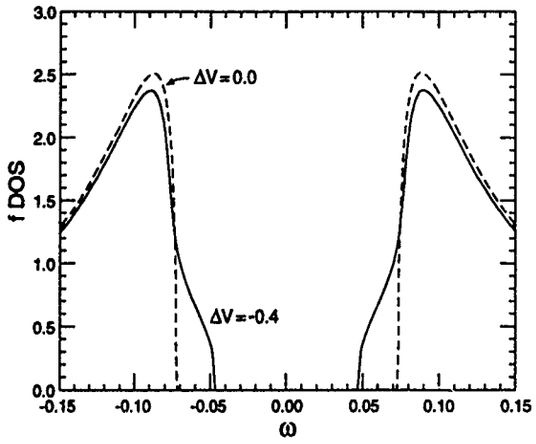

FIG. 6. f DOS for $V=1$, $U=1$, $D=10$, $\epsilon_f=0$ (Hartree–Fock corrected), $c=0.05$, and $\Delta\epsilon_f=W=0$. The solid curve corresponds to $\Delta V=-0.4$, while the dashed one is the pure Kondo insulator. Note that two tails appear at the band edges, but no impurity band develops in the gap.

So-called Kondo holes can be described by three scattering parameters, which correspond to a local change in the f level energy, a potential scattering of the conduction electrons and a local reduction of the hybridization matrix element. Depending on the characteristics of the impurity very different properties may arise. In most of the cases a bound state is formed in the hybridization gap of the Kondo insulator, but as shown in Sec. III not all scattering parameters will lead to a pole in the denominator of the t matrix, i.e., to a bound state. The two most important examples of impurities discussed are (i) the missing f electron (obtained in the limit $\Delta\epsilon_f\rightarrow\infty$), representing, e.g., the substitution of Ce by La or Th, and (ii) the ligand defect, characterized by $\Delta V\neq 0$ ($\Delta V\neq 0$ is typically negative). If the bound state pins the Fermi level (i.e., depending on the effective charge of the defect) the properties of the impurity are magnetic, i.e., it can be represented by an effective spin 1/2, although the origin of the defect is usually nonmagnetic. If the charge balance is such that there is no pinning of the Fermi level the bound state is nonmagnetic. The bound states are strongly localized, that is, they only extend over a few unit cells.

If the concentration of Kondo holes is finite the bound states acquire a finite lifetime and an impurity band (missing f electron) or impurity tails at the band edges (ligand defects) arise. Depending on the charge characteristics of the defects the Fermi level lies in the continuum or in the reduced gap. This determines the thermal properties of the impure Kondo insulator, i.e., either a specific heat proportional to T and a Curie–Weiss susceptibility or a thermally activated small effective gap semiconductor. The former case is unquestionably the more exciting one, which could lead to a spin-glass phase or to an insulator-metal transition as a function of c. The impurity band is expected to affect the infrared optical properties.

There are several experimental studies on impure Kondo insulators. The predicted $c^{1/2}$ dependence of γ has been verified for La-substituted $Ce_3Bi_4Pt_3$.[3,17] The valence instability and electrical properties of Yb and La-substituted SmB_6 have been studied long ago.[18] The gap of CeNiSn was found to close with 15% La substitution[19] and is also smeared with increasing x in $CeNi_{1-x}Pt_xSn$.[20]

The Coulomb interaction within the f shell is introduced perturbatively via a self-energy to second order in U. This approach is of course only valid for small U, but unless the Kondo insulator becomes antiferromagnetic we do not expect qualitative changes for larger U. For very large U in the asymmetric case the $1/N$ expansion (or mean field slave bosons) could be the more appropriate method to study the impurity bands.[21]

Structural and magnetic ordering in the cerium hydride (abstract)

Depending on the H concentration at the octahedral (O) sites, x(O), various tetragonal phases, due to H ordering, are observed in the Ce hydride at low temperatures. While our single crystal work showed that the tetragonal phase for H/Ce≈2.7, corresponding to x(O)≈3/4, is only stable in a region of x(O)=±0.05, the other one was believed to be caused by a single H ordering process for 0.15≤x(O)≤0.5 up to now. However, strong discrepancies in the structure were reported from different neutron diffraction studies.[1] We have studied both the structural H ordering and the magnetic ordering by neutron diffraction work for 0.2≤x(O)≤0.5. It will be shown that the H ordering for x(O)=1/4 and 1/2 are completely different (Space groups: I4/mmm and $I4_1$/amd, respectively). Accordingly, for x(O)=1/2 the Ce atoms are crystallographically identical, while for x(O)=1/4 two different Ce atoms are present in the lattice. Also the magnetic order is completely different for the two phases. For x(O)=0.5, a commensurate magnetic phase appears below T_N≈3.5 K. The structure is described by a canted ferromagnet with μ_F=1.3 μ_B/Ce atom along the *c* axis and μ_{AF}=1.1 μ_B/Ce atom within the plane normal to c. On the other hand, for 0.2≤x(O)≤0.25, an incommensurate AF phase with a long period, described by the wave vector τ=(0.12, 0.12, 0), is obtained at 1.4 K. Above 2.6 K, this phase is progressively replaced by the commensurate lines discussed before. For x(O)=0.265, the two phases coexist at 1.4 K, while for x(O)=0.28 only the commensurate phase is retained. Apparently, the long period phase is characteristic of the ideal H ordering around x(O)=1/4, whereas it is strongly affected by the H occupation of the new positions for higher concentrations.

Recent developments in multi-channel Kondo physics (invited) (abstract)

Kevin Ingersent

The two-channel Kondo model for a single spin-one-half magnetic impurity coupled to two degenerate bands of conduction electrons predicts the existence of a zero-temperature quantum critical point, leading to "marginal-Fermi-liquid" behavior at low temperatures. A two-channel Kondo description has been proposed[1] for several U and Ce-based heavy-fermion materials whose thermodynamic and transport properties exhibit anomalous temperature and magnetic field dependence.[2] This talk will review recent theoretical work on multi-channel Kondo behavior. Two factors may be particularly important in determining the relevance of the multi-channel Kondo effect for real systems: (1) Channel asymmetry: Any difference between the coupling of the two conduction bands to the impurities leads to the recovery of Fermi-liquid behavior at sufficiently low temperatures.[3] (2) Inter-impurity interactions: Numerical renormalization-group calculations for a two-impurity model show that any nonzero Ruderman–Kittel–Kasuya–Yoshida (RKKY) coupling between the impurities destabilizes the single-impurity critical point.[4] Depending on the strength and sign of the RKKY coupling, the system may be driven either to a Fermi-liquid or to a novel regime of non-Fermi-liquid behavior governed by nonuniversal critical exponents. The experimental implications of these findings will be discussed.

Giant magnetoresistance in $Fe_{0.95}Cr_{0.05}$/Cr multilayer films

L. H. Chen, S. Jin, T. H. Tiefel, R. B. Van Dover, E. M. Gyorgy, and R. M. Fleming
AT&T Bell Laboratories, Murray Hill, New Jersey 07974

We have studied the effect of Cr alloying addition to the Fe layers on the magnetoresistance behavior of the Fe/Cr superlattice films [Fe(15 Å)/Cr(8–20 Å)]$_{30}$. The alloyed superlattice films $Fe_{0.95}Cr_{0.05}$/Cr exhibited significantly improved giant magnetoresistance effect ($\Delta R/R \sim 12.2\%$ at 4.2 K), as compared to the unalloyed Fe/Cr multilayer films ($\Delta R/R \sim 6.9\%$). The M–H loops indicate that antiferromagnetic coupling exists in both films, which is believed to be responsible for the observed giant magnetoresistance. The improvement in $\Delta R/R$ in the Cr-alloyed superlattice films is attributed to the stronger spin-dependent scattering of conduction electrons caused by the introduction of Cr impurities in the ferromagnetic layers. The alloyed superlattice films also exhibit reduced coercivity and saturation magnetization.

I. INTRODUCTION

The giant magnetoresistance (GMR) phenomenon observed in the Fe/Cr type multilayer films[1–10] is attributed to the spin-dependent scattering at the interface of multilayer thin films, as well as the spin-dependent bulk scattering.[3] In the applied field, the spins in ferromagnetic layers align in the field direction, and as a result, a reduced electrical resistance (ρ_F) is obtained in the film. However, if the field is removed, the ferromagnetic layers adjacent to the nonmagnetic spacer layer in between exhibit an antiferromagnetic coupling (antiparallel magnetization), and as a result a higher resistance (ρ_{AF}) is obtained (e.g., due to the spin-flip scattering when the conduction electrons cross the interfaces, and move into the neighboring ferromagnetic layers.) The change in magnetoresistance is defined as a resistivity ratio $\Delta\rho/\rho=(\rho_{AF}-\rho_F)/\rho_F$ or a resistance ratio $\Delta R/R$.

In the two current mode,[11] the current is carried by the spin ↑ and spin ↓ electrons. Here ↑ and ↓ indicate majority and minority spins. At high applied fields (ferromagnetic state), and low temperature, the total current of multilayer thin films is determined by the spin ↑ and spin ↓ current in parallel. The spin ↑ and spin ↓ currents could become significantly different if certain transition metal impurities are purposely introduced to a ferromagnetic material to disproportionately scatter the spin ↑ and spin ↓ electrons. In multilayer thin films, small-thickness nonmagnetic layers and the interface areas could be interpreted as the scattering impurities in ferromagnetic layers.[2,3,5] However, a direct alloying of impurities into the ferromagnetic layer itself to modify the scattering behavior, and hence the GMR effect has not been attempted.

In this paper, we report a significant increase in GMR effect (almost twofold improvement) by intentional Cr alloying of the Fe layer in the Fe/Cr multilayer superlattice.

II. EXPERIMENT

Multilayer thin films of ($Fe_{0.95}Cr_{0.05}$)/Cr and Fe/Cr were prepared by DC magnetron triode sputtering system with computer-controlled rotating shutter and substrate. These films, typically consisting of 30 double layers of Fe(~15 Å thick) and Cr(~11 Å thick), were deposited on the Si(100) substrate wafers, which were chemically cleaned (with a 10% HF solution) before deposition. As shown schematically in Fig. 1, a Cr overlayer of 50 Å was added on top of the multilayer structure to protect the deposited films from oxidation. A Fe buffer layer of 40 Å was used between the Si substrate and the multilayer to improve the quality of the superlattice interfaces. Because the magnetoresistance effect is very sensitive to the deposition parameters, such as applied accelerating voltage and distance between substrate and target, Ar atmosphere pressure, substrate temperature, and the nature of substrate materials, etc., the study of the Cr alloying effect was made on samples carefully prepared under the same sputtering conditions. Sputtering was carried out in a 3×10^{-3} Torr argon atmosphere; with a base pressure of 2×10^{-7} Torr before sputtering. A sputtering rate of ~100 Å/min was used for all targets by adjusting the applied acceleration voltage between the substrate and target to be 90 V for the Cr target and 140 V for the Fe and $Fe_{0.95}Cr_{0.05}$ targets. The film thickness was determined by Rutherford Backscattering Spectrometry (RBS) using a calibration

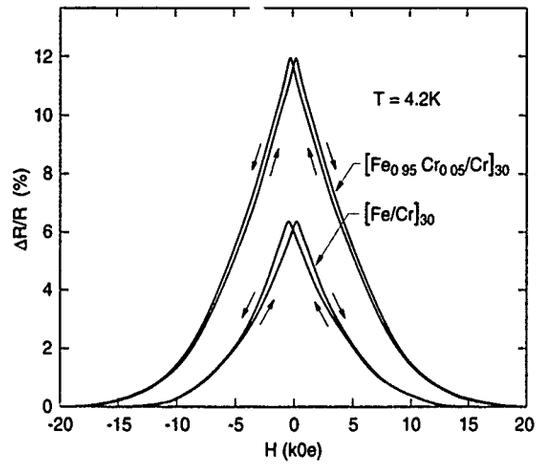

FIG. 2. $\Delta R/R$ vs H at 4.2 K.

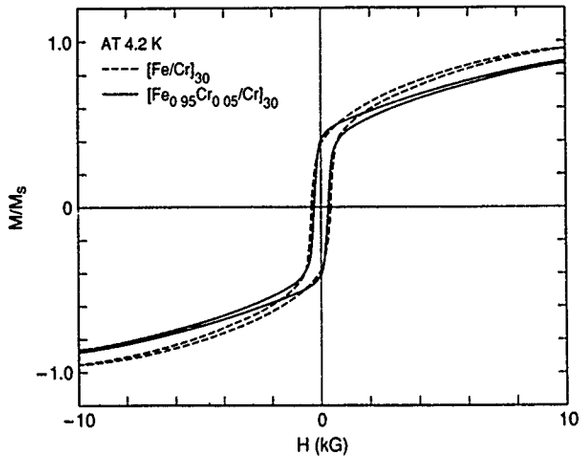

FIG. 3. M–H loops at 4.2 K.

sample of about 1000 Å thick single layer films of Fe, $Fe_{0.95}Cr_{0.05}$, and Cr, prepared under the same deposition conditions.

The crystal structure and texture of the deposited films were evaluated by x-ray diffraction (XRD) using K_α(Cu) radiation. Small angle XRD was also carried out to characterize the interface roughness of the multilayer thin films. Conventional four probe method was used to measure the electrical resistance with a magnetic field applied in the film plane along the current flow direction. The measurements were carried out at various temperatures (4.2–295 K) and fields up to 30 K Oe. The in-plane magnetization loops were measured at room temperature and 4.2 K by using a vibrating sample magnetometer.

III. RESULTS AND DISCUSSION

The high-angle x-ray diffraction study indicates that the main diffraction peaks are Fe(110) and Cr(110). The low-angle diffraction measurements show a characteristic peak associated with the layer structure for both $Fe_{0.95}Cr_{0.05}$/Cr and Fe/Cr superlattice films. The superlattice wavelength calculated from the peak position is within 10% of nominal thickness obtained from the calibration films. Comparison of the measured intensity versus 2θ curves suggests that the flatness of the interface in the Fe/Cr superlattice film is not drastically altered by Cr alloying to the Fe layers.

Shown in Fig. 2 are the magnetoresistance ratio [$\Delta R/R=(R-R_s)/R_s$, where R_s is the resistance at the saturation field] versus applied magnetic field curves (in-plane field parallel to the current flow direction) at 4.2 K for both $[Fe_{0.95}Cr_{0.05}$ (15 Å)/Cr (11 Å)$]_{30}$ and [Fe(15 Å)/Cr(11 Å)$]_{30}$ films. As is evident from the figure, the magnetoresistance ratio of ~11.8% for the $Fe_{0.95}Cr_{0.05}$/Cr superlattice is much larger, compared with ~6.4% for the Fe/Cr superlattice. (Slightly higher values of 12.2% and 6.9% are obtained if the Cr interlayer thickness is optimized to 10 and 9 Å, respectively, for the $Fe_{0.95}Cr_{0.05}$/Cr and Fe/Cr superlattice films, as discussed later.) The $\Delta R/R$ vs H curves at 4.2 K for both superlattice films show the well-known hysteresis behavior because of the relatively large coercivity. Essentially similar $\Delta R/R$ behavior is observed at room temperature, except that the magnetoresistance ratios are somewhat lower than at 4.2 K, and the hysteresis is not as obvious due to the smaller coercivity at room temperature. A peak room temperature value of ~7% is obtained for the Cr-alloyed superlattice, and ~4% for the unalloyed superlattice film. The magnetoresistance ratios obtained in the present study are considerably smaller than the values previously reported by other researchers. The MR ratio in superlattice films is known to be very sensitive to various processing and materials parameters.[10,12] The exact reason why the MR values in the present films are generally low is not clearly understood at the moment.

The M–H loops of the [$Fe_{0.95}Cr_{0.05}$(15 Å)/Cr(11 Å)] and [Fe(15 Å)/Cr(11 Å)$]_{30}$ superlattice films are shown in Fig. 3 for 4.2 K. The Cr alloying reduces the coercivity, increases the remanence, and decreases the saturation moment. Essentially similar M–H characteristics are observed at room temperature, except that the coercivity values decrease from ~200 and ~150 Oe at 4.2 K to ~50 and ~35 Oe at room temperature for the Fe/Cr and $Fe_{0.95}Cr_{0.05}$/Cr superlattice, respectively. All the M–H curves saturate at a relatively high field (above 12 KOe), and show the antiferromagnetic coupling effect between two neighboring ferromagnetic Fe layers separated by the nonmagnetic Cr layer. At a high saturation field, all the ferromagnetic Fe layers in the superlattice align the magnetic moment in the field direction. When the field is decreased to a certain low value, but still in the same direction, the magnetization direction of every other Fe layer is gradually reversed, due to the increasing antiferromagnetic coupling between two neighboring Fe layers. Thus, at low field, the magnetization of the superlattice is small and the magnetization direction of two neighboring Fe layers is antiparallel. When the field is raised to the saturation field in the opposite field direction, the previously antiparallel layers slowly reverse their magnetization over the range of ~0.5 to ~30 KOe until the superlattice is saturated.

The saturation moment (M_s) of the [$Fe_{0.95}Cr_{0.05}$(15 Å)/Cr(11 Å)$]_{30}$ film is estimated to be about 1190 emu/cm^3 at 4.2 K which is slightly smaller, when compared with ~1300 emu/cm^3 for the [Fe(15 Å)/Cr(11 Å)$]_{30}$ superlattice. The

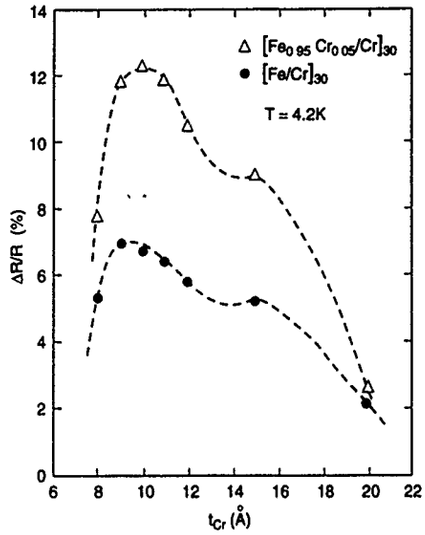

FIG. 4. $\Delta R/R$ vs Cr interlayer thickness at 4.2 K.

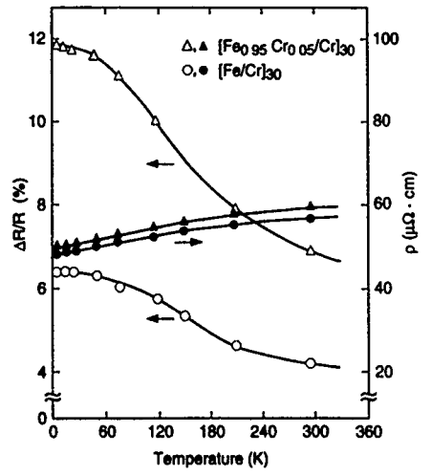

FIG. 5. $\Delta R/R$ and ρ vs temperature for the superlattice films.

smaller saturation moment is believed to be caused by the Cr alloying of the Fe layers. As shown in Fig. 3, the remanent magnetization values of both superlattices are still substantial, around $0.35M_s$, which means the antiferromagnetic coupling between the Fe layers is not perfect.

Shown in Fig. 4 is the change in magnetoresistance at 4.2 K as a function of Cr interlayer thickness for both the $Fe_{0.95}Cr_{0.05}/Cr$ and Fe/Cr superlattices. As is evident from the figure, the maximum magnetoresistance ($\Delta R/R = 12.2\%$ and 6.9%, respectively for $Fe_{0.95}Cr_{0.05}/Cr$ and Fe/Cr superlattice) occurs at a Cr thickness of around 10 Å, in agreement with a previous report,[7] which showed an oscillatory change in magnetoresistance as a function of Cr thickness. It is seen that the magnetoresistance ratio for $Fe_{0.95}Cr_{0.05}/Cr$ is higher than that of Fe/Cr at all Cr thicknesses studied here. Such improved magnetoresistance ratio by adding Cr impurities directly to the Fe layer is attributed to stronger spin-dependent scattering of electrons in the $Fe_{0.95}Cr_{0.05}/Cr$ superlattice, and not to any significant difference in interface roughness, as discussed earlier. As mentioned previously, the Cr impurity (in the form of layers) in the Fe/Cr superlattice makes the spin ↑ and spin ↓ current very different.[11] When Cr impurities are mixed in Fe near the interface, the $\rho\uparrow/\rho\downarrow$ ratio is almost equal to 6 and very large compared with pure iron. Thus, it is believed that in the present $Fe_{0.95}Cr_{0.05}/Cr$ superlattices, the direct mixing of Cr impurities in the Fe layer should yield an additionally increased $\rho\uparrow/\rho\downarrow$ ratio and $\Delta R/R$, as compared to that in Fe/Cr, which is indeed observed in this work.

The temperature dependence of magnetoresistance and that of resistivity for the $[Fe_{0.95}Cr_{0.05}/Cr]_{30}$ and $[Fe/Cr]_{30}$ films are shown in Fig. 5. We find a general trend that the magnetoresistance ratio increases as the measurement temperature is decreased in both types of films. The increases in magnetoresistance ratio for both films when temperature is lowered from room temperature to 4.2 K are caused mostly by the temperature-dependent increase in ΔR at low temperature as the resistivity (or resistance) of the films exhibit relatively small temperature dependence, as shown in the figure.

IV. SUMMARY

The giant magnetoresistance behavior and magnetization properties of the $[Fe_{0.95}Cr_{0.05}/Cr]_{30}$ superlattice films have been studied and compared with those of the $[Fe/Cr]_{30}$ films. Significantly improved magnetoresistance is obtained by direct alloying of Cr in the ferromagnetic Fe layers, which is attributed to the stronger spin-dependent scattering of electrons caused by the introduction of Cr impurities in the ferromagnetic layers.

We have grown Co/Cu multilayers by MBE using a shuttering arrangement wherein half of the sample receives an amount of Au impurities at each interface. Under these controlled conditions, the differences in measurements between each half is attributed only to the effect of the impurities. The samples were characterized by x-ray diffraction and RHEED. We have found that small fractions of a monolayer of Au deposited at the Co/Cu interface significantly decreased the GMR. These results are discussed in the light of current theories on the role of bulk and interface scattering.

INTRODUCTION

The giant magnetoresistance (GMR) found in magnetic multilayers has recently been the subject of great interest, with Fe/Cr and Co/Cu being the most widely studied systems. It is interesting to note that there are important experimental differences regarding the GMR between Fe/Cr and Co/Cu. In Fe/Cr, for example, various methods of causing interdiffusion at the interface—annealing[1] or changing the growth conditions[2]—can lead to an *increase* in the magnitude of the GMR. On the other hand, Hall *et al.*[3] found that for Cu/Co, the GMR *decreased* when interdiffusion was caused by annealing. Moreover, it was not until a growth technique of making the interfaces *smoother* was discovered,[4] that a GMR was observed in MBE-grown (111)-oriented Co/Cu multilayers.

In the present investigation, we employ yet another experimental technique for changing the magnitude of the GMR. For Fe/Cr, it has been found[1] that the GMR is significantly increased if one deposits "extra" Cr impurities at the Fe/Cr interface. We have found that the *opposite* results apply to Co/Cu. That is, the deposition of Au impurities at the Co/Cu interface *decrease* the magnitude of the GMR. We note that various authors[5] have deposited impurities at the interface of Fe/Cr, which resulted in a decrease in the GMR, however, in that work the thickness of the spacer layer (impurity+Cr) was not held constant, thus obscuring the effect of the impurity.

Before describing our data, it is useful to place these results in context. The theoretical model for the GMR suggested by Baibich *et al.*[6] and developed by Camley and Barnas,[7] which is based on separate currents flowing in parallel for different spin directions, explains rather well the general features of the GMR data. This model is based on *spin-dependent* electron scattering as the source of the GMR. Based on these ideas, we recently attributed[3] the very different behavior between the Fe/Cr and the Co/Cu systems to the fact that whereas spin-dependent *interface* scattering is dominant in Fe/Cr, spin-dependent *bulk* scattering determines the GMR for Co/Cu, for the following reason. For the Fe/Cr system, the diffusion of Cr into Fe leads to a resonant virtual bound d state at the Fermi level,[8] and hence to strong spin-dependent scattering at the Fe/Cr interfaces. However, the scattering at the Co/Cu interface should be spin-independent because no such virtual bound state exists when Cu diffuses into Co. Recent results[9] on the diffusion of Cu into NiFe by annealing lend credence to the idea that Cu as an impurity at the interface of magnetic and nonmagnetic layers causes only spin-*independent* scattering.

Further support for these ideas come from the measurements by Parkin *et al.*[10] which have shown that for the Co/Cu system, the magnitude of the GMR as a function of the *Cobalt* thickness has a distinct maximum at about 10 Å. This result has been explained, both by Dieny *et al.*[11] and Mathon[12] on the basis on *bulk* spin-dependent scattering. Moreover, Dieny *et al.*[11] showed that the maximum in the GMR *disappears* if the interface spin-dependent scattering is also included in the calculation of the GMR.

These theoretical results are easy to understand. Increasing the Co thickness leads to an increase in the relative proportion of the bulk scattering to interface scattering, because a thicker Co layer leads to fewer interfaces per unit thickness of the multilayer. Therefore, if *interface* spin-dependent scattering were to be the most important for the GMR, then the GMR would always *decrease* with increasing Co thickness; this is not observed for Co/Cu multilayers. However, if bulk spin-dependent scattering is the most important for the GMR, then the GMR should initially *increase* with increasing Co thickness (which *is* in accordance with the Co/Cu data of Parkin *et al.*[10]) Finally, for sufficiently thick Co layers, the GMR must eventually decrease because the electron becomes "confined" to a single magnetic layer by its finite mean-free path. This explains the observed maximum in the GMR or Co/Cu multilayers as a function of the Co thickness.

Recent results[13] on Co/Cu and Permalloy ($Ni_{81}Fe_{19}$)/Cu multilayers purport to show that in these systems the GMR is entirely determined by spin-dependent interface scattering. Interestingly, in these experiments where the GMR is measured as a function of the thickness of a Co layer inserted between permalloy and Cu, the GMR *continues* to increase until the Co is 8–10 Å thick (consistent with Ref. 10) and no observed decrease, surely if the GMR were determined by the interface alone, a decrease should be observed. It is also difficult to reconcile the interface-only argument in the light of thermopower measurements on Co/Cu,[14] which show that the thermopower goes as the reciprocal of the magnetoresis-

 0021-8979/94/75(10)/7055/3/$6.00 © 1994 American Institute of Physics

tance. These authors point out the essential role of the *bulk* density of states in understanding these results. It also appears[15] that the thermopower of permalloy Cu multilayers is very similar to that of Co/Cu, indicating that the *bulk* density of states of these systems is rather similar. We feel that aspects of both the interface and bulk scattering must be considered.

The purpose of the present investigation is to shed light on the question of the relative importance of interface versus bulk spin-dependent scattering for the Co/Cu system. In particular, we wish to elucidate the role played by impurities deliberately added at the Co/Cu interface. The results we present here are consistent with the conclusion that the dominant source of spin-dependent scattering in Co/Cu is located in the bulk. We have added small ($\ll$1 monolayer) quantities of Au impurities at the interfaces, and have observed a decrease in the GMR that is related to the amount of Au deposited. For example, the GMR decreased from 22% to 6% when the Au shutter was opened for three seconds after each interface was formed. Thus, we have found yet another example of opposite behavior exhibited by the GMR for the Co/Cu system and for the Fe/Cr system. It should be pointed out that other explanations are also possible for the observed decrease in the GMR when Au impurities are added at the Co/Cu interface. Further experimental investigation of this point is in progress.

EXPERIMENTAL

The Co/Cu multilayers were grown in a VG80M MBE facility with a base pressure of 3×10^{-11} mbar. The substrate of GaAs(110) was heated to 600 °C to achieve the RHEED patterns characteristic of GaAs(110) surface reconstruction prior to growth. A 500 Å buffer layer of Ge was deposited at 500 °C at a rate of about 0.16 Å per second. During the evaporation of metallic layers the substrate temperature was held at 100 °C. The first metallic layer was 15 Å of Co deposited at a rate of about 0.2 Å/s, which grew as (100) BCC. A 10 Å layer of Au was then deposited on the Co, because it was found that such a layer is essential to produce a high-quality Co/Cu multilayer. The multilayers then consisted of 20 bilayers of Co(15 Å)Cu(9 Å) grown on the Au layer. To obtain the best samples the substrate is rotated at about 1 Hz. In order to minimize intersample differences, we prepared samples where the Au deposition at the interface affected half a large sample. At the point in the process where Au was to be introduced at an interface, a shutter was used to occlude half of the sample, thereby ensuring that the differences between the two halves were, as near as possible, due to just the Au. To obtain various amounts of Au, the evaporation source was exposed for different short periods of time. Resistivity measurements were performed using the standard four-probe DC method in fields up to 8 T and at temperatures between room temperature and 4 K. The magneto-optical Kerr effect was used to obtain magnetization curves at room temperature and in a maximum field of 0.5 T.

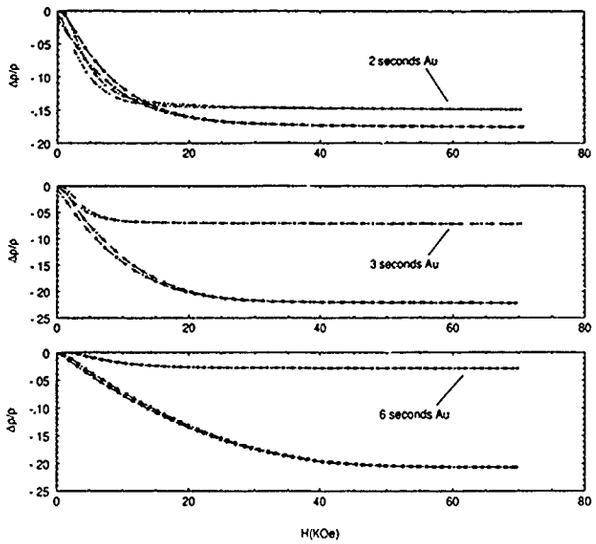

FIG. 1. The field dependence of the normalized resistivity at 4 K for (a) 2 s, (b) 3 s, and (c) 6 s exposure of the Au source.

RESULTS

Different samples were prepared with Au impurities by exposing the source for 1*s*, 2*s*, 3*s*, and 6*s*. We estimate that the Au deposition rate is about 0.05 Å s^{-1}. The samples were characterised *in situ* by RHEED and *ex situ* by low-angle x-ray diffractometry. The x-ray scans show that the first-order Bragg peak corresponding to the bilayer thickness for each sample agree within the experimental error. Qualitatively the data suggests that the Au has had only a small influence on the quality of the layers. Scans with and without Au are similar with many Kiessig fringes, which, if superimposed, are of similar intensity but slightly out of phase with each other. We will present more detailed results in a future publication. Figure 1 shows the magnetoresistance at 4 K for the 2*s*, 3*s*, and 6*s* samples. The 1*s* sample resulted in a less than 1% change in MR. It is evident that even small quantities of Au can result in large changes in MR, but importantly, in all cases the addition of Au at the Co/Cu interface resulted in a *decrease* in MR. It is interesting to note that in all samples, the addition of Au *did not* significantly increase the resistivity. For example, the largest change was in the 6*s* sample with only a 2 $\mu\Omega$ cm increase in resistivity with the addition of Au, yet the MR has decreased by 18%. By comparison, in our annealing work,[3] such a large change in MR was accompanied by a fourfold increase in ρ. We have determined H_S as the saturation field of the MR, by fitting a straight line to the high field region and looking for the point of change in slope. In all cases the saturation field is substantially *less* when Au is deposited at the interfaces. The results for all samples are summarized in Table I.

Turning to the magnetization, Fig. 2 shows the room temperature results for the 3*s* sample. With the 5 KOe field available, it was impossible to saturate the magnetization of any of the samples. The data for the 3*s* sample was typical, in that at these fields and temperatures it was difficult to see a difference in $M(H)$ due to the Au. Figure 2 shows the low

TABLE I. Exposures of the Au source are in seconds and the resistivities are at 4 K. The percentage change in the magnetoresistance (MR%) is for measurements made at 4 K and H_S is the saturation field for the MR. The remanence and coercive field (H_C) are from measurements made at room temperature.

	1(a)	1(b)	2(a)	2(b)	3(a)	3(b)	4(a)	4(b)
Exposure/s	···	1	···	2	···	3	···	6

Remanence%	52	55	60	45	59	44	64	···
H_C/Oe	36	42	34	41	39	32	41	···

field region of the same sample, 3*s*. From this data we have extracted the remanence and coercive field. For all the samples, the coercive field was about the same, 30–40 Oe, whereas the remanence for the samples with Au was *less* than their counterparts without Au (see Table I). It is not possible to connect the changes in MR with changes in the magnetic structure at this point. If one looks at the MR data at the same temperature and field range as the magnetization, there is little difference between samples. Further magnetization studies at low temperature are ongoing. We may qualitatively interpret these results in the same light as our annealing work. The addition of Au at the Co/Cu interface has resulted in an increase in scattering that takes place at the interface. The bulk of the Co has been little affected by the Au, and thus scattering in the bulk is unchanged. Thus there is a net increase in scattering that takes place at the interface over that in the bulk. Since bulk scattering is the most important for the MR in Co/Cu, this has resulted in a *decrease* in the MR. This is another example of the difference between the Co/Cu system and the Fe/Cr system where in the latter, additional scattering at the interface resulted in an *increase* in the MR.

In conclusion we have found that depositing small amounts of Au at the Co/Cu interface has resulted in large *decreases* in MR in proportion to the amount of Au deposited, but without a significant increase in resistivity. The saturation field of the MR was found to fall by a factor of about 2 and the remanence by about 50%, for the samples with Au at the interface.

Low field giant magnetoresistance in discontinuous magnetic multilayers

T. L. Hylton, K. R. Coffey, M. A. Parker, and J. K. Howard
IBM AdStar, San Jose, California 95193

Giant magnetoresistance of order 4%–6% has been observed in fields of 5–10 Oe at room temperature in annealed multilayers of $Ni_{80}Fe_{20}$/Ag prepared by magnetron sputtering. For a wide range of NiFe and Ag thicknesses, no giant magnetoresistance was observed in the unannealed films. We attribute the appearance of giant magnetoresistance to a magnetostatic interlayer interaction that promotes antiparallel order of the moments in adjacent layers fostered by a breakup of the NiFe layers. We discuss the effects of variations in the underlayers, spacer thickness, and the sputtering process on the magnetoresistance. Our results suggest that maximizing magnetoresistance and minimizing hysteresis require samples with continuous Ag layers that prevent contact between the NiFe layers and NiFe layers that are discontinuous but not too severly disrupted.

Recently we reported[1] a giant magnetoresistance (GMR) effect of order 4%–6% with characteristic fields of 5–10 Oe in annealed multilayers of $Ni_{80}Fe_{20}$/Ag. Unannealed films are ferromagnetically coupled with negligible GMR. Upon annealing, GMR develops concurrently with a break-up of the magnetic layers. We have attributed the appearance of the GMR at low fields to magnetostatic interactions that favor antiparallel order of the moments in adjacent NiFe layers, which are prompted by the breakup of the magnetic layers. Devices based on these structures may be able to capitalize on the original promise of GMR, as observed in Fe/Cr multilayer systems[2,3] by offering highly sensitive magnetic field sensors alternative to the "spin-value"[4] and other low-field GMR structures[5,6] for applications such as magnetoresistive heads used in magnetic recording systems. In this paper we concentrate on the role of process variations in the preparation of these structures, how they effect the GMR, and how they relate to our interpretation of the physics. Another paper at this conference will concentrate on the structure of these and related samples, as determined by transmission electron microscopy and x-ray diffraction.[7]

As we have previously discussed,[1,8,9] greater low-field sensitivity in systems of magnetic particles embedded in a nonmagnetic matrix exhibiting GMR[10–12] can be achieved if the particles can be given a flat, disk-like shape and oriented, such that all the particle surfaces are parallel to each other and to the applied field. The in-plane anisotropy induced by departures from a perfectly circular perimeter will be much smaller than in the case of similarly misshapen spherical particles. In an effort to achieve such a structure, we have prepared annealed multilayers of immiscible magnetic (NiFe) and nonmagnetic materials (Ag). Under appropriate annealing conditions, we expect penetration of the nonmagnetic material at the grain boundaries of the magnetic layer. While this may or may not result in a collection of flat, island-like magnetic particles, it will certainly promote a multidomain state within the magnetic layers. In addition, because the grains are columnar (with epitaxy between the NiFe and Ag layers) we expect that discontinuities at the grain boundaries in the magnetic layers will promote antiparallel alignment of the moments in adjacent layers.[1,7]

The multilayers were prepared by *S*-gun magnetron sputtering in a mixture of 4% H_2 and 96% Ar at a pressure of 3 mTorr with substrates at ambient temperature. Substrates were 1 in. Si wafers with a 700 Å thermally grown oxide surface. A typical sample with n NiFe layers of thickness x and Ag layers of thickness y is given by Ta(100 Å)/Ag(y/2)/[NiFe(x)/Ag(y)]$_{n-1}$/NiFe(x)/Ag(y/2)/Ta(40 Å)/SiO2(700 Å)/Si. A magnetic field of approximately 150 Oe applied during deposition resulted in a weak uniaxial anisotropy field of 2–3 Oe with significant dispersion. After deposition, the samples were broken into strips approximately 8 mm×1.5 mm and annealed at atmospheric pressure in a mixture of 5% H_2 and 95% Ar in a rapid thermal processing oven at a variety of temperatures for 10 min. Magnetoresistance measurements were performed with a four-point, in-line geometry of the contacts, with the magnetic field applied parallel to the plane of the sample and either perpendicular or parallel to the current direction. In the figures that follow, all measurements were made at room temperature, with the applied field in the easy axis direction. Similar results have been obtained on samples with no significant uniaxial anisotropy deposited in the absence of an applied field.

As shown in Fig. 1, GMR develops after annealing to

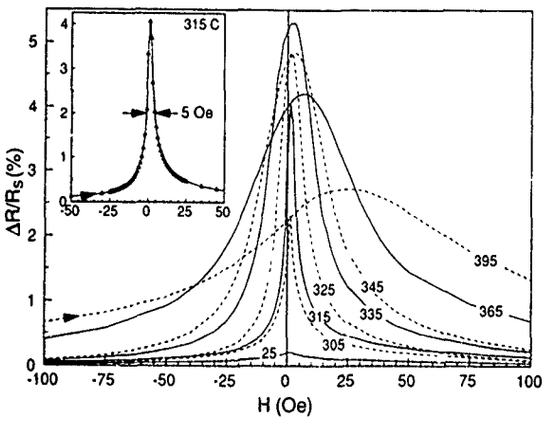

FIG. 1. $\Delta R/R_s$ vs H for a sample Ta(100 Å)/Ag(20 Å)/[NiFe(20 Å)/Ag(40 Å)]$_x$/NiFe(20 Å)/Ag(20 Å)/Ta(40 Å)/SiO2(700 Å)/Si. The field is in the plane of the sample and perpendicular to the current. Arrows indicate the ramping direction of the field. Unannealed samples show only a small AMR effect, but for annealing temperatures above 300 °C, a large GMR effect is evident. Large sensitivities of order 0.8%/Oe are achieved in the sample annealed at 315 °C (inset).

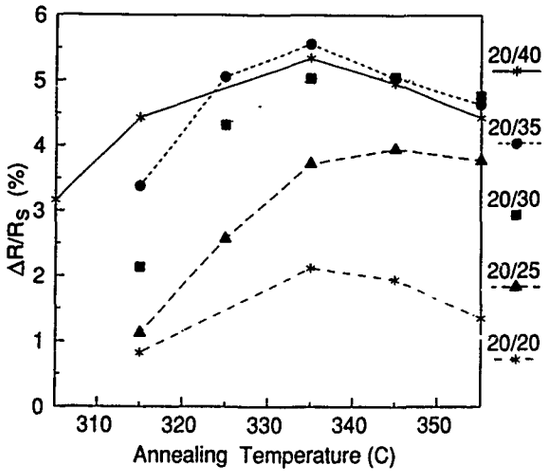

FIG. 2. The amplitude $\Delta R/R_s$ versus annealing temperature for samples Ta(100 Å)/Ag(x/2)/[NiFe(20 Å)/Ag(x)]$_4$/NiFe(20 Å)/Ag(x/2)/Ta(40 Å)/SiO2(700 Å)/Si, where x=20, 25, 30, 35, and 40 Å. Unannealed samples (not shown) exhibit no GMR. Samples with thinner Ag spacers show systematically smaller $\Delta R/R_s$.

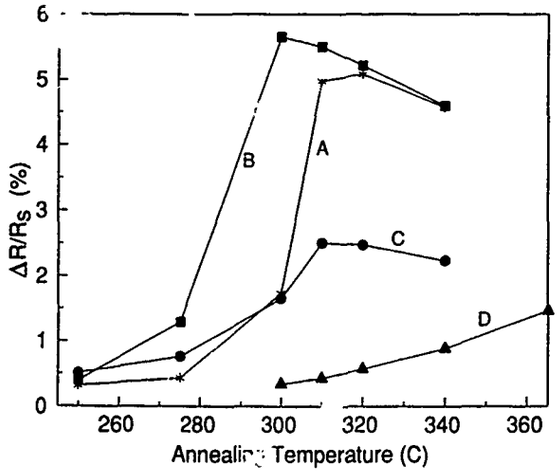

FIG. 3. The amplitude of $\Delta R/R_s$ versus annealing temperature for samples of the type Ta(100 Å)/Ag(20 Å)/[NiFe(20 Å)/Ag(40 Å)]$_{n-1}$/NiFe(20 Å)/Ag(20 Å)/Ta(40 Å)/SiO2(700 Å)/Si prepared with different sputtering pressures and deposition temperatures: (a) 3 mTorr, 25 °C, (b) NiFe layers at 25 mTorr, Ag layers at 3 mTorr, 25 °C, (c) 25 mTorr, 25 °C, and (d) 3 mTorr, 100 °C.

achieve magnitudes of typically $\Delta R/R_s$=4%–6% for a sample with five NiFe layers, where $\Delta R=R-R_s$ and R_s are the change in resistance and the resistance at saturation, respectively. The resistance of the as-deposited sample drops about 15% after annealing at any temperature in the 300 °C–400 °C range. Thus, changes in ΔR dominate the variation in $\Delta R/R_s$ with annealing temperature. A difference in the magnitudes of the GMR for fields applied parallel and perpendicular to the current direction indicates a persistent anisotropic magnetoresistance effect (AMR) of magnitude 0.3%–0.5% in both the unannealed and annealed samples. As the anneal temperature increases, the width and hysteresis of $\Delta R/R_s$ versus the applied field H increase. We find a maximum $\Delta R/R_s$=5.34% after an anneal at 335 °C, with a full width at half-maximum (FWHM) of 22 Oe, but the sample annealed at 315 °C shows the largest change in resistance per unit field, $\Delta R/R_s$/FWHM=4%/5 Oe=0.8%/Oe. As we have previously discussed,[1] the magnetoresistance becomes larger when the ratio of the magnetization remanence to that at saturation M_r/M_s becomes smaller, suggesting that ease of demagnetization plays an important role in determining $\Delta R/R_s$.

In Fig. 2, we show the dependence of the peak values of $\Delta R/R_s$ versus annealing temperature for a series of five-layer samples NiFe(20 Å)/Ag(y), where y=20, 25, 30, 35, and 40 Å. The dependence of the magnetoresistance on the applied magnetic field and its change with annealing temperature is qualitatively similar to that shown in Fig. 1 for all of these samples. In particular, none of the samples shows GMR prior to annealing, and all exhibit peaks in the magnitude of the GMR after annealing at temperatures in the range 335 °C–345 °C and peaks in sensitivity (i.e., the maximum change in $\Delta R/R_s$ per unit field) after annealing in the range 315 °C–325 °C. On the other hand, as the Ag spacer thickness decreases we see a gradual deterioration of GMR, such that $\Delta R/R_s$ and the sensitivity decrease while the hysteresis increases. At spacer thicknesses of 10 Å, we observe no GMR before or after annealing. We point out that there is no evidence of oscillations in the magnitude of the magnetoresistance with changing Ag spacer thickness, contrary to what has been observed in many other transition metal multilayer systems.[13]

The changes that we observe in the GMR with change in Ag spacer thickness and annealing temperature may be the result of several competing interlayer interactions: (i) ferromagnetic exchange interaction mediated by the Ag spacer; (ii) ferromagnetic bridges or "pinholes" through the Ag spacer; and (iii) magnetostatic interactions caused by the breakup of the magnetic layers that promote an "artificial" antiferromagnetic state (i.e., antiparallel alignment of the moments in adjacent layers). Interactions (i) and (ii) inhibit GMR, while interaction (iii) promotes it. A breakup of the magnetic layers in a columnar microstructure serves to break the ferromagnetic order favored by (i) and (ii) in two ways: by providing an antiparallel interlayer coupling mechanism and by isolating regions dominated by pinholes. A possible explanation of the observed deterioration of the GMR with decreasing spacer thickness is that samples with thinner spacer layers have a greater density of ferromagnetic bridges, and that samples with spacers as thin as 10 Å are completely ferromagnetically coupled due to a very large density of pinholes. Others have made similar conclusions in NiFe/Ag multilayers with thin Ag spacers.[14,15] As the annealing temperature increases, the pinhole density may increase and degrade the GMR, consistent with the results of Figs. 1 and 2. We also point out that magnetostatic interactions are very long range, and would not be expected to oscillate with layer thickness, consistent with our observations.

We now examine the effect of variations of the sputtering process parameters in an effort to influence the structure of the films and to determine its effect on the GMR. In Fig. 3, we show the change in amplitude of $\Delta R/R_s$ versus annealing temperature for several samples of [NiFe(20 Å)/Ag(40

Å)]$_5$ deposited at a variety of temperatures and pressures. Samples A and D, deposited at 3 mTorr and 25 °C and 100 °C, respectively, show a very different evolution of the magnetoresistance with annealing temperature. In particular, the sample deposited at low temperature shows a considerably larger $\Delta R/R_s$ appearing at much lower annealing temperature. A possible explanation for this observation is that the Ag layers in the sample deposited at 100 °C are more discontinuous due to increased Ag mobility on the sample surface during deposition. If so, then it is reasonable to expect a greater degree of NiFe bridging in the 100 °C sample, which would then require a greater degree of breakup of the NiFe (i.e., a higher annealing temperature) to effectively isolate the bridged regions and/or overcome the associated ferromagnetic interlayer coupling. A similar explananation can be offered to explain the difference between samples A and C, both sputtered at 25 °C, but at pressures of 3 and 25 mTorr, respectively. The sample sputtered at high pressure shows a uniformly smaller amplitude of $\Delta R/R_s$ again, suggesting a greater degree of interlayer ferromagnetic interaction. As high sputtering pressures are well known to produce more voided grain boundaries,[16] greater bridging of the NiFe through the Ag might be expected. Sample B was prepared by alternately sputtering the NiFe layers at 25 mTorr and Ag layers at 3 mTorr. Interestingly, this sample shows a larger amplitude of $\Delta R/R_s$ at lower annealing temperatures than any of the other samples. The alternation of the sputtering pressure was an effort to create porous NiFe layers separated by continuous Ag layers, thereby enhancing the breakup of the NiFe layers while preventing bridging of the Ag layers. The data presented in Fig. 3 indeed suggest that it is exactly this structure that is desired to produce large $\Delta R/R_s$.

In Fig. 4 we show $\Delta R/R_s$ vs H at the annealing temperature yielding the largest amplitude of $\Delta R/R_s$ for each of the same samples in Fig. 3. Samples with smaller $\Delta R/R_s$ also show considerably greater hysteresis and characteristic fields. This trend is generally true in all the NiFe/Ag multilayer samples that we have examined, and is also evident in Fig. 1 for annealing temperatures higher than that which produces the peak amplitude of $\Delta R/R_s$. The hysteresis evident in these annealed multilayers may be the result of excessive breakup of the NiFe layers and bridging of the Ag spacer layers. We conclude that the ideal structure would have continuous Ag layers and NiFe layers that are not too severly disrupted. By carefully controlling the deposition and annealing parameters, structures such as these may not only yield very large $\Delta R/R_s$ at small fields, but also a nonhysteretic response.

Finally, we comment on the role of the Ta and Ag layers that sandwich the NiFe/Ag multilayer. The Ta underlayer was found to provide an enhanced (111) orientation of the multilayer and greatly improved the quality and reproducibility of the GMR effect. Ta underlayer thicknesses in the range 40–160 Å were found to have a roughly comparable effect. Samples with Cr, Y, or no underlayer showed a generally poorer quality GMR and reduced (111) orientation. For samples without Ta overlayers, Ag was seen to agglomerate on the sample surface after annealing, which we have also observed in annealed NiFeAg alloys exhibiting GMR.[17] The

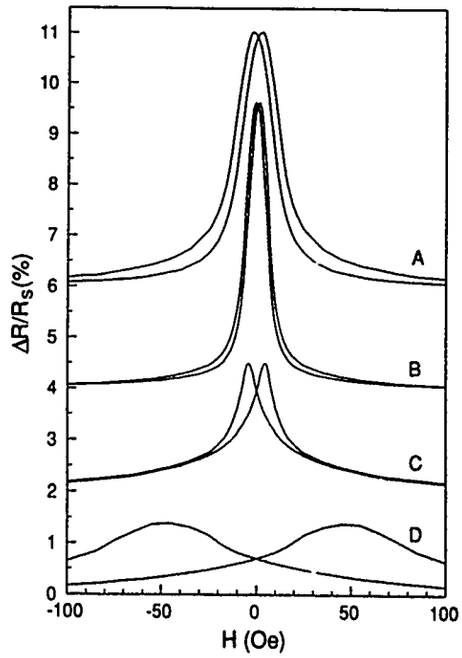

FIG. 4. $\Delta R/R_s$ vs H for the same samples shown in Fig. 3 at annealing temperatures of (a) 320 °C, (b) 300 °C, (c) 310 °C, and (d) 365 °C. Curves are offset along the vertical axis for clarity.

Ta overlayer prevents this agglomeration, as well as providing a thin passivating oxide on its surface. Better reproducibility and higher quality GMR is also obtained on samples that include Ag layers below the bottom NiFe layer and above the top NiFe layer. In these structures each NiFe layer is sandwiched between Ag layers, which may promote a more uniform breakup of the magnetic layers by annealing.

A new epitaxial "spin-valve"-type system for low-field magnetoresistive detection is described. This system is based on Fe/Pd epitaxial multilayers grown on (100)MgO by MBE. These films show a very abrupt transition from positive to negative magnetization as the reverse field is applied during hysteresis measurements. We have used these sensitive magnetic properties to fabricate epitaxial spin-valve structures by epitaxial growth of Fe/Ag, Co/Ag, or Co/Cu bilayers on top of a Fe/Pd bilayer. Hysteresis loops and magnetoresistance curves clearly indicate a significant field range with antiparallel alignment of the two components. Magnetoresistive sensitivities of up to 0.3% per Oe at low temperatures have been observed in these structures. The efficiency of the spin-dependent scattering has subsequently been improved either through the addition of planar Co impurities, in both the soft and hard magnetic layer, or by increasing the number of active Fe/Pd interfaces. This approach leads to a drastic improvement of the sensitivity, up to 1.5% per Oersted at room temperature.

Sensitive magnetic field sensors, based on the magnetoresistive effect, require a large magnetoresistivity at low fields. The discovery of giant magnetoresistance (GMR) in antiferromagnetically exchange-coupled multilayers has opened new avenues for these applications.[1] The principal problem with coupled GMR systems is related to the magnetic field range of the effect, which is usually of 1 kOe or more. To decrease the field scale of GMR, the most promising approach is based on achieving antiparallel alignment *without* antiferromagnetic exchange coupling. This can be obtained by selective rotation of the magnetic layers, using various types of layers with different magnetic properties. For example, a magnetic multilayer can be grown using alternatively magnetically hard and magnetically soft layers.[2] Another method is to block one of the magnetic layers through an exchange coupling with an antiferromagnetic material.[3] In practice, permalloy ($Ni_{79}Fe_{21}$) is often used as the soft material, and the growth of such materials is usually done by sputtering and leads to a polycrystalline structure. These systems, often referred to as a "spin-valve" structures, have led to sensitivities higher than 1% per Oersted[4] at room temperature. Here we propose an alternative system, which makes use of the sensitive magnetic properties of epitaxial Fe/Pd bilayers grown by molecular beam epitaxy (MBE). In epitaxial Fe/Pd superlattices, complete rotation of the magnetization of Fe occurs on very small magnetic field scales ($\approx$1 Oe). By combining a Fe/Pd bilayer with other epitaxial bilayers such as Fe/Ag or Co/Cu in a "spin-valve" structure, we have obtained highly field-sensitive epitaxial multilayers.

The present samples were grown in the same manner as the (100)Fe/Pd epitaxial multilayers studied previously.[5–7] Briefly, we used 1 cm×1 cm (100)MgO substrates, annealed in UHV for 30 min at 450 °C immediately prior to deposition. Fe grows very well on (100)MgO, without any kind of buffer layer. A substrate temperature of $T_S \approx 80$ °C was chosen to yield the best structural properties, as determined by low- and high-angle x-ray diffraction and cross-sectional transmission electron microscopy.[7] Measurements of the magnetic properties of Fe/Pd superlattices show narrow hysteresis loops at all temperatures.[5,6] Although the value of the coercive field H_c depends on the growth parameters such as temperature and deposition rate, and also on the thicknesses of the individual layers, it never exceeds 20 Oe at 15 K, and 5 Oe at 300 K. The Fe layers are ferromagnetically coupled to each other[6] for Pd thicknesses as high as 40 Å. Most importantly, we observe a very abrupt transition from positive to negative magnetization as the reverse field is applied, with a transition width between 1 and 3 Oe. Measurements of the absolute magnetization using wedge-shaped Pd layers have provided evidence of a strong polarization of the Fe/Pd interface,[7] and we have determined that the presence of this polarized interface is directly responsible for the low coercive fields.[8]

Following these results, we have used epitaxial Fe/Pd bilayers to develop new types of epitaxial "spin-valve" systems.[8] For example, we have deposited by MBE an Ag/Fe/Ag trilayer ($Hc \approx 100$ Oe) on top of a Fe/Pd bilayer ($Hc \approx 20$ Oe), resulting in a compound structure of $Fe_{(20\ Å)}/Pd_{(30\ Å)}/Ag_{(30\ Å)}/Fe_{(20\ Å)}/Ag_{(30\ Å)}$. RHEED patterns obtained during deposition indicate a fully epitaxial growth for the entire structure. The hysteresis loop of this structure [Fig. 1(b)] is essentially the sum of the two hysteresis loops obtained for separate $Fe_{(20\ Å)}/Pd_{(30\ Å)}$ and $Fe_{(20\ Å)}/Ag_{(30\ Å)}$ bilayers [Fig. 1(a)]. Thus, the two Fe layers in the structure are uncoupled, structurally as well as magnetically, by the $Pd_{(30\ Å)}/Ag_{(30\ Å)}$ interlayer. Antiparallel alignment of the two Fe layers is therefore achieved after reversal of the first Fe layer. Similar results are obtained as we replace Ag by Cu, and/or the second Fe layer by Co, which is a magnetically harder material. It is worth noting that although the growth proceeds epitaxially throughout the structure, RHEED patterns indicate a degradation of the layer flatness after the second bilayer system (i.e., Fe/Ag or Co/Cu) has been deposited. Therefore, it is not possible to repeat the layer sequence to form a thicker multilayer, since the subsequent

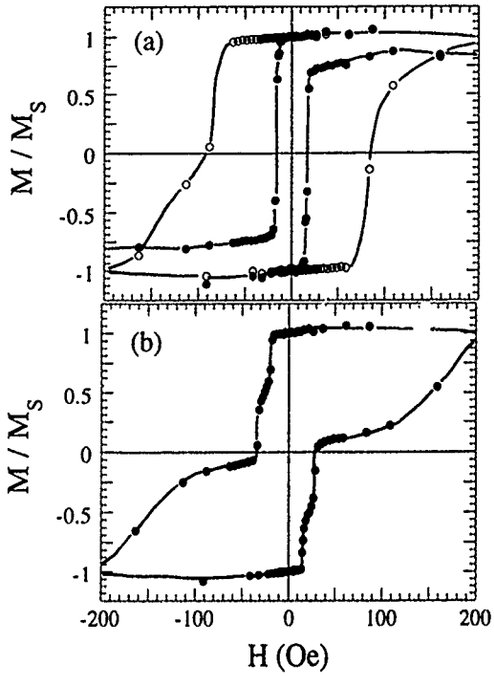

FIG. 1. Magnetic hysteresis loops at $T=15$ K of (a) a $Fe_{(20\ Å)}/Pd_{(30\ Å)}$ bilayer (filled circles) and a $Fe_{(20\ Å)}/Ag_{(30\ Å)}$ bilayer (open circles), and (b) a $Fe_{(20\ Å)}/Pd_{(30\ Å)}/Ag_{(30\ Å)}/Fe_{(20\ Å)}/Ag_{(30\ Å)}$ structure.

Fe/Pd bilayers would not retain the required soft magnetic properties.

The magnetoresistive (MR) response is shown in Fig. 2 for the Fe/Pd/Ag/Fe/Ag structure. The rotation of the magnetization in the first Fe layer, at low fields, induces an abrupt increase of the resistivity when antiparallel alignment is achieved, as is seen in many other multilayer-based GMR systems. The maximum MR response at 4.2 K is 0.8% for Fe/Ag bilayers, 0.5% for Co/Ag bilayers, and 1.5% for Co/Cu bilayers (also shown in Fig. 2), each epitaxially grown on a Fe/Pd bilayer. The magnitude of the MR effect originates in the strength of the spin-dependent impurity scattering that occurs near the magnetic interfaces.[1] Although

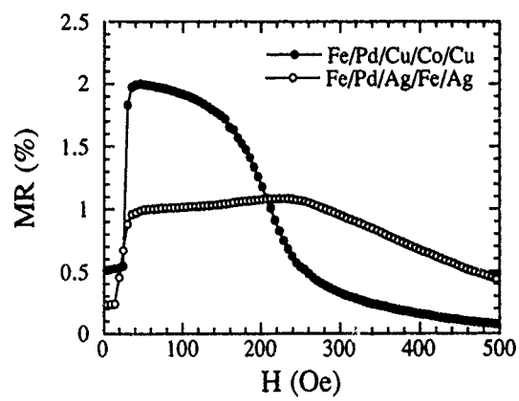

FIG. 2. Magnetoresistance as a function of applied magnetic field at $T=4.2$ K for $Fe_{(20\ Å)}/Pd_{(30\ Å)}/Ag_{(30\ Å)}/Fe_{(20\ Å)}/Ag_{(30\ Å)}$ and $Fe_{(20\ Å)}/Pd_{(30\ Å)}/Cu_{(30\ Å)}/Co_{(20\ Å)}/Cu_{(30\ Å)}$ epitaxial structures.

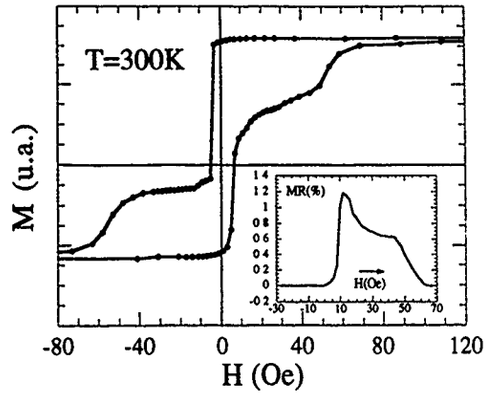

FIG. 3. Magnetic hysteresis loop at $T=300$ K of a $[Fe_{(20\ Å)}/Co_{(4\ Å)}/Pd_{(30\ Å)}]/[Cu_{(30\ Å)}/Co_{(20\ Å)}/Cu_{(30\ Å)}]$ structure. Inset: corresponding magnetoresistive response (shown for an increasing magnetic field).

small total magnetoresistance changes are observed, our interest lies in the small field scales (a few Oe) over which the MR increase is observed (up to 0.3% per Oe). At 300 K, the magnetoresistive effect is strongly decreased. For example, a value between 0.2% and 0.3% is observed for the Fe/Pd/Cu/Co/Cu structure above, depending on the precise value of individual layer thicknesses. Several factors contribute in limiting the maximum MR effect observed. First, the total thickness of the structure is on the order of the electronic mean-free path, therefore the efficiency of scattering within the structure is reduced. Second, unlike the case of exchange-coupled MM's, "spin-valve" structures rely on spin-dependent scattering from different systems. Hence, in our multilayers, strong spin-dependent scattering must occur *both* within the Fe/Pd layers and within the other magnetic layers in order to achieve the maximum MR effect. Unlike the Co/Cu interface, which is well known to exhibit strongly spin-dependent electron scattering ($\alpha=\rho\uparrow/\rho\downarrow\ll 1$), the Fe/Pd interface is not expected to be particularly favorable. Nonetheless, because the field scales over which this MR is observed is actually smaller at room temperature than at 4.2 K, sensitivities close to 0.15% per Oe have still been observed at 300 K.

We have checked several ways to increase the magnetoresistive response of these structures. In particular, we have tried to increase the spin-dependent scattering within the Fe/Pd layers. In a first approach, we have introduced ultrathin layers of impurities (Cr, Cu, or Co) in the Fe layer. Whereas 3 Å of Cr in the Fe layer drastically increases the coercive field, no such adverse effect on the magnetic properties was observed with the use of Cu or Co impurity layers, while the magnetoresistive effect is significantly increased. For example, the introduction of a 4 Å-thick layer of Co in a $[Fe_{(20\ Å)}/Pd_{(30\ Å)}]/[Cu_{(30\ Å)}/Co_{(20\ Å)}/Cu_{(30\ Å)}]$ structure leads to $\Delta R/R$ between 0.7% and 0.8% (a factor of 2 increase). Surprisingly, the effect does not depend on the precise position of the Co layer, i.e., whether it is placed at the Fe/Pd interface (shown in Fig. 3) or 5 Å below the interface. The addition of a second Co layer, resulting in a $[Fe_{(8\ Å)}/Co_{(4\ Å)}/Fe_{(8\ Å)}/Co_{(4\ Å)}/Fe_{(8\ Å)}/Pd_{(30\ Å)}]/$

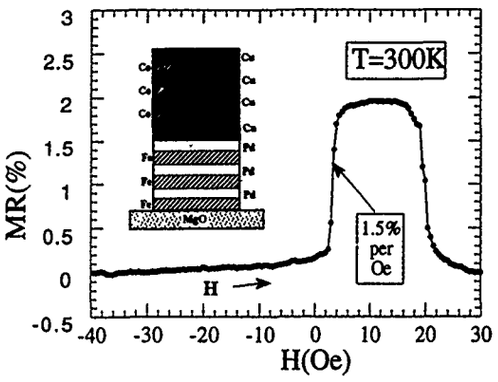

FIG. 4. Magnetoresistive response at $T=300$ K of a $[(Fe/Pd)_3/Pd]/[Cu/(CuCo)_3/Cu]$ structure. Inset: schematic drawing of the multilayer structure.

$[Cu_{(30\ Å)}/Co_{(20\ Å)}/Cu_{(30\ Å)}]$ structure, does not increase the magnetoresistance.

In a second approach, we have simply increased the number of Fe/Pd interfaces by replacing the Fe/Pd layer with a Fe/Pd multilayer. A series of samples was grown with different numbers of Fe/Pd bilayers. It is not trivial to determine precisely the role of the additional Fe/Pd interfaces in these samples, because the quality of the growth in the entire structure may be affected by the respective thicknesses of the first few layers. Moreover, in order to compare the magnitudes of the magnetoresistive responses, we must be sure that the other parameters, such as the structure of the nonmagnetic Pd/Cu layer or the quality of the Cu/Co interface, are identical in each case. Nevertheless, the observed results are quite spectacular, regardless of the small structural differences that may exist. Here we present out results obtained for a series of samples of the form $[Fe/(Fe/Pd)_n/Pd]/[Cu/(Cu/Co)_3/Cu]$, with $n=1,2,3$, or more. One should note that in this structure the soft magnetic layer is formed by a Fe/Pd multilayer, and the hard layer by a Co/Cu multilayer. It has been chosen because it presents a good contrast between the two coercive fields. For $n=1$, as discussed above, we always observed a value of $\Delta R/R$ around 0.4%. This value increases notably for $n=2$ (i.e., three Fe/Pd interfaces) with $\Delta R/R=0.8\%$, and up to $\Delta R/R=1.5\%$ for $n=3$. For a higher number of interfaces the effect appears to saturate. In Fig. 4 we show the best magnetoresistance curve obtained at $T=300$ K for a $[Fe/(Fe/Pd)_3/Pd]/[Cu/(Cu/Co)_3/Cu]$ structure grown directly on (100)MgO. The 2% amplitude leads to a slope at low fields close to 1.5% per Oe.

To verify that the change of $\Delta R/R$ was, in fact, due to the increasing number of the Fe/Pd interfaces, and not simply to the increase in the total Fe thickness, we have also studied a structure with a wedge-shaped Fe layer. The structure is $[Fe/Pd_{(50\ Å)}/Fe_{(wedge\ 20-70\ Å)}/Pd][Cu/(Cu/Co)_3/Cu]$. The first Pd layer is made thick, to ensure that the first Fe/Pd interface will not participate in the spin-valve magnetoresistive effect. The result is that we do not observe any increase of $\Delta R/R$ with increasing total Fe thickness. On the contrary, the effect decreases slowly with a downward step at about 45 Å, which may be due to a structural change of the Fe layer at these large thicknesses. The lack of increase in $\Delta R/R$ shows clearly that the varying thickness of the Fe layer does not significantly modify the magnetoresistance, and that the effect described above can be attributed principally to the increasing number of Fe/Pd interfaces.

In conclusion, we have used the soft magnetic properties of epitaxial Fe/Pd bilayers grown on MgO to fabricate epitaxial "spin-valve" structures, which display sensitive magnetoresistive responses to low fields. Hysteresis loops and magnetoresistance curves of the "spin-valve" structures obtained by epitaxial growth of Fe/Ag, Co/Ag, or Co/Cu bilayers on top of a Fe/Pd bilayer, clearly indicate the successive rotation of the two separate magnetic components. Magnetoresistive sensitivities of up to 0.3% per Oe have been obtained at 4.2 K. By increasing the number of active Fe/Pd layers, we have notably increased the magnetoresistive effect of the structures, and obtained sensitivities of up to 1.5% per Oe at 300 K.

We have investigated giant magnetoresistance (GMR) in Ni_xCo_{100-x}/Cu multilayers for x in the range 20–100. The GMR at room temperature is greater than 12% for magnetic alloys with x near 80, where the magnetocrystalline anisotropy is small. The smallest saturation fields are found near $x=60$ in the region where the magnetostriction vanishes. This combination of large GMR and small saturation field results in large MR field sensitivities up to 0.16%/Oe at room temperature. In order to maximize these parameters, we have also studied the dependence of the MR on the magnetic layer thickness and the number of bilayers.

I. INTRODUCTION

Giant magnetoresistance (GMR) in metallic multilayers composed of alternating magnetic and nonmagnetic layers has been extensively studied in a variety of layered magnetic transition metal and alloy systems. Among them, Cu-based multilayers such as Co/Cu,[1] Fe/Cu,[2] and Ni(Fe,Co)/Cu,[3,4] which exhibit GMR at room temperature and an oscillatory exchange coupling, are important, both for a fundamental understanding of the effect as well as for its technological application. It is now generally agreed that GMR is associated with the reorientation of the magnetic moments in adjacent magnetic layers, and has been interpreted on the basis of spin-dependent electron scattering.[5] A large number of studies have sought ways to increase the magnitude of the GMR. As a potential candidate for magnetic sensors however, a practical requirement along with large MR is high magnetic-field sensitivity, namely an appreciable resistance change upon the application of a small magnetic field.

$Ni_{80}Co_{20}$/Cu multilayers have shown GMR and a well-defined oscillation in the MR as a function of the Cu spacer thickness at room temperature. Small saturation fields have also been observed for Cu thicknesses t_{Cu} near 20 Å, corresponding to the second peak of the oscillation in MR.[6] In this paper, we report the composition dependence of MR and the magnetic properties of Ni_xCo_{100-x}/Cu multilayers for x in the range 20–100 and for t_{Cu} around 20 Å. In addition, we have systematically varied the multilayer configuration, specifically the magnetic layer thickness and the number of bilayers, in order to maximize the magnetic field sensitivity. Throughout the paper, we emphasize the importance of the magnetocrystalline anisotropy and magnetostriction in this magnetically soft multilayer system.

II. EXPERIMENTAL DETAILS

Multilayers with structure NiCo50 Å/[Ni_xCo_{100-x}/Cu]×30 with $t_{Cu}=20$ Å and a series of $Ni_{80}Co_{20}$/Cu samples with the number of bilayers (from 8 up to 100) were prepared by DC magnetron sputtering from separate targets of the appropriate Ni_xCo_{100-x} alloy and Cu onto oxidized Si wafers at room temperature. 50 Å $Ni_{80}Co_{20}$ buffer layer was deposited between Si and multilayers for all the samples studied here. The base pressure in the deposition chamber before sputtering was less than 2×10^{-7} Torr. With a sputtering pressure of 8 mTorr of argon, the deposition rates (determined from the measured thicknesses of single films by low angle x-ray reflectivity measurements) were 1.5 Å/s for Ni_xCo_{100-x} and 1.6 Å/s for Cu. The structural characterization of the samples was performed by low and high angle x-ray diffraction using Cu-K_α radiation.[7] The low angle x-ray reflectivity spectra reveal sharp superlattice peaks for all the samples studied here, indicating a well-defined compositional modulation along the growth direction. High angle x-ray diffraction data show that the films have coherent interfaces and textured polycrystalline structures with the FCC (111) direction normal to the film plane. The magnetoresistance measurements were carried out with four-terminal geometry and a high-resolution AC bridge at temperatures from 4.2 to 300 K and in magnetic fields of up to 1.0 T. Transverse MR is presented in this paper for which the magnetic field was either in the plane of the film or perpendicular to it.[8] The room temperature magnetization of selected samples were also measured using a SQUID magnetometer.

III. RESULTS AND DISCUSSIONS

The saturation MR (measured at 77 and 300 K) of $Ni_{80}Co_{20}$/Cu multilayers as a function of t_{Cu} for $t_{NiCo}=15$ Å is given in Fig. 1. Three well-defined peaks are found, with an oscillation period and phase quite similar to that found in other Cu-based multilayer systems. The fact that the period depends primarily on the Cu layer is consistent with an interpretation that the interlayer exchange coupling depends primarily on the electronic structure of the spacer material.[9] Of particular interest for device applications is the broad second peak with a maximum MR comparable to that of the first

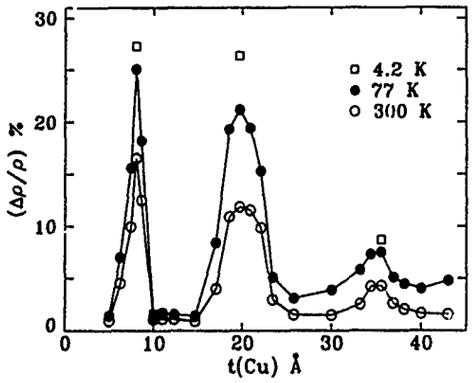

FIG. 1. Variation of the saturation MR with Cu spacer thickness t_{Cu} for a series of multilayer samples with structure Si/$Ni_{80}Co_{20}$50 Å[Cu t_{Cu}Å/$Ni_{80}Co_{20}$15 Å]×30

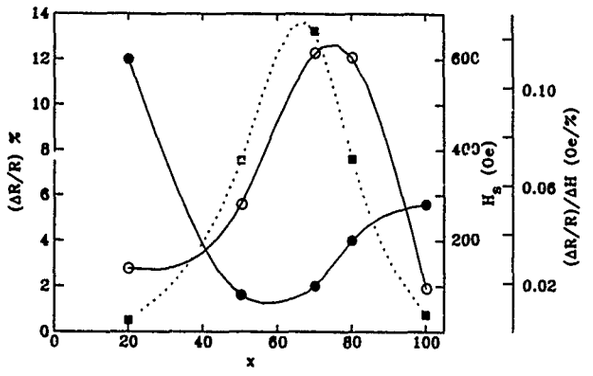

FIG. 3. Composition dependence of the MR (●), saturation field H_S(○), and MR field sensitivity (■) in Si/$Ni_{80}Co_{20}$50 Å[Cu20 Å/Ni_xCo_{100-x}15 Å]×30 multilayers for $20 \leq x \leq 100$.

peak, and small saturation fields, which range between 100–150 Oe, depending on the degree of the antiferromagnetic coupling between the neighboring NiCo layers. As a consequence, large MR field sensitivities, up to 0.12%/Oe, at room temperature are obtained.

Figure 2 shows several room temperature MR curves of Ni_xCo_{100-x}/Cu multilayers with $x=70$ and 80 obtained near $t_{Cu}=20$ Å. These data show a peak GMR between 8% and 12%, significantly larger than the anisotropy MR (AMR) at similar compositions. However, the saturation field H_S, determined from these curves as well as from magnetization versus field measurements varies considerably. For example, H_S is between 120 and 200 Oe for $x=80$, but is reduced to 60–110 Oe for $x=70$. Large H_S at $t_{Cu}=20$ Å is the result of nearly ideal antiferromagnetic coupling, as can be inferred from magnetization curves and neutron scattering data.[10]

In the Ni–Co alloy system, the magnetocrystalline anisotropy K vanishes at 80% Ni, while the magnetostriction coefficient λ_S vanishes at 60% Ni.[11] It is expected that the GMR and magnetostriction will depend, in part, on the competition between these two effects. The composition dependence of the MR, H_S, and the magnetic field sensitivity for [Ni_xCo_{100-x}15 Å/Cu20 Å]×30 multilayers with $20 \leq x \leq 100$ are shown in Fig. 3. A broad maximum MR of 12% is found in the range $x=70$–80; a decrease of the Ni concentration leads to a decrease in the MR, which all but vanishes at $x=20$. In fact, the absence of GMR in $Ni_{20}Co_{80}$/Cu multilayers over a wide range of Cu thickness (6–24 Å), together with magnetic measurements, suggests no antiferromagnetic coupling across the Cu spacer at this composition. The saturation field shows a broad minimum from $x=50$–70, where the magnetostriction is also small. As clearly shown in Fig. 3, the maximum sensitivity appears at a composition between the maximum in the MR and the minimum in the saturation field. Therefore, selecting a magnetic component with intrinsically small magnetoelastic parameters at a weakly or partially coupled Cu thickness region will result in a substantial GMR with low H_S, and hence a large field sensitivity.

The distinctive features of these NiCo/Cu multilayers are the large amplitude and width of the second peak of the oscillation with Cu thickness, combined with the low value of saturation field, as illustrated in Figs. 1 and 3. To deter-

mine the origin of the GMR in these soft multilayers, we have performed magnetization measurements and small angle neutron scattering on several samples. Figure 4 shows the magnetization versus field for a $Ni_{80}Co_{20}$/Cu multilayer at t_{Cu}=20 Å; the contribution of the 50 Å $Ni_{80}Co_{20}$ buffer layer was subtracted from the measured data. There is only small hysteresis and remanence associated with the magnetization curve, as also found in the MR curves. For comparison, we also show a typical magnetization curve for a ferromagnetically coupled sample (t_{Cu}=10 Å). Direct confirmation of the AF coupling for NiCo/Cu multilayers was obtained in neutron scattering experiments in an external magnetic field.[10] GMR and small saturation fields measured in Ni_xCo_{100-x}/Cu multilayers for x=70–80, particularly in the region near t_{Cu}=20 Å, is thus demonstrated in a sample, with weak AF coupling between magnetic layers. The estimated strength of AF coupling in this region is on the order of 0.003 erg/cm^2. This value is much smaller than that found in other Cu-based multilayer systems, confirming that the interlayer coupling is indeed weak.

We have also studied the dependence of MR, H_S, and the MR field sensitivity on the multilayer structure, specifically the magnetic layer thickness and the number of bilayers, for a series of $Ni_{80}Co_{20}$/Cu samples. As shown in Table I, both MR and H_S progressively decrease with increasing t_{NiCo}, while the field sensitivity shows a maximum at t_{NiCo}=15 Å. It is of interest to note that the magnetotransport properties are strongly correlated to the number of bilayers, n. The resistance change ΔR in a saturated magnetic field is maximum for n less than 10, and monotonically decreases with increasing n. The sheet resistance, however, decreases more rapidly as n increases and approaches a saturation value above n=100. The gradual increase of $\Delta R/R_S$ up to n=60 comes mainly from the rapid decrease of the sheet resistance. Structural studies by low and high angle x-ray diffraction have demonstrated that such behavior is strongly related to the multilayer structure. As the number of bilayers increases, the cumulative structural imperfections such as interface roughness and thickness fluctuations increase.[12] Strain built up at the interface become significant, and are reflected in the progressive increase of the saturation field as the bilayer number increases.

IV. CONCLUSIONS

Ni_xCo_{100-x}/Cu multilayers offer a good combination of large GMR and low saturation field for a Cu thickness close to 20 Å and x in the range 60–80. The maximum sensitivity occurs for x=70, roughly midway between the values for which the GMR is greatest (x=80) and H_S is least (x=60). It is shown that the GMR in multilayers with t_{Cu}~20 Å is related to the antiferromagnetic coupling, while the absence of GMR for alloys with x<50 is most likely due to the effects of magnetocrystalline anisotropy. The magnetic and magnetotransport properties are strongly correlated with structural parameters, such as the thickness of the magnetic layer and the number of bilayer periods.

Giant magnetoresistance (GMR) has been observed in $Ni_{66}Fe_{16}Co_{18}$/Cu multilayered uniaxial magnetic thin films prepared by dc magnetron sputtering. Both easy and hard axis loops saturate at very low applied fields. The MR ratio reaches ~80% of its saturation value in less than 30 Oe. A maximum MR ratio of ~10% has been observed in the as-deposited state in a structure containing only ten bilayers. Typical hysteresis values for magnetoresistance loops are ~4 Oe in the as-deposited state. A gradual decrease of this hysteresis has been observed with annealing. An increase in the saturation field is also observed with annealing. Short-term annealing increases the magnitude of the magnetoresistance ratio; prolonged annealing causes a decrease. A field sensitivity of about 0.3% per Oe has been observed and dc magnetoresistance minor loops exhibit no measurable decrease in sensitivity.

I. INTRODUCTION

Many attempts have been made to produce multilayer structures with large magnetoresistance ratios, low magnetoresistance hysteresis, and low magnetostriction.[1] Recently, we have successfully produced NiFeCo/Cu multilayer GMR samples with low hysteresis and low saturation fields in a high rate dc magnetron sputtering deposition system. Interestingly, this system exhibits a nonhysteretic dc minor loop. We confirmed that the hysteresis in the MR loops can be substantially reduced by annealing. There are, however, some drawbacks to this post-deposition annealing process. The MR saturation field increases with annealing, and long-term annealing degrades the magnitude of the magnetoresistance. This effect has also been observed by another group.[2] The hysteretic behavior, saturation field, and magnetostriction in a ternary alloy system of Ni, Fe, and Co in multilayered structure with Cu interlayers largely depends on the ferromagnetic alloy composition. It also depends on the internal stress. Relieving internal stress by annealing may play a role in hysteresis reduction. Saturation magnetostriction numbers were measured for both single layer NiFeCo and NiFeCo, multilayered with Cu interlayers. A typical magnetostriction number is $\lambda_s = -1.8\times10^{-6}$. A gradual change in the MR magnitude and MR peak linewidth was observed with increasing Co in these multilayers.

II. SAMPLE PREPARATION AND EXPERIMENTAL TECHNIQUES

NiFeCo/Cu multilayered uniaxial magnetic thin films were prepared by dc magnetron sputtering (Vac-Tec Model 250 Sputtering System) at ambient temperature. Sputtering was done at 100 W power and at an argon pressure of 2 mTorr. A bias field was applied during deposition to induce uniaxial anisotropy by using a permanent magnet behind the substrate holder. The field strength of the magnet is ~80 Oe. Multilayered and reference films were grown on Corning 7059 glass and on SiO_2 coated [111] Si substrates. Samples grown on both glass and SiO_2 coated substrates exhibit similar properties. The composition of the films was determined by using a JEOL 8600 Electron Probe Microanalyser. Low and high angle XRD scans were performed on a Rigaku D/Max-2BX x-ray diffractometer with a thin film attachment. Magnetic annealing was carried out in flowing argon gas. An aligning field of ~100 Oe was applied in the easy direction during annealing. Magnetoresistance measurements were done on an IBM/Dascon 1 high resolution data acquisition system with a four-point linear probe. Magnetization measurements were performed on a Digital Measurement Systems VSM Model 880. All measurements were made at room temperature.

III. SINGLE COMPOSITION $Ni_{66}Fe_{16}Co_{18}$/Cu MULTILAYER FILMS

Multilayers of $Ni_{66}Fe_{16}Co_{18}$/Cu with ten repeats exhibit large low saturation GMR. The $Ni_{66}Fe_{16}Co_{18}$ layers were ~16 Å and Cu interlayers were ~22 Å thick. The magnetoresistance ratio measured at room temperature is customarily given by $d\rho/\rho = [\rho(H) - \rho(H_{sat})]/\rho(H_{sat})$. The saturation field resistance used for this calculation was measured at 1000 Oe applied field. Easy and hard axis magnetoresistance loops saturate at very low applied fields, as shown in Fig. 1(a). The MR ratio reaches ~80% of its saturation value in less than 30 Oe. A maximum MR ratio of ~10% was observed in the as-deposited state in a structure containing ten bilayers. We did not observe any significant increase in the MR magnitude with an increase in number of bilayers (from 8–14). Typical hysteresis values for these magnetoresistance loops are significantly lower than that reported earlier[1] (~4 Oe in the as-deposited state). A gradual decrease of the hysteresis of the magnetoresistance loops is observed with annealing (both at 200 °C and 250 °C) for the hard axis mea-

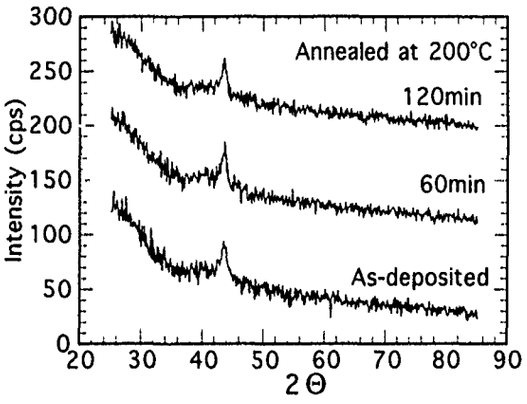

FIG. 3. High angle x-ray diffraction scans for as-deposited, and annealed NiFeCo/Cu multilayers.

surement. This decrease may be due to the stress relief in the film caused by annealing. Figure 1(b) shows MR loops annealed for 1 h at 200 °C and 250 °C. Direct current magnetoresistance minor loops exhibit no measurable decrease in sensitivity, as shown in Fig. 1(c). MR and M–H loops measured after annealing, however, indicate that there is an increase in the antiferromagnetic coupling strength. Interdiffusion of Cu and Ni with annealing can degrade the Cu interlayer, which results in a decrease in pure Cu interlayer thickness, but the aligning magnet helps preserve the uniaxial anisotropy. Figure 2 is a summary plot of MR%, $M-H$ loop coercivity, and MR hysteresis versus annealing time. The figure shows a decrease in H_c and MR hysteresis values with annealing for the hard axis magnetization loop. Short-term annealing produces a small increase in the magnitude of the magnetoresistance ratio; prolonged annealing causes a decrease. A field sensitivity of about 0.3% per Oe is

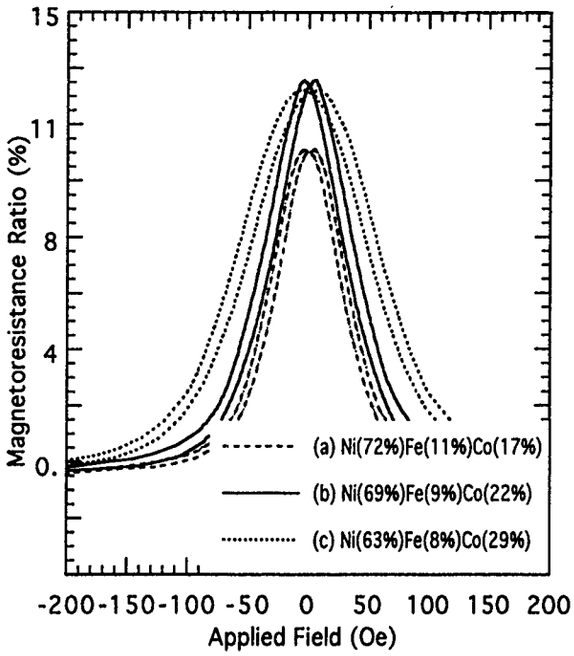

FIG. 5. As-deposited hard axis MR loops for (a) $Ni_{72}Fe_{11}Co_{17}$/Cu, (b) $Ni_{69}Fe_9Co_{22}$/Cu, and (c) $Ni_{63}Fe_8Co_{29}$/Cu multilayered films.

observed. This is calculated by dividing the MR magnitude by the linewidth of the MR peak at the half-maximum. Figure 2 shows a gradual decrease in MR hysteresis with annealing. Figure 3 shows high angle diffraction patterns in as-deposited and in annealed states. The single weak peak suggests that the films are very fine grained. Low angle diffraction indicates that the layers as-deposited are very poorly formed, and may, in fact, be discontinuous (see Fig. 4). Sharpening of the first-order LXRD peak with annealing is a qualitative indication of an improvement in the layered structure. NiFeCo films prepared by dc magnetron sputtering were found to be relatively more Ni-rich compared with the nominal target composition. This can be attributed to the differential sputtering yield of Ni, Fe, and Co. The small negative magnetostriction measured in these films is in agreement with the value of the measured film composition ($Ni_{76}Fe_{10}Co_{14}$).[5]

IV. NiFeCo/Cu MULTILAYER FILMS WITH DIFFERENT NiFeCo COMPOSITIONS

Very recently, we have made samples with several different Ni–Fe–Co alloy compositions layered with Cu spac-

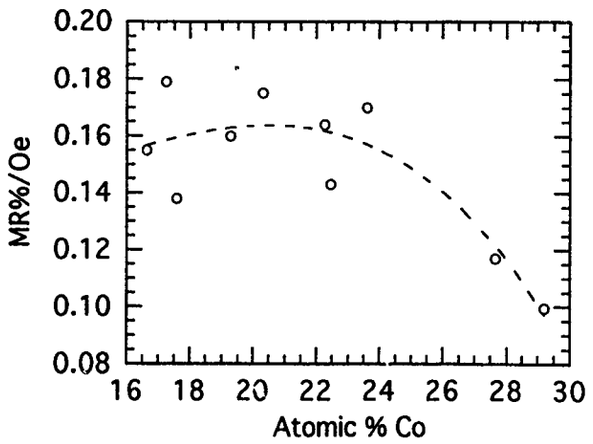

FIG. 6. Plot of MR sensitivity for changing Co concentration in NiFeCo/Cu multilayers.

ers. We observed a sizable (9%–14.5%) GMR effects from all of these samples. A set of representative MR loops are given in Fig. 5. MR loops (a), (b), and (c) correspond to the compositions $Ni_{72}Fe_{11}Co_{17}$, $Ni_{69}Fe_9Co_{22}$ and $Ni_{63}Fe_8Co_{29}$, respectively. These loops indicate a strong dependence of MR magnitude and sensitivity on ternary alloy composition. The compositional variation studied here essentially consists of partially replacing Ni with Co, while the Fe content remains nearly constant. Figure 6 displays the compositional dependence (in terms of Co content) of sensitivity.

V. SUMMARY

High field sensitivity GMR has been observed in NiFeCo alloy/Cu multilayers. The decrease in MR and $M-H$ loop hysteresis may be a result of increasing uniaxial anisotropy caused by magnetic annealing. Stress relief and reduction of imperfections by annealing may also help in reducing hysteresis.

Most theoretical models of the giant magnetoresistance (GMR) in metallic magnetic multilayers developed up to now are for the zero-temperature limit, thus neglecting the spin-flip scattering arising from spin fluctuations (magnons), as well as other scatterings from thermal excitations. To account for the temperature dependence of the GMR, we have introduced electron–magnon and electron–phonon scattering terms in a Camley–Barnas-like semi-classical model. We apply our calculation to the interpretation of the temperature dependence of the resistivity and GMR in Co/Cu.

I. INTRODUCTION

The giant magnetoresistance (GMR) of the magnetic multilayers, first discovered in Fe/Cr structures,[1] has now been observed in many systems. Its interpretation[2–4] is generally based on the simplest version of the two current model for the conduction in ferromagnetic metals.[5] One assumes that the electrical current is carried in *independent channels* by the spin↑ (majority spin direction) and spin↓ (minority) electrons, which is the *low temperature limit* of the two current model. However, at finite temperature, the *spin-mixing* by electron–magnon scattering, which is the transfer of momentum between the two channels, becomes an essential ingredient of the two current conduction in ferromagnets.[5] In multilayers, the spin-mixing effect is expected to play an important role for the temperature dependence of the GMR and must be taken into account in the interpretation at finite temperature. In the paper, we present a model of the temperature dependence of the GMR, taking into account not only the contribution from thermally excited scatterings *within each channel* (that is the electron–phonon scattering and momentum nonconserving part of the electron–magnon scattering called "incoherent electron–magnon scattering" in the notation of Ref. 5), but also the (interchannel) *spin-mixing* contribution from *momentum conserving* (or *coherent* in the notation of Ref. 5) electron–magnon scattering. To our knowledge, the spin-mixing contribution (spin-flip scattering with momentum transfer) has never been taken into account in theoretical models, and only the intrachannel magnon scattering has been introduced in calculations.[6,7]

II. MODEL

We consider an infinite multilayer composed of ferromagnetic metallic layers (Co, for example), separated by nonmagnetic metallic layers (Cu, for example). The current direction is in the plane of the layers.

Our starting point for the *low temperature* limit is the semi-classical model of Johnson and Camley,[8] who take into account interfaces scattering by introducing interfacial layers in which the mean-free path (MFP) is shorter than inside the layers. The spin asymmetry of the MFP in the interfacial layer can also be different from that within the layers. The parameters of the model of Johnson and Camley include the resistivity of the nonmagnetic metal or what is equivalent, the *MFP in the nonmagnetic layers* that we will call $\lambda_{Cu}(4.2\ K)$, in the same way the *two MFP in the magnetic layers* that we call $\lambda^{\uparrow}_{Co}(4.2\ K)$ and $\lambda^{\downarrow}_{Co}(4.2\ K)$ for the spin↑ and spin↓ electrons respectively, the MFP $\lambda^{\uparrow}_{I}(4.2\ K)$ and $\lambda^{\downarrow}_{I}(4.2\ K)$ in the interfacial layers, the thickness of the interfacial layer t_I, and the thicknesses of the effective magnetic and nonmagnetic layers $(t_{Co}\text{-}t_I)$ and $(t_{Cu}\text{-}t_I)$, respectively. In Table I, we have listed the parameters of our fit expressed in terms of resistivity. We also introduce the cut-off in the angular integration suggested by Vedyayev *et al.*[9]

At *finite temperature*, we introduce the following temperature-dependent resistivity terms.

A. Within the layers

(i) A temperature-dependent contribution is added to the resistivity of each channel, i.e., we write

$$\rho_\sigma(T)=\rho_\sigma(4.2\ K)+\delta\rho_\sigma(T). \tag{1}$$

TABLE I. Resistivity terms used in our calculation $\rho^{\uparrow(\downarrow)}_{Cu}$, $\rho^{\uparrow(\downarrow)}_{Co}$, and $\rho^{\uparrow(\downarrow)}_{I}$ are the intrachannel resistivities for the Cu, Co, and interfacial layers, respectively. Their temperature-dependent part $\delta\rho^{\uparrow(\downarrow)}(T)$ are derived from experimental data on bulk materials for Cu and Co in Refs. 10 and 11 and is a free parameter for the interfacial layer. The spin-mixing resistivity $\rho^{\uparrow\downarrow}_{Co}$ is derived from Ref. 11, while $\rho^{\uparrow\downarrow}_{I}$ is a free parameter. (c) and (d) refer to two types of calculation, as explained in the text. The contribution of the resistivity term to the mean-free path inverse is $\rho_0\lambda_0 = (hk_F/ne^2)=1940$ (Ref. 23). All the resistivities are given in $\mu\Omega$ cm.

Triangles: experimental data at 4.2 K for (Co 15 Å/Cu)×30 from Mosca *et al.* (Ref. 13). Dashed lines: calculation with the values of ρ_{Cu}, $\rho^{\downarrow}_{Co}$, $\rho^{\downarrow}_{Co}$, $\rho^{\uparrow}_{I}$, and $\rho^{\downarrow}_{I}$ indicated in the text and Table I.

The intrachannel term $\delta\rho_\sigma(T)$ includes contributions from electron–phonon scattering and also the incoherent part of the electron–magnon (e–m) scattering transferred to the lattice.[5] For Cu, we will use the values of $\delta\rho_{\uparrow}(\mathrm{I}) = \delta\rho_{\downarrow}(T)$ derived from the resistivity data of Ref. 10 for bulk Cu. For Co, we will use values of $\delta\rho^{\downarrow}_{Co}$ and $\delta\rho^{\downarrow}_{Co}$ derived from Ref. 10 and from resistivity measurements on Co-based dilute alloys.[11] All these resistivities are listed in Table I for several temperatures between 4.2 and 300 K.

(ii) A temperature-dependent spin-mixing term $\rho\uparrow\downarrow(T)$ is introduced to couple the Boltzmann equations of the two channels [see Eq. (3) below]. It expresses the fact that the spin-flip scattering by magnons, a part of the electron momentum is coherently transferred to the channel with opposite spin and contributes to the interchannel term $\rho\uparrow\downarrow$.[5] Data for $\rho^{Co}_{\uparrow\downarrow}(T)$ are taken from Ref. 11 and extrapolated up to 300 K by assuming a variation as T^2.

B. Inside the interfacial layers

We also introduce temperature-dependent resistivity terms, which, essentially, should express the scattering by enhanced spin fluctuations at the interfaces. We take into account either intrachannel resistivity terms $\delta\rho^{I}_{\uparrow}(T)$ and $\delta\rho^{I}_{\downarrow}(T)$, or, alternatively, an interchannel spin-mixing term $\rho^{I}_{\uparrow\downarrow}(T)$. The incoherent scattering should be predominant for a disordered interface. When the interchannel spin-mixing term is taken into account, the Boltzmann equation of the channel σ in a given layer is written as

$$\frac{m}{\hbar k_F}\frac{dg^{\sigma}(z,\mathbf{v})}{dz}+\frac{g^{\sigma}(z,\mathbf{v})}{\lambda^{\sigma}v_z}+\frac{g^{\sigma}(z,\mathbf{v})-g^{-\sigma}(z,\mathbf{v})}{\lambda^{\uparrow\downarrow}v_z}=\frac{eE}{\hbar k_F v_z}\frac{\partial f_0(v)}{\delta v_x}, \tag{2}$$

where g^{σ} is the deviation of the electron distribution function from the Fermi–Dirac distribution $f_0(v)$ for the spin direction σ, z and x are the directions, respectively, perpendicular to the layers and parallel to the current, $\mathbf{v}$ is the electron velocity, E is the electric field. The MFP inverses, $(\lambda^{\sigma})^{-1}$ and $(\lambda^{\uparrow\downarrow})^{-1}$, include the contributions from all the scattering mechanisms.

III. RESULT FOR THE Co/Cu SYSTEM

We have applied our calculation to the fit of experimental results by Mosca *et al.*[13] NMR[14] experiments on the same samples have established that the roughness of the interfaces can be modelized by a very dense distribution of monoatomic steps, so that we fix the thickness of the interfacial layer at 2 Å.

At low temperature, we begin by adjusting the MFP $\lambda^{\sigma}_{Cu}(4.2\ \mathrm{K})$, $\lambda^{\uparrow}_{Co}(4.2\ \mathrm{K})$, $\lambda^{\downarrow}_{Co}(4.2\ \mathrm{K})$, $\lambda^{\uparrow}_{I}(4.2\ \mathrm{K})$, $\lambda^{\downarrow}_{I}(4.2\ \mathrm{K})$ to fit the absolute values of the resistivity and the MR ratio for several thicknesses. In Fig. 1 we show the fit of the variation of the resistivity and MR ratio with the thickness of Cu obtained for the values of $\rho^{\uparrow(\downarrow)}_{Cu}(4.2\ \mathrm{K})$, $\rho^{\uparrow(\downarrow)}_{Co}(4.2\ \mathrm{K})$, and $\rho^{\uparrow(\downarrow)}_{I}(4.2\ \mathrm{K})$ listed in Table I. We estimate the error bar on the MFP less than 15%.

To interpret the temperature dependence, we have focused on two samples with respectively thin (15 Å) and thick (60 Å) Co layers in order to determine the relative importance of the bulk and interface temperature-dependent scatterings. We have introduced the different temperature-dependent contributions successively.

The intra-channel terms $\delta\rho_{Cu}(T)$ (derived from Ref. 10), $\delta\rho^{\downarrow}_{Co}(T)$ and $\delta\rho^{\downarrow}_{Co}(T)$ (derived from Refs. 10 and 11) are introduced first. They are not free parameters. As shown by curves (a) in Fig. 2, the contribution from these terms accounts only for a small part of the variation of the resistivity and MR ratio with T.

Then, in addition, we introduce the spin-mixing term $\rho^{Co}_{\uparrow\downarrow}(T)$ derived from Ref. 11. As shown by the curves (b) in Fig. 2, this is still not sufficient to account for the variation with temperature, especially for the resistivity [we have tried fits with enhanced values of $\rho^{Co}_{\uparrow\downarrow}(T)$, without succeeding in accounting for the T dependence of the resistivity and MR ratio at the same time].

We are thus led to include T-dependent scattering by the interfaces, and we have begin by adding up a spin-mixed term $\rho^{I}_{\uparrow\downarrow}(T)$ (the values are listed in Table I). We obtain the curves (c) in Fig. 2, which mean that we can obtain a good fit of the variation with for the resistivity, but not for the MR ratio (or vice versa).

We have then left out the term $\rho^{I}_{\uparrow\downarrow}(T)$ and introduced T-dependent intra-channel terms $\delta\rho^{I}_{\sigma}(T)$ in the interfacial layer (with the same values for the Co 15 Å/Cu 9 Å and Co 60 Å/Cu 9 Å samples). We could obtain a good agreement for the MR ratio of both samples and a good agreement for

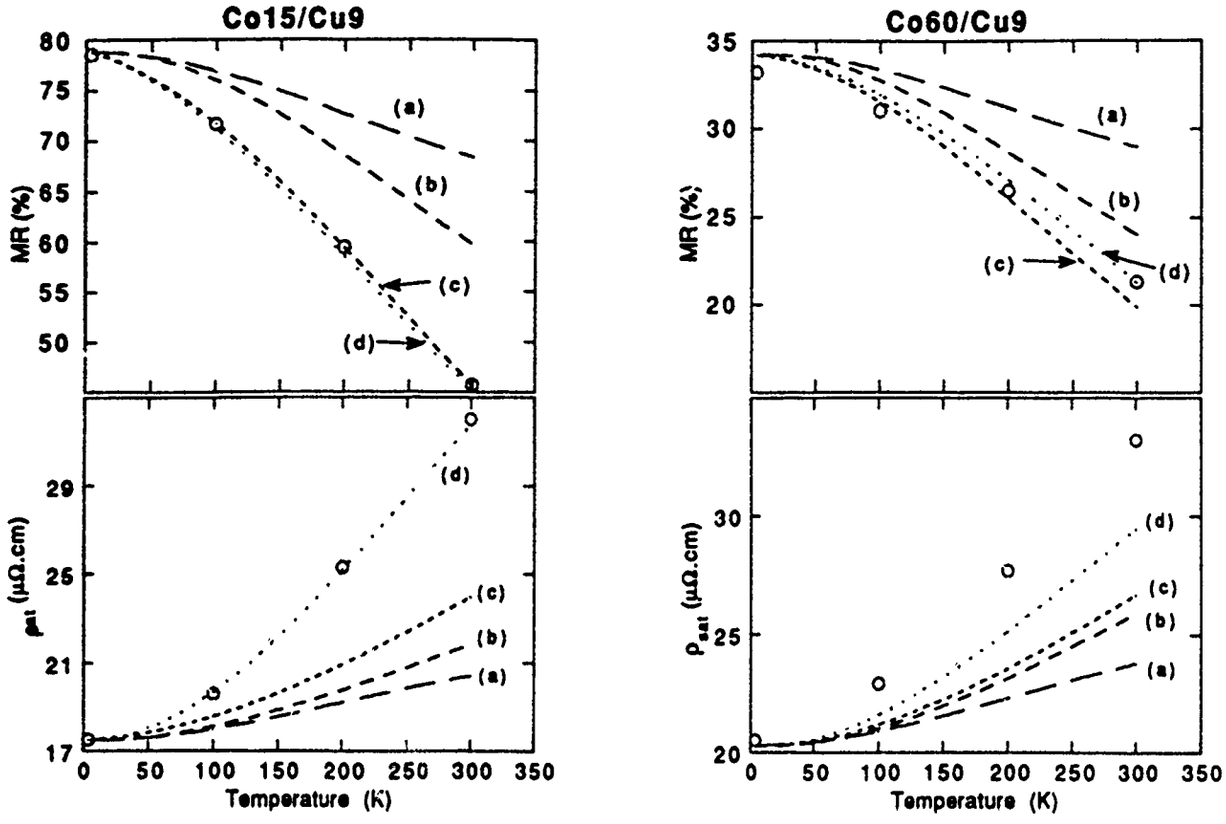

FIG. 2. Variation of the resistivity in the saturated state (bottom) and MR (top) as a function of temperature for (Co 15 Å/Cu 9 Å) (left) and (Co 60 Å/Cu 9 Å). Circles: experimental data from Mosca *et al.* (see Ref. 13). Curve (a): calculation taking into account the phonon and magnon intrachannel resistivities within Co and Cu layers. Curve (b): same calculation than (a) but also taking into account interchannel spin mixing terms within Co. Curves (c) and (d): calculation taking into account temperature-dependent scattering by the interfaces; (c) is calculated with an interchannel term, (d) is calculated with an intrachannel term.

the resistivity of Co 15 Å/Cu 9 Å; see curves (d) in Fig. 2. The variation with T we obtain for the resistivity of Co 60 Å/Cu 9 Å is slightly too small.

IV. DISCUSSION AND CONCLUSION

Our results can be summarized as follows. We have found that introducing within layers the temperature-dependent (intrachannel) resistivity and spin-mixing terms derived from data in bulk materials is not sufficient to account for the variation of the resistivity and MR ratio with T [the weak effectiveness of $\delta\rho_\sigma(T)$ to reduce the MR is partly due to its pronounced spin dependence in Co].[11] The best fits have been obtained by also taking into account temperature-dependent interfacial scattering. It is interesting to notice that the best fit is obtained by introducing intrachannel resistivity terms, and no interchannel spin mixing term in the interfacial zone. This can be ascribed to incoherent scattering by the spin fluctuations at the interfaces. The incoherence is consistent with spin fluctuation within quite disordered interfaces.

The final conclusion is that the temperature dependence of the resistivity and MR of Co/Cu multilayers can be accounted for, at least approximately, by taking into account not only phonon and magnon resistivity terms determined in bulk materials, but also an additional contribution from interfaces.

In recent work [J. Appl. Phys. **70**, 10 (1991)] the spin valve effect (SVE) was measured in Co_xFe_{1-x}/Ag/Fe($x<0.7$) thin layer sandwiches grown by molecular beam epitaxy. The field dependence of the SVE was correlated with VSM magnetization data taken on the samples. It was found that only at low fields was there a correlation between the SVE resistance and the magnetization data. These results indicated a more complex reversal mechanism that included substantial magnetizations in directions not measured in traditional VSM measurements. In order to more accurately determine the field-dependent magnetization of the samples during reversal, the longitudinal and transverse Kerr effects were measured on the layers. The particular geometry used to measure the Kerr effects was for the light scattering plane to be perpendicular to the applied magnetic field. The transverse Kerr effect data, which in this geometry are sensitive to the magnetization parallel to the applied magnetic field, replicated the VSM data. The longitudinal Kerr effect, which is sensitive to the net magnetization perpendicular to the applied field (in the plane of the film), indicated a substantial perpendicular magnetization component. Based upon previous work on epitaxial iron films,[2–4] it appears that the magnetization reversal process proceeds by transitions between easy axes. From these measurements, the anomalous resistances observed as a function of the applied magnetic field in J. Appl. Phys. **70**, 10 (1991), are explained by having one of the films soft, and two easy axes in the plane of the other film.

INTRODUCTION

Recently, considerable attention has been devoted to the study of multilayers and sandwiches composed of alternating magnetic and nonmagnetic layers. In part, this interest has been generated by the large magnetoresistance known as giant magnetoresistance or the spin valve effect (SVE) observed in a number of multilayers, such as Fe/Cr[5] and sandwiches such as CoFe/Ag/Fe/ZnSe.[1] In the previous work[1] on CoFe/Ag/Fe/ZnSe sandwiches, both vibrating sample magnetometry (VSM) and SVE measurements were performed. It was found in that work that only the low field VSM data were correlated with the SVE data. This indicated that a more complex magnetic reversal process was occurring at higher magnetic fields, in at least one of the magnetic layers in the sandwich.

In the present work we describe a series of measurements of both the longitudinal (LKE) and transverse (TKE) magneto-optical Kerr effects on the same six samples used in the investigation detailed in Ref. 1. The six samples investigated varied in the alloy composition of the CoFe film and thickness of individual layers. Previous research[2–4] has shown that measurements of the LKE and TKE provide information on the magnetization components, parallel and perpendicular to an applied magnetic field, of the magnetic material under investigation. Thus, measurements of the TKE, which is sensitive to the magnetization parallel to the applied magnetic field, should reproduce the VSM measurements and be well correlated with the SVE low field measurements. The LKE, being sensitive to the net magnetization perpendicular to the applied field, might be correlated with the high field SVE and/or provide extra magnetic information on the magnetization process.

EXPERIMENTAL DETAILS AND RESULTS

As stated in the Introduction, in the present work we focus on measurements of the Kerr effect, two of which are depicted in Fig. 1. The Kerr measurements are made with a fixed scattering plane, perpendicular to the applied magnetic field, and fixed polarizer angle. In these measurements, the analyzer is rotated to obtain the signals for longitudinal and transverse Kerr effects. The analyzer is held at an angle of $\Phi_a=5°-15°$ from the polarizer orientation to obtain the transverse magnetization (the LKE). The longitudinal magnetization component is obtained with the analyzer at an angle of $\Phi_a=80-85$ from the polarizer orientation[2,3] (the TKE).

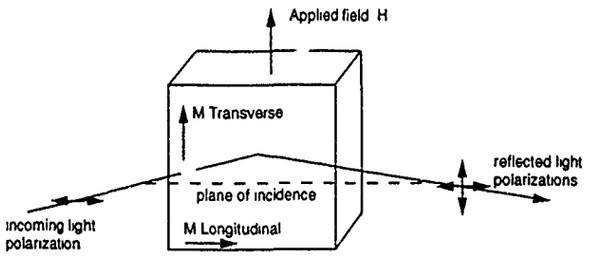

FIG. 1. Geometries of the transverse and longitudinal Kerr effects. The two Kerr effects measured are depicted. In the longitudinal Kerr effect, the magnetization measured is parallel to the plane of incidence, but perpendicular to the applied magnetic field. The longitudinal effect is characterized by a rotation of plane of polarization. The amount of rotation is proportional to the component of magnetization parallel to the plane of incidence. In the transverse Kerr effect, the magnetization is perpendicular to the plane of incidence, but parallel to the applied magnetic field. The transverse effect is depicted by a change in reflectivity of the light polarized parallel to the plane of incidence, not a rotation of polarization.[6] The transverse Kerr effect thus measures the same magnetization variations as a VSM.

 0021-8979/94/75(10)/7073/3/$6.00 © 1994 American Institute of Physics

In the longitudinal Kerr effect, the detected magnetization is parallel to the plane of incidence. The longitudinal effect is characterized by a rotation of the plane of polarization between the incident and reflected light, where the amount of rotation is proportional to the component of magnetization parallel to the plane of incidence. In the transverse Kerr effect, the sensed magnetization is perpendicular to the plane of incidence. The transverse effect results in a change in the reflectivity of the light polarized parallel to the plane of incidence, not a rotation of polarization.[2,3]

The six sandwiches used in this experiment were grown on gallium–arsenide (GaAs) substrates. The substrates were GaAs[001], which result in [001] Fe film grown on the ZnSe buffer layer. The zinc–selenide (ZnSe) epilayer was grown both to smooth or flatten the rough surface of the GaAs substrate and to inhibit the subsequently grown ferromagnetic film from chemically interacting with GaAs. The samples differed by the individual layer thicknesses and CoFe alloy composition. The sample structures were of the form Co_xFe_{1-x}/Ag/Fe/ZnSe/GaAs[001], where x is varied from 0 to 0.7. The alloy composition was varied to change the coercivity and other magnetic properties of one of the magnetic layers. The final Ag layer was a protective coating layer, while the buried Ag layer was a nonmagnetic, spacer layer. The thickness of the Ag spacer layer was large enough to decouple the CoFe and Fe layers.

The VSM measurements of the six Co_xFe_{1-x}/ Ag/Fe/ ZnSe samples were consistent with the film growth planes being (001) planes. This results in two magnetically intermediate ⟨110⟩ axes and two magnetically easy ⟨100⟩ axes of magnetization in the plane of the films. This is the same magnetic film configuration as was previously investigated in single layer epitaxial iron films.[2]

For brevity, only two of the samples from the series will be discussed. These samples both exhibited distinct SVE effects in applied fields, where there was no concomitant VSM signature. These are the Ag(1.9)/Fe(8.1 nm)/Ag(3.9 nm)/ $Co_{30}Fe_{70}$(8.4 nm) and Ag(2.8 nm)/Fe(12.4 nm)/Ag(5.5 nm)/ Fe(13.1 nm) sandwiches. The transport data from the previous study will be compared with the TKE and LKE data presented here.

Figure 2 shows both the VSM and SVE data for the sandwich containing the CoFe alloy film with the applied magnetic field close to a ⟨110⟩ axis (an intermediate axis). One should notice that the largest resistance signatures are well correlated with the VSM data. However, there is an extra SVE signature at fields on the order of 130 Oe, which does not have a VSM signature. The TKE data on this sample were consistent with the VSM data. The longitudinal Kerr effect measurement provided a signature that was correlated with the SVE at 130 Oe. These data are shown in Fig. 3.

Figure 4 again shows both the VSM and SVE data for the other sandwich, the one with only elemental Fe films. Again, the field is applied close to an intermediate (110) axis. Also, the VSM data and the SVE anomalies are well correlated at the lower magnetic fields, on the order of 75 Oe, but there is no VSM signal for the SVE peak at 250 Oe. Similar to the other film, Fig. 5 shows how the longitudinal Kerr

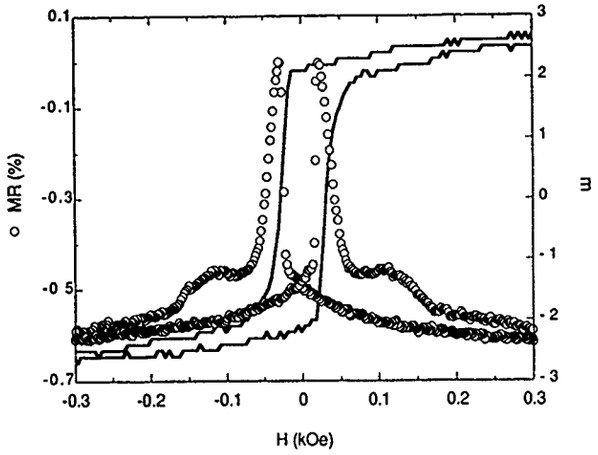

FIG. 2. Magnetization and magnetoresistance data for the Ag(1.9)/Fe(8.1 nm)/Ag(3.9 nm)/$Co_{30}Fe_{70}$(8.4 nm) sample with the applied field along the ⟨110⟩ axis. The transport data were taken with the applied magnetic field parallel to the current direction. The main reversal of the magnetization occurs at the same field where the SVE has a maximum resistance. As the magnetization continues to rotate to the ⟨110⟩, parallel to the applied field, there is another SVE maximum. For this second maximum there is not a signature in the magnetization data.

effect data indicate the presence of a substantial magnetization component perpendicular to the applied field up to 250 Oe.

DISCUSSION AND CONCLUSIONS

The spin valve or magnetoresistance effect has been attributed to the antiparallel alignment of magnetic moments in thin film sandwiches. Three possible causes of the variation of SVE resistance with an applied field are exchange bias pinning of one of the ferromagnetic films, antiferromagnetic coupling between the layers, and different coercivities in sandwich layers. That in simple sandwiches like those investigated here, there are multiple resistance maxima, indicate a rather complex magnetization process in at least one of the

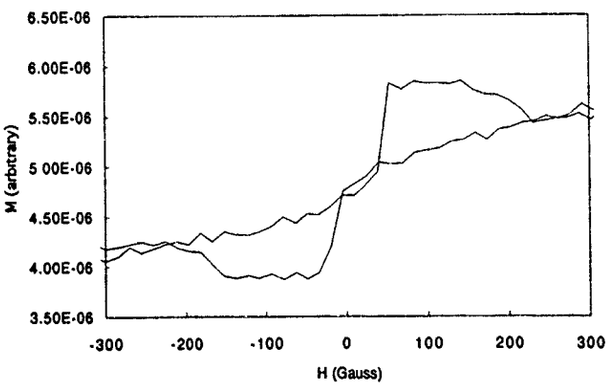

FIG. 3. Longitudinal Kerr effect data for the Ag(1.9)/Fe(8.1 nm)/Ag(3.9 nm)/$Co_{30}Fe_{70}$(8.4 nm) sample, with the applied field along the ⟨110⟩ axis for the component of the magnetization. The more positive curve in positive applied magnetic fields was taken with increasing magnetic field. Notice that the maximum in the net perpendicular magnetization component from 50 to 200 Oe is correlated with the second SVE maximum shown in Fig. 2.

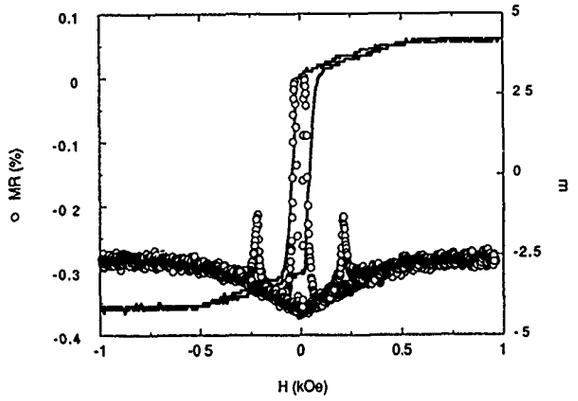

FIG. 4. Magnetization and magnetoresistance data for the Ag(2.8 nm)/Fe(12.4 nm)/Ag(5.5 nm)/Fe(13.1 nm) sample with the same field and current directions as in Fig. 1. As before, note the main reversal of the magnetization occurs at the same field where the SVE has a maximum resistance and that as the magnetization continues to rotate to the ⟨110⟩ direction there is another SVE maximum. For this second maximum there is not a signature in the magnetization data.

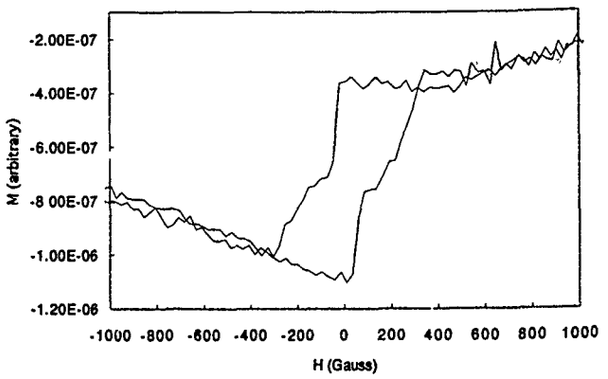

FIG. 5. Longitudinal Kerr effect data for the Ag(2.8 nm)/Fe(12.4 nm)/Ag(5.5 nm)/Fe(13.1 nm) sample, with the applied field along the ⟨110⟩ axis for the component of the magnetization. The more negative data at the zero applied field was taken with increasing magnetic fields. Notice that a transition in the perpendicular magnetization from 50 to 350 Oe includes the range where the second transition occurs in Fig. 4.

films. In order to understand this process, we will follow the magnetization of single layer Fe films as detailed in Ref. 2. The necessary information to be considered is that for these films and those in Ref. 2, there are two easy axes in the film planes, separated by intermediate axes.

With a saturating field close to, but not parallel to, an intermediate axis, the total magnetization is parallel to the applied field. As the field is reduced, the magnetization rotates toward an easy axis and a magnetization component perpendicular to the field develops. This is what occurs in both sandwiches, and can be seen in the magnetization data and the LKE data.[7] When the major portion of the magnetization switches at the coercive field, the SVE signature is due to the slightly different coercivities or anisotropy energies of the films. In this process, the magnetization has flipped from one easy axis to another, but the net perpendicular magnetization has not changed. In other words, the magnetization has flipped or rotated from one easy axis to another, which is a 90° rotation.

The higher magnetic field transition occurs with the magnetization jumping to the other easy axis (the original one, but now with the magnetization in the opposite direction), resulting in the perpendicular magnetization changing sign. It is important to note that this process can, at most, only slightly alter the magnetization parallel to the applied field, and is thus undetected in the VSM data. It is during this later process that the extra SVE anomaly occurs. The remainder of the magnetization process is the rotation of the magnetization from the easy axis to parallel with the applied field (almost along the ⟨110⟩ direction). At the completion of the later process, the moments are again parallel, resulting in a low resistance state.

The above magnetization process is one scenario that would generate the data presented here. No quantitative correlation between the Kerr measurements and the SVE was attempted. In part, this is because the samples had deteriorated in the time between the SVE measurement and the Kerr studies. This study does point out that the two magnetic films in a single sandwich are not identical. This is true, even in the iron/silver/iron sandwich. One should note that this last statement does not require one of the iron films to be a polycrystal. It merely requires that the two iron films have different coercive fields for the magnetization processes described in the above.

In summary, the longitudinal Kerr effect has been shown to be correlated with SVE anomalies not understood by usual magnetization studies, i.e., VSM measurements. Although not accomplished in detail, it provides another tool to enable a detailed analysis of the reversal processes present in complex sandwiches possible.

[7] It is interesting to note that it is also observed in the SVE data. This indicates that either the easy axes in the two films are not parallel or that the magnetizations break up into domains. It is not possible to distinguish between these two possibilities.

Effective internal fields and magnetization buildup for magnetotransport in magnetic multilayered structures

Peter M. Levy, Horacio E. Camblong,[a] and Shufeng Zhang
Department of Physics, New York University, New York, New York, 10003

Starting with the Kubo formula for electric conductivity we derive a set of equations that define the spin diffusion that is present when current is driven through inhomogeneous magnetic media. We show the spin accumulation, or nonequilibrium magnetization, attendant to charge transport through regions of inhomogeneous magnetization is governed by the same equations found in a thermodynamic approach to magnetoelectric transport.

There have been two approaches to understand the giant magnetoresistance (MR) of magnetic multilayered structures for currents perpendicular to the plane of the layers (CPP). The first has been a linear response theory based on either the Kubo formula[1,2] or the Boltzmann equation,[3] in which one calculates the current in response to an external electric field. The second is a thermodynamic approach,[4] in which one introduces a magnetization potential H^* in addition to the electric potential V, to describe charge and nonequilibrium magnetization transport.[5,6] For some systems both H^* and V are externally applied potentials, e.g., when one discusses the spin-polarized transport between the injector and detector in a spin-injection experiment,[5] one introduces both electric and magnetization currents. However the CPP-MR, one applies *only* a voltage, and only an electric current flows into and out of the multilayered structure. While there may be a nominal magnetic field applied to the structure, it is largely irrelevant as a thermodynamic variable; the magnetization current and potential H^* are *internal* to the system. They represent the rearrangement of spin (magnetization) when an electric current is driven through the structure.

With this background in mind, there has been some questions[7] as to whether the linear response approach,[1] which considers only the voltage V or electric field as the only variable in calculating the current neglects the effects of the nonequilibrium (current-driven) magnetization, or spin accumulation on the CPP-MR. Here we point out that the CPP-MR calculated by linear response theory *does* contain the effects of spin accumulation, even though one only considers the externally applied potential V. By using the Kubo formalism for charge transport in magnetic multilayered structures, we derive the equation that controls the spin accumulation. When one uses the approximation of a local self-energy, the spin-diffusion equation reduces to that assumed by the thermodynamic approach. We are able to clarify the conditions for the validity of the thermodynamic approach.

We begin with the linear response to an electric field, which for multilayered structures with *collinear* magnetization, i.e., ferro- and antiferromagnetically aligned layers, reduces to a one-dimensional problem[2]

$$j^s(z)=e\int \sigma^s(z,z')\frac{\partial}{\partial z'}V(z')dz', \tag{1}$$

where s is the spin index, and we have expressed the *external* electric field in terms of the classical potential, i.e., $E_{\rm ext}(z)=e(\partial/\partial z')V(z')$. The conductivity is given in the Kubo formalism by the diagrams shown in Fig. 1. It includes the simple bubble diagram Fig. 1(a), the ladder diagrams due to non-spin-flip scattering Fig. 1(b) and the spin-flip diagrams represented by the wiggly lines [Fig. 1(c)]. Other diagrams, in which wiggled lines cross the shaded ladders have been neglected. Therefore, we only focus on spin-flip and non-spin-flip scattering processes, which are *local*. This type of scattering includes spin-orbit and paramagnetic impurity scattering, but excludes the magnon scattering, which is not local.

Rather than dealing with these diagrams explicitly in the conductivity $\sigma^s(z,z')$, we introduce an effective field $E^s(z')$,

$$j^s(z)=\int \sigma_b^s(z,z')E^s(z')dz', \tag{2}$$

where σ_b^s is the bubble diagram contribution to the conductivity, Fig. 1(a), and

$$E^s(z')=e\frac{\partial}{\partial z'}V(z')+e\int \Gamma^s(z',z'')\frac{\partial}{\partial z''}V(z'')dz'', \tag{3}$$

where Γ^s is the sum of the ladder diagrams, Figs. 1(b) and 1(c), without external legs. Γ^s is also called the diffusion propagator. The key difference between the diffusion propa-

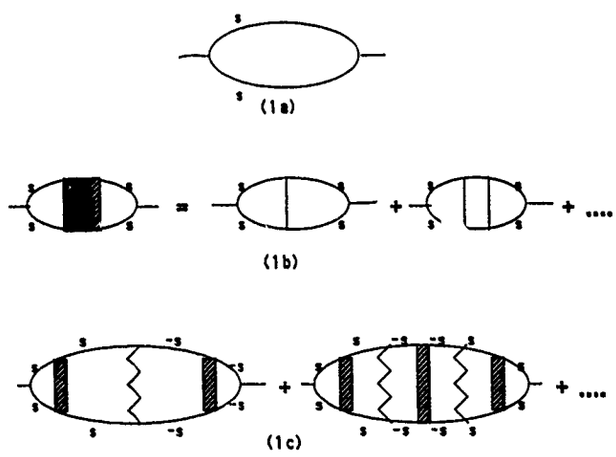

FIG. 1. Diagrams contributing to $\sigma^s(z,z')$. (a) is the bubble conductivity $\sigma_b^s(z,z')$ and (b) is the ladder contribution due to non-spin-flip processes and (c) is that due to spin-flip processes.

[a]Present address. Department of Physics, University of San Francisco, San Francisco, CA 94117.

 0021-8979/94/75(10)/7076/3/$6.00 © 1994 American Institute of Physics

gator and the bubble conductivity is that the former is long range while the latter has a length scale of the mean-free path. The asymptotic form of Γ in three dimensions is $1/|\mathbf{r}'-\mathbf{r}''|$.[8] The main contribution of the diffusion propagator to the effective field, Eq. (3), is from the contribution for large separations of $z'-z''$, and one can assume that Γ^s in Eq. (3) only depends on the $z'-z''$. By integrating the second term in Eq. (3) by parts, and by using $(\partial/\partial z'')\Gamma^s(z',z'') = -(\partial/\partial z')\Gamma^s(z',z'')$, we find that Eq. (3) can be written as

$$E^s(z') = e\frac{\partial}{\partial z'}\left(V(z') + \int \Gamma^s(z',z'')V(z'')dz''\right) \equiv e\frac{\partial}{\partial z'}\mu^s(z'), \tag{4}$$

where the last identity defines the spin-dependent chemical potential μ^s.

In the following, we assume the spin-diffusion length is much larger than the mean-free paths, $\lambda_{sdl} \gg \lambda_{mfp}$, i.e., that spin-flip processes are much rarer than non-spin-flip scattering. In this case $\sigma_b^s(z',z'')$ varies on the length λ_{mfp} (the Green's functions decay over distances given by the elastic mean-free paths), while the current $j^s(z)$ varies over distances λ_{sdl}. We now invert Eq. (2) and treat the current density as a constant within the mean-free path. We can remove the current density from the integration, and arrive at

$$j^s(z) = \frac{e}{\rho^s(z)}\frac{\partial}{\partial z}\mu^s(z), \tag{5}$$

where

$$\rho^s(z) = \int \rho_b^s(z,z')dz', \tag{6}$$

and $\rho_b^s(z,z')$ is the inverse of the conductivity $\sigma_b^s(z,z')$. In the local relaxation time approximation, $1/\rho^s(z) = Cl^s(z)$, where $C = (e^2/h)(2k_F^2/3\pi)$ and $l^s(z)$ is a local mean-free path. This local relation between current density and the chemical potential is Ohm's law for each spin channel. It is valid as long as the current density for each spin channel does not change significantly within a mean-free path.

To obtain information about spin-diffusion, one has to calculate the ladder diagrams. From Figs. 1(b) and 1(c), the diffusion propagator satisfies the following integral equation:

$$\Gamma^s(z',z'') = d^s(z',z'') + \int d^s(z',z_1)P_{sf}(z_1)\Gamma^{-s}(z_1,z'')dz_1, \tag{7}$$

where P_{sf} is the probability of spin-flip scattering and d^s is the diffusion propagator in the absence of the spin-flip scattering; see Fig. 1(b). In general, P_{sf} depends on energy. In our case we only consider nearly elastic spin-flip scattering, so that we set all the energy variables at the Fermi level. Equation (7) is the spin-diffusion equation in integral form. To write it in differential form, we use the fact that the diffusion propagator in the absence of spin-flip scattering satisfies[8,9]

$$\frac{1}{3}\frac{\partial^2}{\partial z'^2}d^s(z',z'') = -\left\{\frac{1}{l^s(z')}\right\}^2\delta(z'-z''). \tag{8}$$

By taking the Laplacian of both sides of Eq. (7) and by using the above identity, we find

$$\frac{\partial^2}{\partial z'^2}\Gamma^s(z',z'') = -3\left[\frac{1}{l^s(z')}\right]^2\{\delta(z'-z'') + P_{sf}(z)\Gamma^{-s}(z',z'')\}. \tag{9}$$

Upon taking the derivative of the definition of the spin-dependent chemical potential Eq. (4) and by using Eq. (9), we arrive at

$$3\{l^s(z)\}^2\frac{\partial^2}{\partial z^2}\mu^s(z) = -\frac{l^s(z)+l^{-s}(z)}{l_{sf}(z)}\{\mu^{-s}(z)-V(z)\}, \tag{10}$$

where we have used $(\partial^2/\partial z^2)V(z)=0$ for the classical potential, and we have defined the spin-flip mean-free path $l_{sf} \equiv (l^s+l^{-s})/P_{sf}$ to express the diffusion equation in terms of l_{sf}, as one usually does. Note that we have dropped the first term in Eq. (9) in calculating the chemical potential from the second term of Eq. (4) because it has already been included in the first term of Eq. (4).

Equation (10) is our main result; it controls the spin diffusion. To write it in a more familiar form for layered structures, we assume the local mean-free path is piecewise constant, i.e., $l^s(z)$ is a constant in a specific layer. In this case, Eq. (10), along with the equation given by interchanging s and $-s$ in Eq. (10), can be written as

$$\frac{\partial^2}{\partial z^2}[\mu^s(z)-\mu^{-s}(z)] = \frac{\mu^s(z)-\mu^{-s}(z)}{\lambda_{sdl}^2(z)}, \tag{11}$$

where we have defined the spin-diffusion constant $\lambda_{sdl}(z)$ as $1/\lambda_{sdl}^2 \equiv [3l^s l_{sf}]^{-1} + [3l^{-s}l_{sf}]^{-1}$ and

$$\frac{\partial}{\partial z}\left\{l^s(z)\frac{\partial}{\partial z}\mu^s(z) + l^{-s}(z)\frac{\partial}{\partial z}\mu^{-s}(z)\right\} = 0. \tag{12}$$

Equation (11) is exactly the one assumed by the thermodynamic approach,[5,6] while Eq. (12) represents the conservation of charge, i.e., the total current is constant. These two equations determine the spin-dependent chemical potentials; then the electric current and the magnetization current are obtained from Eq. (5). We point out that one should use Eq. (10) rather than Eqs. (11) and (12) when the local mean-free paths and local spin-diffusion constant are not piecewise constants. For example, one could grow multilayers with continuously varying compositional differences.

We have reproduced and generalized the equations that define spin-diffusion in magnetic multilayered structures, when they are subject to an electric field. To understand the range of validity of these equations, we consider the different thicknesses of the layers d_{in} relative to the mean-free path and spin-diffusion length. The current derivation is in the limit $\lambda_{mfp} \ll \lambda_{sdl}$, so that one can view it as a spin-diffusion process. The general solution of Eq. (11) contains an exponentially decaying part, with respect to the spin-diffusion length. For $d_{in} \ll \lambda_{sdl}$, which includes the cases of $d_{in} \ll l^s$ (homogeneous limit) and $d_{in} \approx l^s$, the solution to Eq. (11) is simple; all the quantities, e.g., chemical potentials, are peri-

odic functions with a period of d_{in}, so that the exponential decay within the length of d_{in} is negligible and one can neglect the right side of Eq. (11).

We should point out that if one neglects spin-diffusion processes, this does not imply that one is omitting the spin accumulation or magnetization buildup. In fact, the magnetization buildup is largest when one neglects spin-flip processes. One can easily check this conclusion by calculating the chemical potential difference $\mu^s(z)-\mu^{-s}(z)$ from one layer to the next; the variation is largest when the spin-diffusion length is infinite. Most experiments are actually in this limit. Therefore, our original model[1] predicated on neglecting spin-flip processes can be used to analyze data on multilayered structures currently being studied. The diffusion equation begins to play a role when the layer thicknesses are comparable to the spin-diffusion length. In this case, one is in the local limit because the mean-free path is much smaller than the layer thicknesses. It is precisely in this limit that the diffusion equation, Eq. (10), has been derived. However, when λ_{mfp} is comparable with λ_{sdl},[10] additional terms in Eqs. (5) and (10) will appear, and the derivation presented here fails. The derivation for the vertex corrections and effective fields where $\lambda_{mfp}\approx\lambda_{sdl}$ will be presented elsewhere.[11]

In summary, we have shown that a linear response theory of transport for CPP is able to reproduce the spin-diffusion equations derived in the thermodynamic approach, provided one is in the limit where the concept of spin diffusion makes sense, i.e., far fewer spin-flip scattering processes than non-spin-flip ones, so that $\lambda_{mfp}\ll\lambda_{sdl}$.[12] When λ_{mfp} is comparable to λ_{sdl}, the concept of spin diffusion is not valid *nor are the spin-diffusion equations*. From this derivation, we can unequivocally respond in the affirmative as to whether linear response theory[1,2] accounts for the spin accumulation, attendant to charge driven through regions of inhomogeneous magnetization, i.e., the case of CPP of magnetic multilayered structures. For currents in the plane of the layers (CIP) there is no spin accumulation, provided the size of the magnetic domains in the layers are larger than the spin-diffusion length. The reason is that, in the direction of magnetic inhomogeneities perpendicular to the layers, there is no net charge transport for CIP.

While not a difference in results, there is one in outlook between the linear response and thermodynamic approaches. In linear response theory single-site (local) spin-flip processes contribute on an equal footing with nonlocal spin-flip processes due to magnons; although they produce quite different results, and we have not discussed magnons in this paper. In the thermodynamic approach the single-site spin-flip processes contribute to changing the magnetization potential and nonequilibrium magnetization, while the magnons contribute as momentum conserving spin-flip processes, and are accounted for by the potentials that fix the currents. This distinction that appears in the thermodynamic approach is a result of discriminating between spin accumulation and electric currents. This may be useful in spin injection experiments, where one applies spin-polarized (charge and magnetization) currents to a system. However, for CPP in magnetic multilayered structures, magnetization currents develop only *inside* the structures; these convert the external electric field into the internal fields seen by the electrons. When the medium is magnetized or when the scattering of the electrons is spin dependent, these effective internal fields are spin dependent. This accounts for both the electric and magnetization currents that develop in CPP in magnetic multilayered structures.

We have performed a comparative study of Fe/Cr superlattices prepared by sputtering and molecular beam epitaxy. Detailed structural and magnetic measurements show that structural parameters are important in controlling the magnitude of the magnetoresistance. X-ray diffraction results show that films grown by molecular beam epitaxy (MBE) and sputtering are structurally different, and corresponding to these differences are large changes in the values of the magnetoresistance and its dependence on Cr thickness. The results indicate a strong dependence of the magnetoresistance on the structure of the superlattices.

Direct measurement of spin dependent mean free paths in metals (abstract)

Bruce A. Gurney, Virgil S. Speriosu, Harry Lefakis, Dennis R. Wilhoit, and Omar U. Need
IBM Research Division, Almaden Research Center, 650 Harry Road, San Jose, California 95120-6099

We describe results obtained using a new spin valve structure that is specifically designed to measure the spin up and spin down mean free paths in ferromagnetic metals. We report how these mean free paths can be measured more directly and with greater accuracy than previous methods, which were based mostly on indirect evidence from magnetoresistance in ternary alloys. The technique is based on the "backed" spin valve layered structure: substrate/seed/80 Å FeMn/50 Å NiFe/23 Å Cu/20 Å NiFe/t Å b/50 Å Ta where the back layer of material b with thickness t is probed by the rest of the structure, which forms a spin polarized conduction electron source. As t is varied the majority carrier mean free path λ_b^+ in the layer b is obtained directly from the form taken by the change in film conductance between parallel and antiparallel magnetization states, ΔG, whose solution of the Boltzmann transport equation shows is well approximated by the form $\Delta G=\Delta G_0+\Delta G_b\{1-\exp([t-t_x]/\beta\lambda_b^+)\}$, where ΔG_0 arises from the 20 Å NiFe layer, t_x is the high resistivity region of intermixing at the b layer interfaces, and $\beta\simeq 1$ from observations with b=Cu. The minority carrier mean free path in a ferromagnetic layer b, λ_b, is obtained by comparing ΔG and λ_b^+ with $\Delta G'$, and $\lambda_{b'}^+$, of a nonmagnetic b' layer of similar resistivity to b; it is a less direct measurement than that of λ^+ since it relies on the connection between conductivity and mean free path for the minority subband. We have obtained room temperature results for $Ni_{80}Fe_{20}$ ($\lambda^+=46\pm 3$ Å, $0<\lambda<6$ Å), Fe ($\lambda^+=15\pm 2$ Å, $\lambda=21\pm 5$ Å), and Co ($\lambda^+=55\pm 4$ Å, $0<\lambda<8$ Å). The connection of spin dependent conductivity and mean free paths in ferromagnetic metals is crucial in exploring the mechanism of giant magnetoresistance and, more broadly, is central in all theories of transport in magnetic metals; this new technique should prove a powerful tool in measuring these fundamental quantities.

Giant magetoresistance in epitaxial sputtered Fe/Cr(211) superlattices (abstract)

M. J. Conover, Eric E. Fullerton, J. E. Mattson, C. H. Sowers, and S. D. Bader
Materials Science Division, Argonne National Laboratory, Argonne, Illinois 60439

We report giant magnetoresistance (GMR) as high as 150% at 4.2 K in epitaxial Fe/Cr superlattices. Samples prepared by magnetron sputtering on MgO(100) produced the expected Fe/Cr(100) orientation; however, deposition on MgO(110) produced a novel (211) low-miller-index orientation. The crystallographic orientations and superlattice nature of the samples were confirmed by both low- and high-angle x-ray diffraction. The Fe/Cr(211) superlattices have an in-plane uniaxial anisotropy ($K_u = 9 \times 10^5$ ergs/cm^3) along the Fe[$0\bar{1}1$] which give the sample a rich magnetic behavior. The GMR with the current along the [$0\bar{1}1$] is $\approx$20% higher than that along the [$\bar{1}11$] direction of the (211) plane. The GMR for the (211) superlattices shows four oscillations with Cr thickness. Both orientations shows the expected long-period oscillation of 18 Å Cr and a GMR increase by a factor a 4 when cooled from room temperature to 4.2 K.

Compositional dependence of the structural and magnetic properties of PtMnSb films

R. Carey, H. Jenniches, D. M. Newman, and B. W. J. Thomas
Centre for Data Storage Materials, Coventry University, Coventry, CV1 5FB, United Kingdom

Nonstoichiometric, Pt deficient, PtMnSb films have been investigated for evidence of the increase in coercivity suggested by the work of Marinero [Appl. Surf. Sci. **43**, 117 (1989)]. Structural, magnetic, and magneto-optic properties of thin PtMnSb films of different compositions annealed in under 30 s using a rapid thermal processing (RTP) system [Carey *et al.*, IEEE Meeting on Current Topics in Applied Magnetism, Keele University, 4 November 1992 (unpublished), Paper 15; J. Magn. Soc. Jpn. **17**, 290 (1993)], have been determined. It is shown that the crystalline texture of the films can be controlled by adjustments in composition and RTP time and that Pt deficiency produces increases in coercivity. The production of coercivity does not correlate with the marked changes in texture but appears to be associated with the development of MnSb phases within the PtMnSb microstructure.

INTRODUCTION

The Heusler alloy PtMnSb is a half-metallic ferromagnet that, in its crystalline stoichiometric form, exhibits the largest polar Kerr rotation at room temperature of all known metallic systems. Following the first report of this large magneto-optic effect in the bulk material by van Engen *et al.* in 1983,[1] several authors have presented details of the preparation and properties of the alloy in thin film form.[2–4] The large polar Kerr rotations of these films at wavelengths relevant to optical storage are clearly of interest for improved magneto-optic readout. Unfortunately, thin films of PtMnSb do not possess the magnetic properties, e.g., perpendicular anisotropy and high coercivity, required of magneto-optic data storage materials. A number of attempts have been made to develop significant perpendicular anisotropy.[5–8] Limited success has been reported with the adoption of complex preparation techniques. Extensive post deposition annealing, necessary for the development of the crystalline structure for the material to exhibit spontaneous magnetization and a large polar Kerr effect, has been a common feature of the reports. Annealing usually occurs in a vacuum at temperatures ≈500 °C for at least one hour. Significant perpendicular magnetic anisotropy has only been achieved by annealing PtMnSb thin films in an Ar/O_2 atmosphere at 450 °C for one hour.[9]

In this paper nonstoichiometric, Pt deficient, PtMnSb films have been investigated for evidence of the coercivity increase suggested by Marinero.[1]

EXPERIMENT

The PtMnSb films used in this study were prepared by rf-sputtering from mosaic targets onto unheated glass substrates using a rf power of 30 W and an argon pressure of 10 mTorr. The films were all of similar thickness (≈200 nm) and the different compositions were produced by varying the number of Pt squares placed on top of a MnSb target. The range of compositions prepared in this way is shown in Table I.

All samples were subjected to between 15 and 30 s heat treatment in a rapid thermal processing (RTP) system.[10,11] Film structure was determined using a Philips PW 1700

TABLE I. The compositions of the samples investigated.

Sample No.	Pt%	Mn%	Sb%
1	33.7	34.5	31.8
2	26.6	39.7	33.7
3	23.7	40.0	36.3
4	21.6	42.0	36.4
5	20.4	42.1	37.5

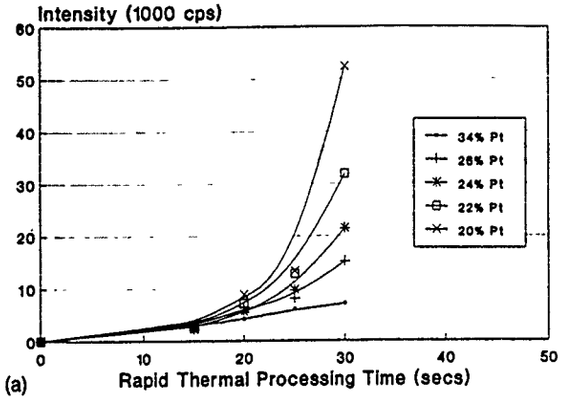

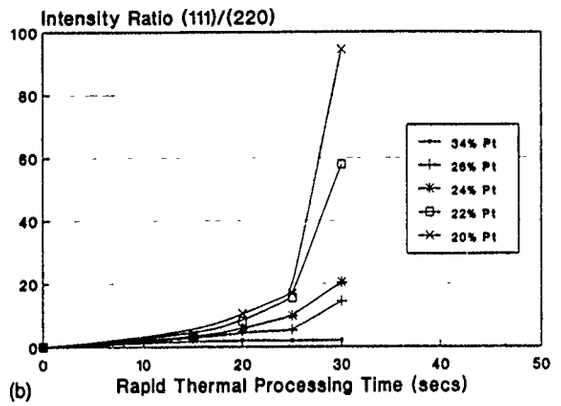

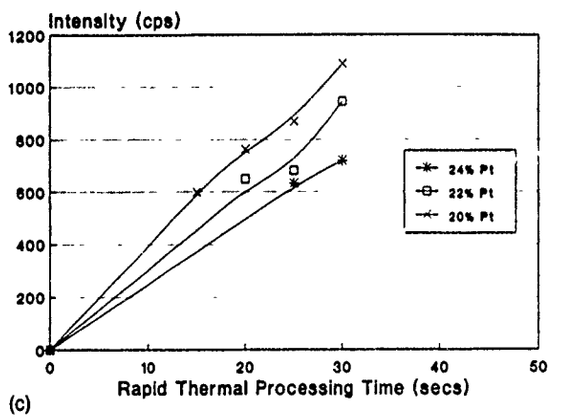

FIG. 2. (a) Development of PtMnSb (111) peak with RTP time. (b) Development of PtMnSb (111) texture with RTP time. (c) Formation of MnSb phases as measured by the development of MnSb (101) peak with RTP time.

x-ray diffraction system and their magnetic and magneto-optic properties investigated using a vibrating sample magnetometer (VSM) and polar Kerr hysteresis loop plotter operating at wavelengths of 670 and 825 nm.

RESULTS

All as deposited films evidenced no x-ray diffraction structure and no magnetic or magneto-optic activity. After RTP the near stoichiometric films (sample 1) developed the characteristic $C1_b$ structure, displaying the nine significant peaks shown in Figure 1(a). The dominant peak is the one representing the (111) plane with an intensity twice as large as the most significant of the other peaks, which is attributed

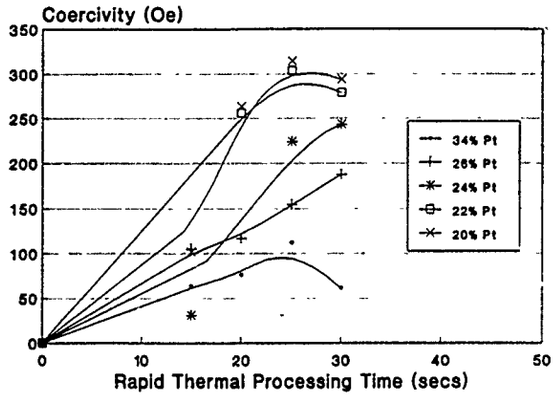

FIG. 3. Development of out of plane coercivity with RTP time.

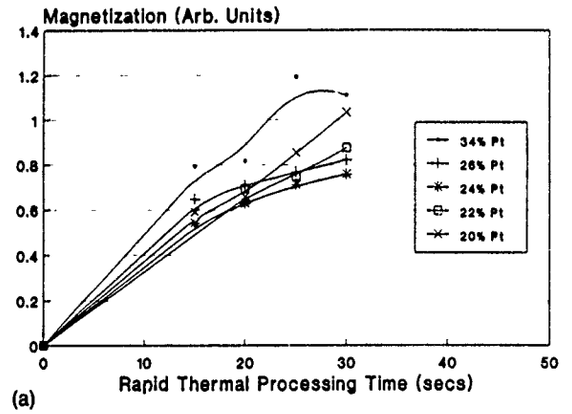
to the (220) plane. The ratio of the two intensities for the (111) and the (220) planes is used as a measure of the (111) texture in the PtMnSb films. In contrast the Pt deficient samples, after the same RTP, exhibited marked changes in this (111) texture and evidence of growth of MnSb phases, as shown in Fig. 1(b) for sample 5.

The development of the (111) peak and its texture, as defined above, is displayed for all five compositions as a function of RTP time in Figs. 2(a) and 2(b). In Fig. 2(b) the texture is seen to increase rapidly with decreasing Pt content as the (111) peak height increases and the (220) peak height



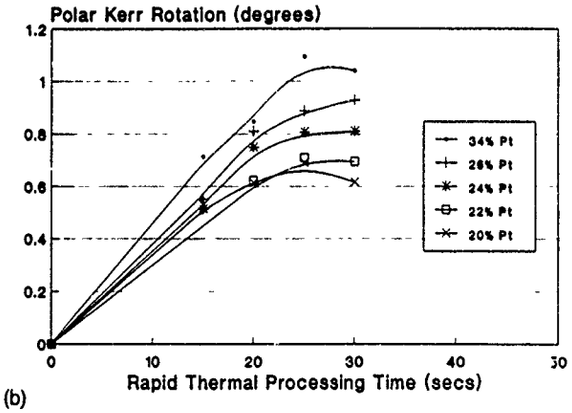


FIG. 4. (a) Development of magnetization with RTP time. (b) Development of polar Kerr rotation with RTP time.

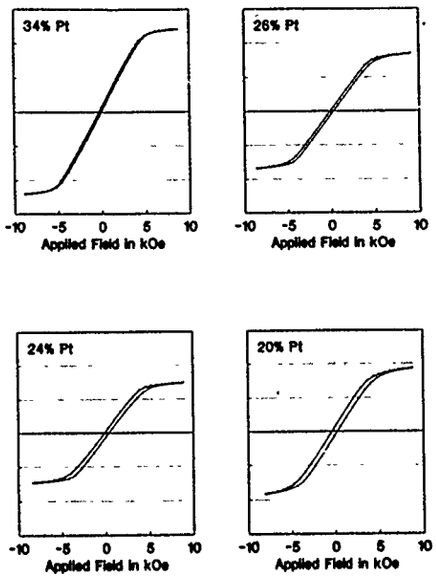

FIG. 5. VSM hysteresis loops (out-of-plane) for four different compositions after 30 s RTP.

decreases for processing times in excess of 20 s. Figure 2(c) demonstrates the development of MnSb phases in the most Pt deficient samples by plotting the growth of the identified MnSb (101) peak with processing time.

The corresponding variation of out of plane coercivity with RTP time is shown in Fig. 3 and the variations in magnetization and polar Kerr rotation in Figs. 4(a) and 4(b). Examples of the out of plane VSM hysteresis loops obtained for the various compositions after 30 s RTP are presented in Fig. 5.

DISCUSSION

The above results indicate very clearly that the texture of PtMnSb films can be effectively controlled by small adjustments in composition and RTP time. It is also evident that the very marked changes in texture do not produce a significant change in coercivity although, in agreement with the suggestion made by Marinero,[1] an increase in coercivity is produced with Pt depletion. However, the clear correlation between the data presented in Figs. 2(c) and 3 suggests that, in line with the work of Kunimoto *et al.*,[9] it is the increase in coercivity with the measured development of MnSb phases in the Pt deficient PtMnSb films that is of significance. Although the Pt deficient samples exhibit some reduction in polar Kerr rotation it still remains relatively large.

Secondary ion bombardment effects on the magnetic properties and microstructures of ion-beam-deposited TbFe thin films

S. Yatsuya and M. B. Hintz
Information, Imaging and Electronics Sector Materials Application Laboratory, 3M Co., St. Paul, Minnesota 55144

TbFe films were produced by ion beam deposition both with and without 300 eV secondary ion bombardment (SIB). The magnetic properties and microstructures of the films were investigated. SIB was found to increase the perpendicular anisotropy coefficient, but decrease the magnetization-coercivity product (MH_c=energy product) of the films. The microstructure of the films changed dramatically; the film made in the absence of SIB is amorphous while the film made with SIB during deposition consists of nanocrystals in an amorphous matrix.

I. INTRODUCTION

It has been shown that secondary ion bombardment (SIB) during deposition, which is generally called ion assisted deposition, can alter the growth, density, and appearance of vapor-deposited films.[1]

This paper compares the magnetic properties and microstructures of ion-beam-deposited (IBD) TbFe films made with and without 300 eV SIB.

II. EXPERIMENTAL

A dual ion beam system[2] was used to prepare specimens for this study. Base pressure prior to deposition was $\leq 5\times10^{-8}$ Torr. The Ar working gas pressure during deposition was 3×10^{-4} Torr. The Fe-Tb films were sandwiched between thin (15–20 nm) SiC films for environmental protection. The primary ion beam energy was 650 eV with a total beam current of 230 mA; this yields an ≈3 nm/min Fe-Tb deposition rate over the planetary swept area. The secondary ion source was operated at 300 eV energy and an average total current of 30 mA; it is estimated that this corresponds to an average current density of ≈10 μA/cm^2 at the substrates. The secondary ion beam incidence angle is ≈45° to the substrate surface normal. Fe-Tb film chemistry was determined by inductively coupled plasma analysis (ICP).

MH loops were measured using a vibrating sample magnetometer; torque measurements 45° to the film normal as a function of applied field[3] were used to determine the uniaxial magnetic anisotropy constant, Ku.

Microstructural characterization of the films was carried out by transmission electron microscopy (TEM) using JEOL200CX and 2010 microscopes operated at 200 kV. Selected area diffraction and high resolution bright-field imaging were the primary modes of operation. Microbeam diffraction with a probe size of ≈2 nm was also employed. A film stack of SiC_x/TbFe/SiC_x was deposited on TEM grids with SiO support films, NaCl(100) single crystals, and Si(100) wafers. The first two substrates were used for plane view observation while the Si wafers were used for cross-sectional TEM specimen preparation and magnetic property measurements. The films grown on NaCl substrates were prepared for observation by floating off in water and transferring to TEM grids. Cross-section view samples were prepared by dimpling and ion beam milling.

Diffraction patterns and Kikuchi lines from the Si crystal substrate were used to align the specimens with the incident electron beam nearly parallel to the substrate surface.

III. RESULTS AND DISCUSSION

A. Specimen A: IBD TbFe film without SIB during growth

The ICP composition of the specimen A film is 74.1 at.% Fe and 25.9 at.% Tb. The film exhibits no magnetic compensation temperature from −160 °C to the ≈145 °C Curie temperature, which is consistent with its Fe/Tb ratio. Saturation magnetization (M_s) and energy product (MH_c) at 20 °C are 110 emu/cm^3 and 2.7×10^5 ergs/cm^3, respectively. The squareness ratio of the loops is close to one. The uniaxial anisotropy constant, $Ku=1.6\times10^6$ ergs/cm^3.

An electron micrograph of the specimen A SiC_xTbFe/SiC_x film stack on a SiO substrate is shown in Fig. 1 with the corresponding electron diffraction pattern. The TbFe film looks featureless and has one broad diffraction ring. The film is most likely amorphous.

Figure 2 shows a TEM cross-sectional view of the specimen A film stack. The individual layers of TbFe and SiC_x on the Si wafer can be seen. The region of the TbFe film close to the boundary with the SiC_x layer looks darker than the region away from the boundary because of the thickness. The Si single crystal film shows the structure image in the direc-

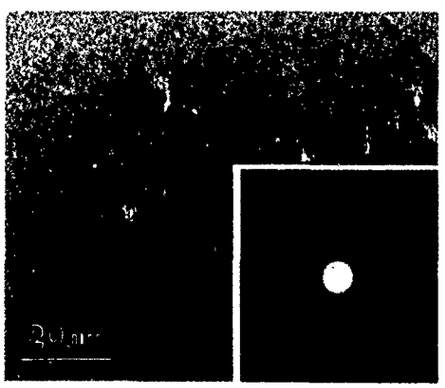

FIG. 1. Plane view of the specimen A SiC/TbFe/SiC film stack on SiO substrate and corresponding electron diffraction pattern.

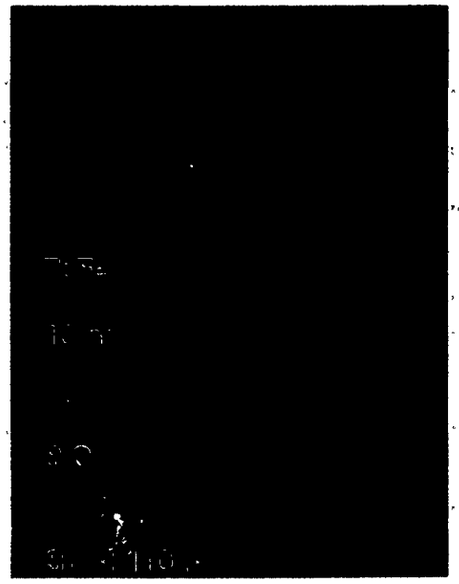

FIG. 2. Cross-sectional view of the specimen A SiC/TbFe/SiC film stack grown on a Si wafer (100)

tion of ⟨110⟩. It appears that the Si substrate surface is covered by an amorphous SiO_x layer around 2 nm thick. The interface between the SiC_x layer and the TbFe is quite sharp. The SiC_x layer grown on the Si substrate looks amorphous. The TbFe film grown on the SiC film does not have columnar structures and looks featureless. The film is most likely amorphous.

B. Specimen B: IBD TbFe film with SIB during growth

The ICP composition of the specimen B film is 79.8 at.% Fe and 20.2 at.% Tb. The reduced Tb concentration of this film relative to that of specimen A is probably due to preferential sputtering of the Tb by the secondary ion flux.[4] The film exhibits a magnetic compensation temperature of −130 °C. Saturation magnetization (M_s) and energy product (MH_c) at 20 °C are 45 emu/cm^3 and 1.3×10^5 ergs/cm^3, respectively. The squareness ratio of the loops is close to one. The uniaxial anisotropy constant, Ku, is $\approx2.2\times10^6$ ergs/cm^3. We have observed that SIB generally increases Ku in IBD TbFe films over a range of compositions.

The microstructure of the specimen A and B films is remarkably different. Figure 3 is a plane view of the specimen B SiC_x/TbFe/SiC film stack on a SiO substrate, along with the corresponding diffraction pattern. The TbFe film contains dark particles or clusters of ≈2 nm in size in an amorphous matrix. The diffraction pattern is composed of a strong broad ring which is broader than for the specimen A TbFe film, and exhibits a sharp intensity decline at the outer rim of the ring. The diffraction pattern shows that the film structure is significantly changed by SIB. The sharp intensity drop is considered to indicate the existence of small crystallines in the film.

Figure 4 shows the cross-sectional view of the specimen B film stack. The SiC films are most likely amorphous. The

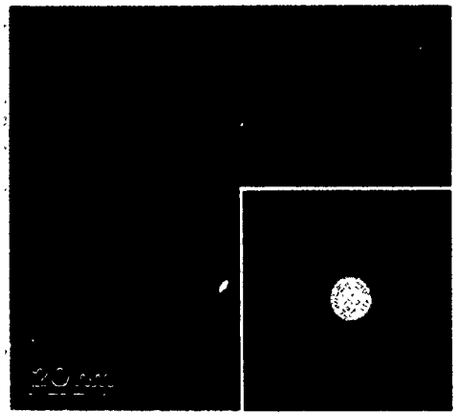

FIG. 3. The plane view of the specimen B SiC/TbFe/SiC film stack on SiO substrate and corresponding electron diffraction pattern.

cross-sectional view of the TbFe film also reveals ≈2 nm clusters in the amorphous matrix, which is consistent with the data from the plane view. The fact that the clusters are seen both in the plane and cross-sectional views indicates that the clusters are not an artifact of TEM sample preparation or post-deposition oxidation. There is no evidence for columnar structure in the films.

Figure 5 shows a highly magnified micrograph of the TbFe film. The film contains 2–3 nm size nanocrystals with lattice fringes as shown by arrows. It is certain that the film contains nanocrystals. The microbeam diffraction pattern from the dark clusters in the specimen B TbFe film is shown in Fig. 6(a); the presence of diffracted spots indicates the dark regions are nanocrystals. On the other hand, microbeam diffraction from the light portions reveals diffuse rings characteristic of amorphous materials as shown in Fig. 6(b).

Inspection of the Figs. 1–6 micrographs clearly demonstrates that the SIB has resulted in a microstructural transformation from what appears to be an entirely amorphous structure (specimen A) to an amorphous matrix containing a nominally uniform distribution of nanocrystals (specimen B).

The presence of nanocrystals of α-Fe or Co in TbFeCo films made by sputtering has also been reported.[5] Phase

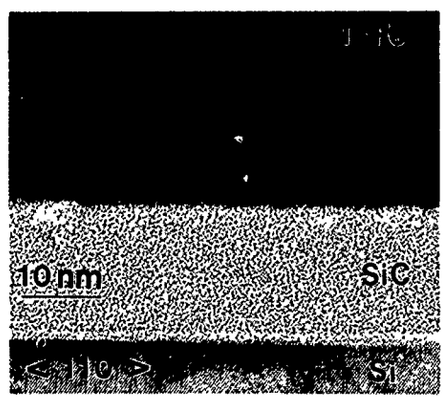

FIG. 4. The cross-sectional view of the specimen B SiC/TbFe/SiC film stack grown on a Si wafer (100).

FIG. 5. High resolution electron micrograph of the specimen B TbFe. Arrows indicate nanocrystals with lattice fringes.

separation on a 2.5–3.5 nm scale as a function of the substrate bias voltage also have been observed in GdCoAu thin films.[6] We are, however, unaware of any previous direct evidence that SIB can induce crystal formation in RE–TM alloys such as TbFe. SIB may be a useful tool for microstructure control in RE–TM films such as TbFe.

We speculate the reason why the ion assisted IBD film contains nanocrystals in the amorphous matrix as follows;

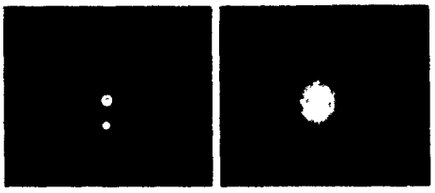

FIG. 6. Microbeam diffraction patterns from the dark portion (a) and from the light portion (b) of Fig 5.

ion bombardment played a role of making nucleation sites for the formation of the nanocrystals, because ion bombardment can create surface defects which act as nucleation sites for depositing film atoms.[7] It is also known that ion bombardment of a growing film can influence crystalline orientation.[8,9]

Several investigators have shown that ion bombardment during growth can influence the magnetic properties of rare earth-transition metal (RE-TM) alloys.[10–14] For example the uniaxial magnetic anisotropy constant Ku was explained in terms of selective resputtering of atoms in different surface sites.[12–14] However, none of the models considered a structure containing nanocrystals. We propose a possible model in which the presence of nanocrystals may affect Ku of the films made with SIB,[5] and other magnetic properties.

Optical and magneto-optical constants of Pr substituted TbFeCo films

R. Carey, D. M. Newman, J. P. Snelling, and B. W. J. Thomas
Centre for Data Storage Materials, Coventry University, Coventry CV15FB, United Kingdom

Optimization of tri- or quadrilayer magneto-optic recording media requires knowledge of the optical and/or magneto-optical constants for all of the individual active or passive layers that together comprise the complete disk structure. The optical $(n+ik)$ and first-order magneto-optical (Q_1+iQ_2) constants for two series (i) $(Tb_{23}Fe_{72.5}Co_{4.5})_{100-x}Pr_x$, (ii) $(Tb_{27}Fe_{65}Co_8)_{100-x}Pr_x$ of Pr substituted TbFeCo films, for which x varies between 0 and 30, have been determined by a combination of ellipsometry and Kerr polarimetry. Ellipsometry has also been used to determine independently the optical constants of the optimized SiN passivation layers developed to protect these samples. Using constants determined experimentally on thick samples, the variation of the polar Kerr rotation and ellipticity as a function of magnetic film thickness has been calculated for light incident from both the air and substrate side of a typical trilayer magneto-optic disk structure in which material from the above series, the magnetic and thermomagnetic properties of which have been previously reported [Carey *et al.*, J. Magn. Magn. Mater. (to be published)], forms the active storage layer. The agreement obtained with measurements demonstrates the self-consistency of the modeling process and the validity of the determined constants.

INTRODUCTION

Practical magneto-optic (MO) rare earth–transition metal (RE/TM) based recording media typically consist of tri- or quadrilayer structures in which a thin layer of active RE/TM material is sandwiched between dielectric protection/passivation layers and usually backed by a thin metallic reflector. Optimization of the readout properties of such structures requires the ability to model the magneto-optical behavior of the RE/TM material as a function of film thickness. This in turn requires knowledge of the optical and magneto-optical constants of the RE/TM material. Determination of these constants for such reactive material is not simple. Measurements must either be made *in situ* immediately following preparation or through the essential protection/passivation layers if the sample is to be removed from the preparation system.

In this paper we report the determination of the optical and magneto-optical constants for two series (i) $(Tb_{23}Fe_{72.5}Co_{4.5})_{100-x}Pr_x$, (ii) $(Tb_{27}Fe_{65}Co_8)_{100-x}Pr_x$ of Pr substituted TbFeCo films in which x varies between 0 and 30. All samples are identically protected between passivation layers of SiN prepared by rf magnetron sputtering from a Si_3N_4 target in a 9.5 mT Ar/N_2 (10:1) atmosphere. The thickness and optical constants of the protection layers were independently determined.

A detailed description of the preparation and analysis of the samples, together with their magnetic and thermomagnetic properties, has already been reported.[1]

EXPERIMENTAL TECHNIQUES

The samples used for the determination of the optical and magneto-optical constants were all 80 nm thick and protected above and below by SiN passivation layers 15 nm thick.

The ellipsometer used for the optical measurements is a semiautomated null instrument operating over the wavelength range 400–850 nm. Initially it was used to measure the optical constants of a single SiN layer, the thickness of which had been previously determined by a multiple beam interferometric technique. Ellipsometric measurements on the SiN coated RE/TM films were then made through the SiN. Values for n and k were then evaluated over the above spectral range.

Further, a previous publication[1] has presented the measured normal incidence polar Kerr rotation θ_K and ellipticity ϵ_K for these samples at the diode laser wavelengths of 670 and 825 nm, and from these values (together with the optical constants of the SiN overlayer and the magnetic layer) the complex magneto-optical constants (Q) of the magnetic layers were calculated.[2]

RESULTS AND DISCUSSION

Table I shows the ellipsometric parameters and derived optical constants obtained from a 128-nm-thick silicon nitride layer deposited onto a glass substrate as a function of wavelength in the range 400–825 nm. For comparison it is noted that Serenyi *et al.*[3] give $n=1.65$ and $k=0.12$ at 830 nm for equivalent sputtering conditions.

Tables II and III similarly show the optical constants obtained for the Pr substituted TbFeCo samples that constitute series (i) and (ii), respectively. In comparison with some results[4–6] reported in the literature the results for the real part of the refractive index (n) appear a little on the low side at the longer wavelengths (650–825 nm), although other results[7] agree more closely to those presented here in this range. The radically different nature of the multitarget scanning preparation process[1] may be significant when comparing the present results with most in the literature.

Values evaluated for the first-order magneto-optic constants Q_1 and Q_2 are tabulated in Tables IV and V. At this time there are no Q values for Pr substituted TbFeCo available for direct comparison but values for the base TbFeCo alloys are in good agreement with those quoted elsewhere. Atkinson *et al.*,[4] for example, have given values of $Q_1 \approx 0.016$ and $Q_2 \approx -0.005$ for $Tb_{27}Fe_{62}Co_{11}$ at 614 nm while McGahan *et al.*[6] reporting on $Tb_{20.3}Fe_{71.7}Co_8$ at 670 nm cite $Q_1 \approx -0.024$ and $Q_2 \approx 0.004$. The sign reversal between these two measurements is due to the reversal in polar Kerr rotation between RE and TM dominant material.

Using the experimentally evaluated values of the optical and magneto-optical constants the thickness dependence of the polar Kerr rotation and ellipticity have been calculated for both series of Pr substituted TbFeCo compositions at the

two laser wavelengths of the Kerr polarimeter. Figure 1 compares the calculated thickness dependence of this magneto-optic behaviour for both the free surface (FS), and through the glass substrate (BS) side of the material, with experimental measurements made on films of varying thickness for the composition $Tb_{23}Fe_{72.5}Co_{4.5}$ at a wavelength of 825 nm. Figure 2 makes a similar comparison between calculated and experimental data for $(Tb_{23}Fe_{72.5}Co_{4.5})_{89}Pr_{11}$. The form of these results is typical of the samples in both series (i) and (ii). It can be seen that these plots establish that there is an acceptable correspondence between calculated and experimental data, thereby demonstrating the self-consistency of the evaluated material constants used in this modeling process.

Moreover, it is clear that the substitution of Pr into TbFeCo alloys degrades their magneto-optic behavior, at least for these compositions and wavelengths. An interesting feature though, to emerge from this investigation is the large increase in ellipticity with decreasing MO film thickness in these structures, being particularly large from the substrate side of the film. To a lesser extent there is a similar enhancement to the Kerr rotation from the substrate side of these films.

These through the substrate enhancements to θ_K and ϵ_K are simply explained by the limited coherence length of the diode laser radiation ($\approx$1 mm) used in the Kerr polarimeter relative to the thickness of the glass substrate (1.2 mm). The resultant noncoherency of the light within the MO layer system for the substrate measurement can then be computed to be the cause of the improvement in MO signal. The free surface measurement does not similarly suffer as the film thickness is very much less than this coherence length.

CONCLUSION

The effective modeling of trilayer structures relevant to practical MO media has been demonstrated using experimen-

Thermal stability of NdGd/FeCo multilayers

X. Y. Yu, T. Suganuma, H. Watabe, S. Iwata, S. Tsunashima, and S. Uchiyama
Department of Electronics, Nagoya University, Nagoya 464-01, Japan

Thermal stability has been investigated for the structure and the perpendicular anisotropy K_u of $Nd_{44}Gd_{56}/Fe_{89}Co_{11}$ multilayer films with the bilayer period of 1 nm, where K_u becomes the maximum. From the results of isothermal annealing at temperature T_a, it has been found that the saturation magnetization M_s scarcely changes up to T_a=400 °C, while K_u is almost constant up to T_a=200 °C but decreases rather quickly for T_a above 200 °C. The decrease in K_u for T_a>260 °C is accompanied by the decrease in the peak intensity of low angle x-ray diffraction, namely by the deterioration of the layered structure.

INTRODUCTION

Rare earth (RE)–transition metal (TM) amorphous films, especially Tb-FeCo films, are now commercially used as media for magneto-optic (MO) recording. In order to increase the recording density, shorter wavelength light such as 687 or 532 nm is going to be used in the next generation MO recording. As is well known, the Kerr rotation of Tb-FeCo, hence the figure of merit for readout, decreases with decreasing wavelength, and development of new media with a larger Kerr rotation at a shorter wavelength has been desired. In this connection, it was found that the MO effect of Nd-Co and Pr-Co amorphous films became larger than those of heavy RE-Co films at a shorter wavelength around 500 nm.[1–3] However, since the magnetization of (Nd,Pr)-TM films is larger than that of heavy RE-TM, it is very difficult to prepare perpendicularly magnetized films.

Some efforts have been made on multilayer films with perpendicular magnetization by using interfacial anisotropy[4,5] such as Nd/Fe[5] and NdCo/Fe. We have prepared $Nd_{36}Gd_{64}/Fe_{89}Co_{11}$ and $Pr_{36}Gd_{64}/Fe_{89}Co_{11}$ multilayers with good Kerr hysteresis loop, which is expected as a candidate for the next MO media.[6,7] However, like other MO media, we should be attentive to the thermal stability of the multilayers, especially interfacial structure. In this paper, thermal stability of the structure and the anisotropy is reported for NdGd/FeCo multilayers.

EXPERIMENTAL METHOD

All films under investigation were prepared on glass or fused quartz substrate by rf diode sputtering method as described in Ref. 6. A bilayer period of multilayer (ML) films was chosen as 10 Å, where the perpendicular anisotropy becomes the maximum as shown in Refs. 6 and 7. The thickness ratio of the RE layer to the TM one is 1:1. The ML films with total thickness of 1200 Å were covered by a SiAlON layer to prevent the films from oxidation. Compositionally modulated structure and crystal structure have been confirmed by low angle and high angle x-ray diffractometry, respectively. Magnetization and anisotropy were measured by a vibrating-sample magnetometer and a torque magnetometer. Annealing was done under a vacuum below 5×10^{-6} Torr.

RESULTS AND DISCUSSION

Figures 1 and 2 show the patterns of x-ray diffraction at low and high angle, respectively. It is seen that the peak intensity at low angle becomes smaller with increasing annealing temperature while the patterns of high angle have scarcely changed at the annealing temperatures below 370 °C. The decrease of the low angle peak intensity means that interdiffusion occurs and compositionally modulated structure gradually changes into a uniform structure.

From the fact that some peaks appear at high angle after annealing, we can say that the amorphous film is crystallized above 450 °C.

In Fig. 3, the change of the perpendicular magnetic anisotropy K_u with annealing time is shown. The values of K_u are almost constant by annealing at 100 and 185 °C. By annealing at around 300 °C, the anisotropy seemed to be decreased with annealing time, and at 400 °C it was drastically reduced within half an hour.

The change of the saturation magnetization with the annealing time is shown in Fig. 4. In contrast to the change in

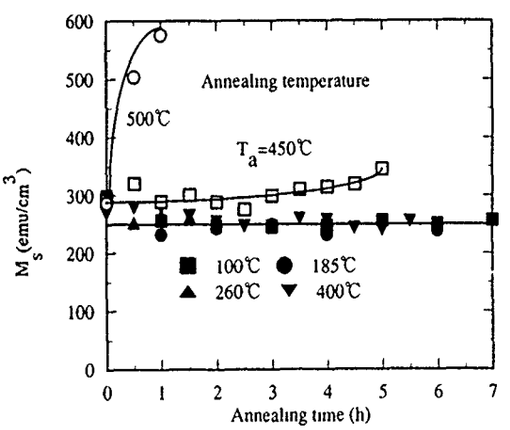

FIG. 4. Saturation magnetization M_s as a function of annealing time for $Nd_{44}Gd_{56}/Fe_{89}Co_{11}$ multilayers.

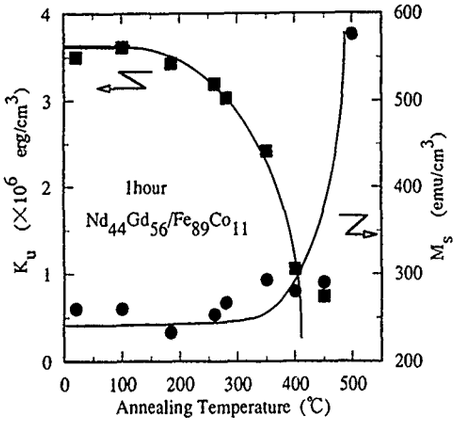

FIG. 5. Dependence of perpendicular magnetic anisotropy and saturation magnetization M_s on the annealing temperature

anisotropy, the saturation magnetization did not change with annealing time up to 400 °C. At 450 °C, however, it became slightly larger with annealing time and increased abruptly at 500 °C.

The dependence of the anisotropy and the saturation magnetization on the annealing temperature is shown in Fig. 5 for the annealing time of 1 h. The change starts around 200 and 400 °C for the anisotropy and the saturation magnetization, respectively. The difference between the change of the anisotropy and the magnetization may come from the difference in the mechanism. For example, anisotropic structures of atoms at the interface of multilayers are said to be of the origin of the perpendicular anisotropy while the effective composition of magnetic atoms is thought to decide the saturation magnetization.

The relationship between the anisotropy and the first peak intensity in low angle x-ray diffraction is shown in Fig. 6, where C/C_0 show the first peak intensity after annealing normalized with that before annealing. The samples plotted here are confined to the films annealed at temperatures below

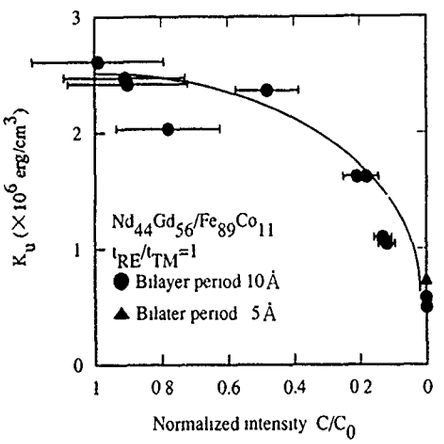

FIG. 6. The relationship between the perpendicular magnetic anisotropy K_u and the normalized intensity of the low angle first peak, C/C_0 for $Nd_{44}Gd_{56}/Fe_{89}Co_{11}$ multilayers.

400 °C, where the films keep the amorphous structure. Since the K_u decreases with decreasing C/C_0, it is suggested that the K_u is closely related to and enhanced by the compositionally modulation structure.[8,9]

CONCLUSION

Thermal stability of structure and magnetic properties has been investigated for GdNd/FeCo multilayers. The saturation magnetization M_s scarcely changes for annealing temperatures up to T_a=400 °C, while K_u decreases rather quickly for $T_a \geq 300$ °C. The decrease in K_u for $T_a > 300$ °C is accompanied by the decrease in the peak intensity of low angle x-ray diffraction, namely by the deterioration of the layered structure, suggesting that K_u is closely related to modulation structure.

Physical and magnetic microstructure of rapid thermally annealed thin film bismuth-doped garnets

W. R. Eppler, B. K. Cheong, D. E. Laughlin, and M. H. Kryder
Data Storage Systems Center, Carnegie Mellon University, Pittsburgh, Pennsylvania 15213

Bismuth-doped iron garnets are promising materials for blue light magneto-optic recording media. These materials have been deposited on glass substrates with bulk magnetic and magneto-optic properties suitable for magneto-optic recording. However, these films exhibit a very low carrier to noise ratio (CNR) when crystallized in conventional furnaces. The low CNR is due to the inability to write circular domains in these materials. Rapid thermal annealing (RTA) has been reported to produce films with a much finer grain size. We have confirmed by transmission electron microscopy that RTA does indeed reduce the grain size over an order of magnitude from films crystallized in a conventional furnace. Faraday microscopy has shown that films processed by RTA with smaller grain size (~30 nm) support circular magnetic domains of much greater regularity than films crystallized in conventional furnaces. The improved regularity of static thermomagnetically written domains, in films crystallized by RTA, lends promise that the noise in these materials can be reduced.

INTRODUCTION

Bismuth-substituted iron garnets are promising short wavelength magneto-optic recording materials since they have a strong magneto-optic effect at wavelengths less than 550 nm.[1] Shono *et al.*[2] demonstrated that bismuth-substituted garnet films grown on single crystal GGG substrates exhibit 54 dB of CNR (30 kHz bandwidth, 5 MHz writing frequency, 14 m/s linear velocity, 514 nm wavlength, and 1.4 μm bit length). The single crystal GGG substrates are expensive and limited in size so a more practical substrate is needed. Garnet films deposited on glass disks, crystallized *in situ* by deposition at elevated temperatures, or by post-deposition annealing have exhibited low CNR's due to high media noise. The media noise is due in part to the inability to write regular circular domains when the grain size is comparable to the magnetic domain size.[3] The magnetic domain walls follow the grain boundaries thus the irregularity in domain shape is a result of the average grain size being of the order of the written domain size.

Much effort has been made to control the grain size and film morphology through different dopants,[4,5] underlayers,[6,7] and annealing schedules[8,9] with only limited success. Suzuki *et al.*[10] reported that rapid thermal annealing (RTA), a process which employs arc lamps or flash lamps as the thermal source and can provide heating rates as high as 200 °C/s, was successful in reducing the grain size to about 30 nm. In a transmission electron microscope (TEM) study Bechevet *et al.*[11] observed an inhomogeneous microstructure of large crystallites (450 nm) embedded in a matrix of small crystallites (35 nm) in cerium-substituted iron garnets crystallized by RTA. The purpose of this work was to confirm Suzuki's results for bismuth-substituted garnets and to determine if the reduced grain size enables regularly shaped magnetic domains to be written in these materials.

EXPERIMENTAL DETAILS

Thin films were deposited by rf magnetron sputtering onto Corning No. 7059 glass substrates with the sputtering conditions listed in Table I. The as-deposited films were amorphous and were crystallized by either conventional annealing at 670 °C for 3 h in an air atmosphere or by RTA in an AG Associates 610i heat pulse system with a heating rate of 100 °C/s and a dwell time of 2 min at 710 °C in a nitrogen atmosphere.

Microstructural investigations were conducted on planar ion-milled specimens in a Philips 420 T TEM. Micromagnetic investigations were conducted using Faraday microscopy (50×0.5 or 125×0.8 NA) with an argon ion laser (λ =488 nm), modulated by an electro-optic modulator, as the writing source.

RESULTS AND DISCUSSION

A TEM image of a film annealed in a conventional furnace is shown in Fig. 1. This film has a polycrystalline microstructure with a grain size of the order of 1 μm. A Faraday microscope image of thermomagnetically written domains in this film using a writing power of 20 mW, pulse width of 1 μs, and a bias field of 70 Oe is shown in Fig. 2. The written domains are clearly irregularly shaped. In a previous paper[3] it was shown that the domain walls are located along grain boundaries, thus the film microstructure plays a dominant role in determining the written domain shape. Further, it was shown that for films crystallized by post-deposition annealing the garnet phase nucleated at sites

spaced approximately 1 μm apart which grew rapidly until they impinged upon one another forming the grain boundaries. Therefore, the grain size is controlled by the density of garnet nuclei obtained before significant grain growth could occur.

A TEM image of an identical film crystallized by RTA is shown in Fig. 3. The average grain size is approximately 30 nm in agreement with Suzuki's results measured by scanning tunneling microscopy and x-ray diffraction. No evidence was found of the inhomogeneous microstructure, of large crystallites imbedded within a matrix of smaller crystallites, observed by Bechevet. A Faraday microscope image of domains written in this film using identical writing conditions as the conventionally annealed sample is shown in Fig. 4. These domains are much more circular than the domains written in the conventionally annealed sample, which lends promise that the noise in these materials can be reduced.

These results can be qualitatively understood in terms of the effects of different heat treatments on the nucleation and growth kinetics o the garnet phase. When the heating rate is slow (~0.1 °C/s) nucleation of the garnet phase will commence at a relatively low temperature. This means that the nucleation proceeds under a small driving force, thus leading to a low nucleation rate (number of garnet phase nuclei per unit volume of untransformed region per unit time). The small number of nuclei, which occur at the lowest temperatures, are given time to grow with the rising temperature and consume other possible nucleation sites. This produces a low effective nucleation density and therefore the large crystallite size observed of approximately 1 μm.

In the case of RTA, the rapid temperature rise will enable the nucleation to start at a relatively higher temperature (i.e., under a larger driving force). Further, the rapid temperature rise does not provide sufficient time for those nuclei which occur at the lowest temperatures to grow and consume the other possible nucleation sites. This creates a high effective nucleation density and the fine grained microstructure observed.

FIG. 2. Faraday micrograph of thermomagnetically written domains in post-deposition annealed garnet film (20 mW writing power, 1 μs pulse width, and 70 Oe bias field).

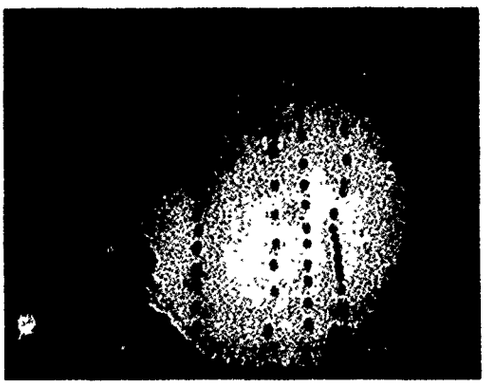

FIG. 4. Faraday micrograph of thermomagnetically written domains in RTA crystallized film (20 mW writing power, 1 μm pulse width, and 70 Oe bias field).

CONCLUSIONS

We have confirmed Suzuki's results that RTA significantly reduces the crystallite size of bismuth-doped iron garnet films on glass substrates. Further, we have shown that films crystallized by RTA with the smaller grain size support circular magnetic domains of much greater regularity than films crystallized in conventional furnaces. The improved regularity of static thermomagnetic written domains in these films lends promise that the media noise problems of these materials can be solved. We believe the reduced grain size in the RTA processed films is a result of improved nucleation of the garnet phase and suppression of grain growth from the rapid temperature rise. A quantitative understanding of the kinetics of the phase change in these materials would be helpful in determining the optimal heating rate and crystallization temperature and possibly point to better methods of controlling the crystallite size in these materials.

Uniaxial anisotropy of double-layered garnet films and magneto-optical recording characteristics

Katsuji Nakagawa, Seiji Kurashina, and Akiyoshi Itoh
Department of Electronic Engineering, College of Science and Technology, Nihon University, Funabashi, Chiba 274, Japan

For reducing the critical diameter of the written domain in magnetic garnet films for magneto-optical (MO) recording, double-layered garnet films were investigated. The coercivity of the double-layered garnet film was increased, when the upper layer was crystallized. This increase of the coercivity is caused by the increase of the uniaxial anisotropy energy. The increase of the uniaxial anisotropy energy also leads to a decrease in the noise level of the MO readout signal. As a consequence, the critical diameter of written domains was reduced to 0.2 μm. This critical diameter is smaller than the reading out beam spot for the case with a green laser and a high numerical aperture objective lens. The garnet films are sufficient for high density next generation MO recording.

INTRODUCTION

The fundamental characteristics required of magneto-optical (MO) recording media are high carrier to noise ratio (CNR) and high memory density. The high density is accomplished by small written domains and a small beam spot for reading out which is achieved by using short wavelengths. It is necessary for the candidates of the next generation of the MO media to have a large MO effect. Bi-substituted garnet films are excellent media for MO recording memory, because the figure of merit of the Bi-substituted garnet film is 3–6 times as large as those of the multilayered Co/Pt and the conventional TbFeCo media at a wavelength of 515 nm. The figure of merit is defined as the value of the Faraday or Kerr rotation angle multiplied by the reflection coefficient, and it is directly proportional to the MO readout signal strength. CNR of the garnet films was improved by reducing the grain size,[1] improving homogeneity of the film,[2] and using the double-layered structure.[3] However, there are no reports of the critical diameter of written domains of garnet films for MO recording.

For the purpose of improving the memory density, the critical diameter of written domains was reduced by using the double-layered film. This decrease of the critical diameter is caused by the increase of the coercivity H_c. The mechanism of increasing the H_c was clarified by investigating the uniaxial anisotropy energy K_u.

EXPERIMENTAL

The under layer of the $Bi_{0.9}Dy_{2.1}Fe_{4.2}Al_{0.8}O_{12}$ garnet films doped with 1 at. % of Rb was prepared by pyrolysis on glass substrates. The films were post-annealed for crystallization, and the diameter of the grain of the Rb-doped garnet films was approximately 30 nm.[1] After the crystallization of the under layer, the upper layer of the garnet films was prepared by pyrolysis. The upper layer was also post-annealed for crystallization.

The critical diameter d_c is determined by the following:[4]

$$d_c = \sigma_w/(M_s \times H_c), \tag{1}$$

where σ_w is the wall energy density, M_s is the saturation magnetization, and H_c is the coercivity. σ_w is derived from the exchange stiffness constant and the uniaxial anisotropy energy K_u. The values of M_s, H_c, and K_u were measured by a vibrating sample magnetometer, a torque magnetometer,[5] and a Faraday hysteresis loop tracer, respectively. The exchange stiffness constant at room temperature was approximated by using the Curie temperature T_c of the film.[6] T_c was measured by the dependence of Faraday rotation coefficient on temperature.

The crystallization kinetics of the upper layer were evaluated by Johnson, Mehl, and Avrami as follows:

$$x = 1 - \exp[-(k \times t_a)^n], \tag{2}$$

where x is the transformation quantity, t_a is the annealing time, k is the rate constant, and n is the Avrami exponent. Since the models of the crystallization kinetics have been reported for the values of the Avrami exponent n,[7,8] the crystallization kinetics can be determined by the values of n. The transformation quantity x from the amorphous phase to the crystalline phase was determined by the change of the Faraday rotation coefficient of the films.

The MO recording and reading characteristics were measured by using 515 nm in wavelength of Ar ion laser. CNR was measured under the condition as follows. A frequency and a duty cycle for writing pulse were 500 kHz and 50%, respectively. Linear velocity of the films was 5.2 m/s. Bandwidth of a spectrum analyzer was 10 kHz.

RESULTS AND DISCUSSION

To know the crystallization kinetics of the upper layer, the Avrami exponent n for the upper layer was obtained from the Avrami plot as shown in Fig. 1. The value of n for the upper layer is approximately one. The model of the crystallization for $n=1$ is diffusion controlled growth of cylinders in an axial direction. This model of the upper layer is different from the model of the single layer, which is the disk-shaped diffusion controlled growth with a constant thickness.[9] It was confirmed by using a transmission electron microscope that the grain shape of the cylinders was observed in a cross-sectional image.[2] The activation energy E_a

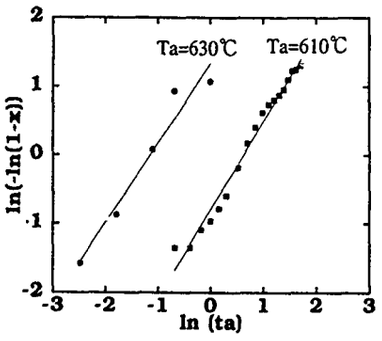

FIG. 1. The Avrami plot for the upper layer of $Bi_{0.9}Dy_{2.1}Fe_{4.2}Al_{0.8}O_{12}$ garnet on the under layer of 1 at. % of Rb-doped $Bi_{0.9}Dy_{2.1}Fe_{4.2}Al_{0.8}O_{12}$ garnet. Avrami exponent n is approximately one. The thickness of the upper and under layers are 100 nm, respectively.

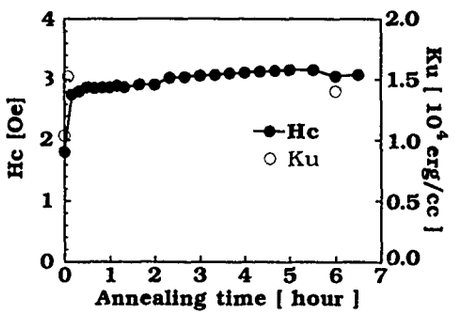

FIG. 3. The dependence of the coercivity H_c and the uniaxial anisotropy energy K_u of the double-layered garnet film on the annealing time for the crystallization of the upper layer. The composition of the under layer is 1 at. % of Rb-doped $Bi_{0.9}Dy_{2.1}Fe_{4.2}Al_{0.8}O_{12}$ garnet. The annealing temperature and time of the under layer are 630 °C and 3 h. The composition of the upper layer is $Bi_{0.9}Dy_{2.1}Fe_{4.2}Al_{0.8}O_{12}$ garnet. The annealing temperature of the upper layer is 610 °C. The thicknesses of the upper and under layers are 100 nm, respectively.

of the upper layer for crystallization was derived from the Arrhenius plot as shown in Fig. 2. The value of E_a is due to both the processes of nucleation and growth of the nucleated crystallites. The value of E_a of the upper layer is 4.7 eV, while E_a of the under layer is 5.3 eV. This difference of E_a is probably caused by the difference of the nucleation mechanism between the upper and under layer. As a result, the model of the crystallization kinetics seems to be interpreted as follows. The crystallites of the upper layer are nucleated at the surface of the grain of the under layer, and the crystallites grow along the film normal with the shape of cylinders.

To increase the memory density of garnet films, it is important to increase M_s and H_c. We found the effect that H_c was increased without a change of M_s by using a double-layered film as shown in Fig. 3. H_c was increased to 3 kOe. H_c of the under layer before the deposition and crystallization of the upper layer was 1.8 kOe. After the coating of the upper layer without annealing, H_c of the double layer was not changed. However, H_c was increased to 3.0 kOe after the 10 min annealing for the double-layered film.

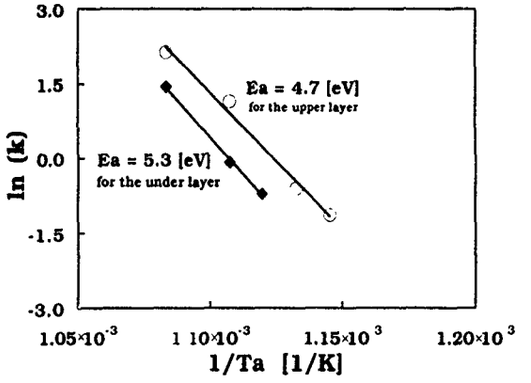

FIG. 2. The Arrhenius plots for the under layer of 1 at % of Rb-doped $Bi_{0.9}Dy_{2.1}Fe_{4.2}Al_{0.8}O_{12}$ garnet and the upper layer of $Bi_{0.9}Dy_{2.1}Fe_{4.2}Al_{0.8}O_{12}$ garnet on the under layer. The activation energy E_a for the under and upper layer is 5 3 and 4 7 eV, respectively. The thicknesses of the upper and under layers are 100 nm, respectively.

To know the reason why H_c was increased, the dependence of K_u on the annealing time was measured, as shown in Fig. 3. While K_u of the under layer was 1.0×10^4 ergs/cm^3, K_u is increased to 1.4×10^4 ergs/cm^3 after only a short annealing time. Since this dependence of K_u is very similar to the change of H_c, the increase of H_c may be caused by the increase of K_u.

This change of K_u can result from the shape anisotropy, the crystal growth anisotropy, or the stress-induced anisotropy. The shape anisotropy energy of the observed shape of cylinders is 0.07×10^4 ergs/cm^3. This value of the shape anisotropy energy is lower than the change of K_u. After the short annealing time, the total volume of the crystallized grains of the upper layer is 3% of the coated upper-layer volume. This value was estimated from the transformation quantity x from the amorphous to the crystalline phase. Since the shape anisotropy is less than 0.07×10^4 ergs/cm^3, the change of K_u is not caused by the shape anisotropy. For the single-layer film after the crystallization, H_c was not changed by the additional annealing. Therefore, the crystal growth anisotropy of the under layer does not seem to be increased by the annealing of the upper layer. If tensile stress is induced in the under layer, the stress-induced uniaxial anisotropy energy will be increased, because the magnetostriction constant of the under layer is negative. If the crystallites of the Bi-rich composition of the garnet are crystallized at the surface of the under layer, tensile stress can be induced in the under layer. Therefore, the increase of K_u of the under layer can be caused by the increase of the stress-induced anisotropy energy. However, it is necessary to measure the depth profile of the composition and the internal stress for the double-layered films.

The MO recording and reading characteristics were measured by using 515 nm in wavelength of Ar ion laser. The increase of K_u leads to the decrease in the noise level for reading out signal, because the fluctuation in the orientation of magnetic moments becomes lower by the increase of K_u.[2] By the effects of the increased H_c and K_u, CNR of 55 dB was achieved for the double-layered film by using 515 nm in

wavelength of Ar ion laser, while CNR was 52 dB for the single-layer garnet films. H_c and K_u of the double-layered film are 1.7 and 1.4 times as large as those of the single-layered film, respectively, and d_c is 0.7 times as small as the value of the single-layer film. As a result, the critical diameter d_c was reduced to 0.2 μm. This critical diameter is smaller than the reading out beam spot for the case with a green laser and a high numerical aperture objective lens. The garnet films are sufficient for high density next generation MO recording.

CONCLUSIONS

For the purpose of improving the memory density, the double-layered garnet films were investigated. The crystallization kinetics of the double-layered garnet films was investigated, and the model of the crystallization of the upper layer is the diffusion controlled growth of cylinders in the axial direction. The coercivity H_c of the garnet film was increased and the critical diameter d_c was decreased by using the double-layered film. This increasing of H_c is caused by the increasing the uniaxial anisotropy energy. By using this effect, the higher density MO recording memory can be achieved. The increase of the uniaxial anisotropy energy also leads to a decrease of the noise level for MO reading out signal. In the future, it is necessary to measure the depth profile of the composition and the internal stress for the double-layered films.

Crystalline Co spinel ferrite films were prepared by rf sputtering on glass substrates without buffer layer and annealed at temperatures from 400 to 600 °C for 2 h in air. (100) texture was obtained in these films. The anisotropy constant, magnetic hysteresis loops, and magneto-optical Faraday spectra of the films were measured. The texture became poor when the films were annealed below 500 °C, but the perpendicular anisotropy constant K_u, squareness ratio $R=(Mr/Ms)_\perp/(Mr/Ms)_\parallel$ increased and showed peak values of 2.2×10^5 ergs/cm^3 and 0.94, respectively, at an annealing temperature $T_a=500$ °C. For the film annealed at 600 °C (higher than the Curie temperature, 520 °C, of Co spinel ferrite), the texture recovered, but K_u and R dropped. The Faraday rotation spectra of Co spinel ferrite films showed a broad peak centered around 720 nm. The peak value increased monotonically with increasing annealing temperature. These results may be related to the Co ion-induced anisotropy and Co ion distribution in tetrahedral sites and octahedral sites.

I. INTRODUCTION

Thin ferrite films have attracted much attention in recent years as one of the candidates of magneto-optical (MO) recording media because of their large Faraday effect and good corrosion resistance.[1] An important problem people are concerned about is to make ferrite films which meet the requirements of MO recording such as perpendicular anisotropy by a technology that is as simple as possible. Co spinel ferrite films are promising candidates for having good MO properties and perpendicular anisotropy.[1-4] However the mechanism of perpendicular anisotropy and Faraday effect is not quite certain. In this paper the results of our study on the anisotropy and Faraday effect of Co ferrite films made by rf sputtering and annealed at different temperatures are reported.

II. EXPERIMENTS

$CoFe_2O_4$ films were prepared by rf sputtering with a sintered $CoFe_2O_4$ ceramic target. The base vacuum was 7.5×10^{-6} Torr. The pressure of sputtering gas, argon, was 20 mTorr without additional reactional oxygen gas. The films were deposited directly on glass substrates cooled by running water. The samples were annealed in temperatures ranging from 400 to 600 °C for 2 h in air and rapidly quenched to room temperature.

The atomic ratio between the content of Fe and Co in the as-sputtered samples determined by EDXA was found to be about 2:1. The structure and phase components of the sample were analyzed by x-ray diffraction with CuK_α radiation. The thickness of the films measured by an optical interference technique was about 1 μm. The room temperature hysteresis loops of the samples were measured by a vibrating-sample magnetometer with applied fields up to 20 kOe. Torque magnetometry was used to determine the effective perpendicular anisotropy constant of the films with a magnetic field of about 10 kOe. In our experiments, the angle of the torque curve is that between the magnetic field and normal direction of the film. A setup was established using a polarization modulation technique to measure the Faraday rotation spectra of the films in the range 600–800 nm.

III. RESULTS AND DISCUSSION

The x-ray diffraction patterns of an as-prepared film and films annealed at different temperatures are shown in Fig. 1. The patterns of all the films show the diffraction lines corresponding to the spinel structure. The diffraction pattern of an as-prepared sample exhibits a strong (400) peak and a weak (311) peak compared with the diagram of isotropic Co ferrite powder, indicating a texture of [100] axis perpendicular to the film plane. The texture becomes poorer with increasing annealing temperature below 500 °C. It is noted that the (100) texture develops again when the annealing temperature reaches $T_a=600$ °C. The same phenomena were also observed in annealed $Co_{0.8}Fe_{2.2}O_4$ with (111) texture and $Co_{0.3}Fe_{2.7}O_4$ with (110) texture under the same heat treatment conditions.

The anisotropy constants K_u and $K_\perp$ shown in Fig. 2 were defined by $K_u=K_\perp+2\pi Ms^2$, where $K_\perp$ is the effective perpendicular anisotropy constant determined from the measured torque curves. The value of K_u increases with annealing temperature from negative to positive and reaches a maximum value of 2.2×10^5 ergs/cm^3 at 500 °C. This trend of variation is in agreement with that of the squareness ratio $R=(Mr/Ms)_\perp/(Mr/Ms)_\parallel$. Figure 2 also displays the change of the squareness ratio $R=(Mr/Ms)_\perp/(Mr/Ms)_\parallel$ with annealing temperature. R is determined by measuring hysteresis loops in both directions perpendicular and parallel to the film plane. The change of R with annealing temperature is similar to that of K_u. The increase of R and positive K_u indicate that perpendicular anisotropy developed in the films after annealing.

The coercive forces ($Hc_\perp$) were measured in a direction perpendicular to the film plane. With increasing annealing temperature, $Hc_\perp$ increases below annealing temperature

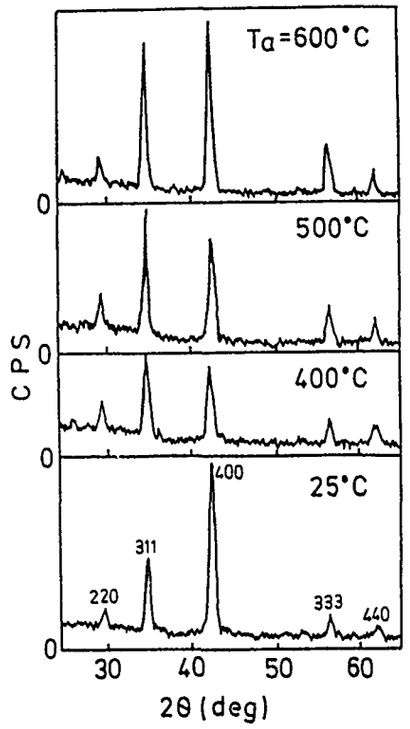

FIG. 1. X-ray diffraction patterns of $CoFe_2O_4$ films annealed at different temperatures (T_a), T_a=25 (as prepared), 400, 500, and 600 °C.

T_a=500 °C. The variation of coercive force $Hc_\perp$ with annealing temperature goes parallel to the change of the perpendicular anisotropy constant K_u.

It is worthwhile noting that the pronounced (400) peak in as-sputtered film exhibits a preferential orientation of [100] axis normal to the film plane, which should lead to a positive perpendicular anisotropy constant in the films according to the literature.[1] But the values of K_u and R of as-sputtered films show in-plane anisotropy.

The possible origins of the anisotropy in Co spinel ferrite films were assumed as follows: (1) shape anisotropy of films, (2) thermal stress-induced anisotropy, (3) crystalline anisotropy, (4) Co^{2+} induced uniaxial anisotropy.

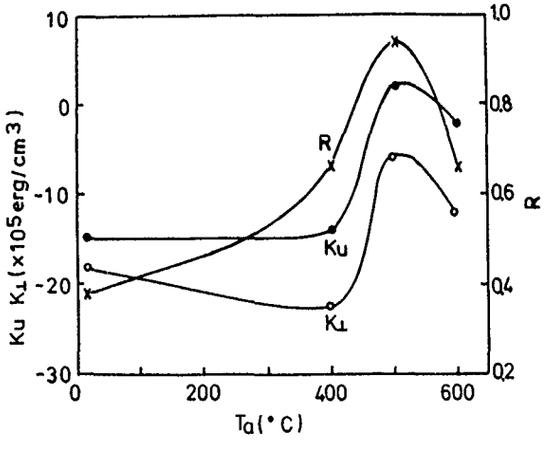

FIG. 2. The variation of anisotropy constants K_u, $K_\perp$ and squareness ratio $R=(Mr/Ms)_\perp/(Mr/Ms)_\parallel$ with annealing temperature.

The shape anisotropy of films caused by the demagnetizing field of the film, expressed as $-2\pi Ms^2$, has been considered in calculating $K_u=K_\perp+2\pi Ms^2$.

Thermal stress-induced anisotropy may exist in our films. There is tensile stress in our films prepared on glass substrates.[1] The effective anisotropy constant due to the thermal stress (K_σ) is $-3\lambda\sigma/2$. Here λ is the magnetostriction coefficient. For Co spinel ferrite: the (100) magnetostriction coefficient is $\lambda_{100}=-590\times10^{-6}$,[4] the magnetostriction in isotropy polycrystalline samples is $\lambda_s=-110\times10^{-6}$. Thus thermal stress leads to a positive-induced perpendicular anisotropy which should be larger for the samples with (100) texture and smaller for isotropy samples. However the stress-induced anisotropy does not conform with the maximum perpendicular K_u, which appeared in the sample annealed at 500 °C, in which the (100) texture is poorer, thus the magnetostriction effect in the film plane is smaller. The variation of K_σ did not follow the experimentallv observed variation of K_u. Thermal stress-induced anisotropy is therefore not the main origin of the presently observed K_u variation with annealing temperature.

Co spinel ferrite is of cubic symmetry and has a large positive anisotropy constant K_1, 2.4×10^6 ergs/cm^3. [100]-type axes are the easy magnetization axes. The magnetocrystalline anisotropy of the sample with (100) texture may give rise to a uniaxial anisotropy as measured by torque magnetometry. However the magnetocrystalline anisotropy cannot explain the large negative anisotropy constants of the films with (100) texture and there is an inconsistency between the variation of (100) texture and the measured perpendicular anisotropy. Therefore magnetocrystalline anisotropy is not the main origin of the anomalous variation of anisotropy in the films with T_a either.

Large uniaxial anisotropy induced by magnetic field annealing in Co spinel ferrite is well known. Penoyer and Bickford[5] reported the mechanism of this induced anisotropy due to the migration of the cobalt ions. It has been reported that the distribution of divalent Co ions may change with thermal history of the sample.[6,7] When our films were annealed without external magnetic field, the induced anisotropy also existed in the direction of the spontaneous magnetization. Thus Co^{2+} induced uniaxial anisotropy cannot be neglected in these films. The following is our tentative idea to explain our experimental results.

The magnetization is in the film plane during sputtering and annealing because of the demagnetizing field of the film, the induced anisotropy constant due to the anisotropic distribution of Co^{2+} should be negative, if present at all. During sputtering, the substrate temperature may be as high as about 300 °C and thus the as-sputtered film crystallizes. It is reasonable to assume that a negative-induced anisotropy K_i due to the anisotropic distribution of Co^{2+} ions develops during sputtering. Such induced anisotropy can also be assumed for the annealing and subsequent quenching process. Therefore the total anisotropy of the films is the sum of positive crystalline anisotropy K_a, positive stress anisotropy K_σ, and negative K_i, $K_u=K_a+K_\sigma+K_i$. For the as-sputtered film an

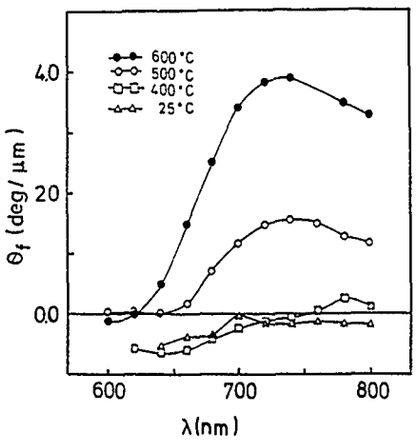

FIG. 3. The Faraday spectra of Co spinel ferrite films annealed at different temperatures.

absolute value of K_t is larger than K_a+K_σ and may be the origin of negative K_u. For annealed films a positive K_a may decrease slightly due to a slight decrease of (100) texture and positive K_σ may increase due to higher annealing temperature, but the magnitude of negative K_t surely decreases for higher annealing temperature because $|K_t|$ is proportional to the square of magnetization at annealing temperature T_a which is lower for higher T_a and is inverse proportional to T_a. The increase of K_u from negative to positive, with annealing temperature for $T_a \leq 500$ °C, is mainly due to the decrease of $|K_t|$. But it remains a problem to explain the decrease of K_u at 600 °C. It may be related to an increase of the number of divalent Co ions in tetrahedral sites, which we found from the Faraday spectra of films reported below. The single ion anisotropy of Co^{2+} in tetrahedral site is -79×10^{-17} ergs/ion which is $+850\times10^{-17}$ ergs/ion (at 0 K) in octahedral site.[8]

The Faraday spectra of prepared films shown in Fig. 3 were measured in the wavelength range from 600 to 800 nm. A peak centered near 720 nm in the spectra developed with increasing annealing temperature, reaching a maximum value of 3.8×10^4 deg/cm at wavelength 720 nm when $T_a=600$ °C.

One origin of the increase of Faraday rotation angle with annealing temperature is the improvement of crystal structure including oxygen absorption of the film during annealing. The improvement of crystal structure can be reflected from the increase of magnetization with annealing temperature. The magnetization of as-sputtered film is 305 emu/cm^3 and increases to 384 emu/cm^3 at $T_a=400$ °C, and 400 emu/cm^3 at $T_a=600$ °C. The Faraday rotation peak increases more rapidly than the magnetization for $T_a>400$ °C. Mechanisms other than the improvement of the crystal structure may exist.

The mechanism of enhanced Faraday effect around 720 nm in Co spinel ferrites is associated with the crystal field transition of divalent cobalt ions in the tetrahedral sites.[9] De Guire *et al.*[10] reported the transformation of cobalt spinel ferrite from inverse to normal in a sample subjected to large cooling rates. An increase of the number of Co ions in tetrahedral sites was reported to enhance the Faraday effect at a wavelength of 720 nm.[1,3,9] An increase of the number of divalent cobalt ions in tetrahedral sites may therefore be another reason for the observed increase of the Faraday rotation in our films annealed at higher temperature.

IV. CONCLUSION

(100) texture is necessary in Co spinel ferrite films to get perpendicular anisotropy according to the current literature.[1,4] In contrast, our different experimental results indicate that the poorer (100) textured films exhibit a better perpendicular anisotropy. Thermal stress-induced anisotropy may be one origin of a positive perpendicular anisotropy in our films. The main reason of the variation of the perpendicular anisotropy in our films with annealing temperature, however, is thought to be annealing-induced anisotropy and Co ion distribution in tetrahedral sites and octahedral sites. The increase of Faraday rotation with annealing temperature seems to have two origins: (a) the improvement of crystal structure, (b) the increase of the number of divalent Co ions in the tetrahedral sites.

Magnetic and magneto-optical properties of (Tb,Dy)Nd/FeCo multilayers (abstract)

X. Y. Yu Y. Fujiwara, H. Watabe, S. Iwata, S. Tsunashima, and S. Uchiyama
Department of Electronics, Nagoya University, Nagoya 464-01, Japan

Nd-Co and Nd-FeCo amorphous films are known to have larger Kerr rotation θ_k at shorter wavelength and ultraviolet light compared with other RE-TM (rare earth-transition) amorphous films. This property is desirable for MO (magneto-optical) media for the next generation. In order to satisfy the perpendicular magnetization condition, we replaced a part of Nd by Gd to decrease the saturation magnetization *Ms* and applied the multilayer (ML) structure to enhance the perpendicular anisotropy Ku. Then we succeeded in getting a new ML medium of $Nd_{0.34}Gd_{0.66}/Fe_{0.9}Co_{0.1}$ with a bilayer period of 1 nm. However, the substitution of 66% Gd resulted in undesirable decreases of Kerr rotation and coercivity. In this experiment, a part of Nd is replaced by either Tb or Dy instead of Gd with an expectation that the amount of replacement to get the perpendicular magnetization configuration may be smaller since Tb and Dy have large one ion anisotropy compared with Gd. The magnetic and MO properties of Nd(Tb,Dy)/FeCo MLs will be reported. In the case of Tb, for example, a square Kerr hysteresis loop is obtained by the substitution of about 40%. However, θ_K at 400 nm is about 0.30°, which is larger than that of Tb-FeCo but smaller than NdGd/FeCo MLs.

Magnetization reversal dynamics in CoPt alloys and Co/Pt multilayers (abstract)

J. Valentin and Th. Kleinefeld
Universität Duisburg, FB10/Angewandte Physik, D-4100 Duisburg, Germany

D. Weller
IBM Almaden Research Center, 650 Harry Road, San Jose, California 95120

We have studied the dynamics of magnetization reversal processes in magneto-optic recording CoPt samples with perpendicular anisotropy. Thin films of subatomic layered $Co_{25}Pt_{75}$ alloys as well as Co/Pt multilayers with total thicknesses up to 300 Å were investigated. By means of polar Kerr microscopy we were able to obtain the magnetic domain pattern. High temporal resolution was achieved by using a rapid scanning CCD camera system. Depending on film parameters, we found wall motion dominated and nucleation dominated magnetic reversal processes. Detailed analysis of the domain topography shows evidence for a correlation of the fractal dimension of the domain shape to the macroscopic coercivity measured with a VSM and conventional Kerr hysteresis loops. In particular, we investigated the dynamics of magnetization reversal and observed magnetic aftereffect phenomena. The time constant of the relaxation of the magnetization is strongly affected by the film structure and by the film thickness. We discuss our results in terms of the theoretical relaxation model of Fatuzzo and recent computer simulations.

$(BiDy)Fe_5O_{12}$ films in the amorphous state were made by rf magnetron sputtering from a sintered $Bi_2DyFe_5O_{12}$ ceramic target onto quartz substrates and confirmed by x-ray diffraction. The films were annealed at different temperatures ranging from 500 to 800 °C for 1 h in air. The crystallization temperature was about 650 °C, as measured by DTA method. Magnetization M versus temperature relation of well crystallized films showed both a compensation temperature T_{comp} (80 K) and Curie temperature T_C (563 K). The M-T curve from 1.5 to 600 K of amorphous film showed no definite T_C or T_{comp}; M measured in a field of 20 kOe decreased monotonously. The Faraday rotation (500–700 nm) of amorphous films was small. The M and Faraday rotation (633 nm) increased rapidly at the crystallization temperature. The Bi ion induced peak (550 nm) in the Faraday spectra got higher with the increasing annealing temperature and was up to 9.14 degree/μm. The Faraday spectra of films annealed at 650 °C for different times showed that the films were well crystallized after annealing for 10 min. The optical absorption of the films in the visible region varied little during the transformation from amorphous to polycrystalline.

Epitaxial Bi-content ferrite-garnet film memory (abstract)

E. I. Il'yashenko
Applied Engineering Systems (A.E.S.), Moscow, Russia

V. P. Klin, A. D. Nickolsky, and A. G. Solovjov
Institute of Electronic Materials, Kaluga, Russia

Memory conception in epitaxial ferrite-garnet films on a compensation wall has been developed in recent work.[1] Further original solutions for memory element formation by heat treatment under Si layers have been found but this method has not been used in practice due to the difficulty of reproducing results. In this work the possibility of a memory matrix on the ferrite-garnet films by rf treatment has been investigated. In comparison with other work[2] this memory element formation method arrived at by an M_S decrease due to Ga redistribution from octahedral into tetrahedral positions provides the possibility to decrease significantly the device power intensity, to increase the speed of response, and to simplify the designing and technology. The work has been carried out with $(YBi)_3(FeGa)_5O_{12}$ films doped by Lu, Tm, Gd, Pr, and grown by the LPE method on GGG and GGG+CaMgZr substrates. The treatment mode and film composition influence upon the element switching stable threshold has been studied and read-only memory formation parameters have been found. Experimental results of rf-treatment influence upon epitaxial layer magnetic and magneto-optic features and main display parameters (optical transmission, contrast, speed of response) have been provided. The possibility of element formation from 1 up to 20 μm with a space of 12 μm and over has been shown. Figure 1 shows memory file elements with 60 and 20 μm space between them.

Ferromagnetism of YFe_2H_x

Kazuo Kanematsu
The Physical Science Laboratories, Nihon University at Narashino, Funabashi, Chibaken 274, Japan

Isothermal hydrogen absorption of YFe_2 at several temperatures forms four types of hydrides: δ, γ, β_1, and β_2. The δ hydrides with an orthorhombic $MgCu_2$-type structure, $YFe_2H_{4.1}$, are ferromagnets of $3.8\mu_B$/f.u. ($YFe_2H_{4.1}$) and T_c=310 K. The Mössbauer spectrum is analyzed with the direction of magnetization along [111]. The γ hydride $YFe_2H_{2.4}$ is a rhombohedral-type ferromagnet of $3.5\mu_B$/f.u. and T_c=500 K. The spectrum is analyzed with the direction of magnetization along the c axis. Both β_1 hydride $YFe_2H_{1.9}$ and β_2 hydrides $YFe_2H_{1.3}$ are rhombohedral-type ferromagnets of $3.5\mu_B$/f.u. and T_c=570 K. The β_1 hydride shows a smooth decrease of magnetization but the β_2 hydride shows a large decrease of magnetization between 200 and 400 K. The Mössbauer spectra of both hydrides are analyzed with the direction of magnetization in the c plane. The magnetization decrease in the β_2 hydride is discussed, assuming high- and low-magnetization phases.

I. INTRODUCTION

The cubic Laves phase compound YFe_2 forms a hydride, YFe_2H_4, by hydrogenation at room temperature. The hydrogenation brings an increase in magnetization and a decrease of Curie temperature.[1-3] Recently, four kinds of YFe_2H_x hydrides were found in the isothermal hydrogen absorption at a temperature of 293 K$\leq T\leq$573 K.[4] The hydrogenation at 293 K forms δ hydride with an orthorhombic $C15$-type of structure. The hydrogenation in 323 K$\leq T\leq$423 K forms γ hydrides with a hexagonal structure of a=0.55 nm and c=2.65 nm. The hydrogenation in 473 K$\leq T\leq$573 K forms β hydrides with a hexagonal structure of a=0.515 nm and c=2.46 nm. The temperature dependence of magnetization shows that the β hydrides are classified in β_1 and β_2 hydrides formed at 473 K$\leq T\leq$500 K and 523 K$\leq T$, respectively. Mössbauer studies were performed for the representatives of δ, γ, β_1, and β_2 hydrides and the spectra were analyzed. In the present article the details of experimental results and the analyzed results are reported and the ferromagnetism of each hydride is discussed.

II. EXPERIMENTAL PROCEDURE

The host compound YFe_2 was prepared by arc melting a mixture of Y (99.9% pure) and Fe (99.9% pure) with stoichiometric compositon in argon atomsphere. Arc melting was repeated several times for homogeneity. Then the compound was sealed in an evacuated silica tube and annealed at 1100 K for 0.26 Ms (3 days). After the crystal structure was ascertained by x-ray diffraction, the powder with particles smaller than 0.3 mm was used for hydrogen absorption as the host compound. The isothermal hydrogen absorption was carried out in hydrogen pressure up to about 0.9 MPa after heating in vacuum at 670 K for about 4 ks (1 h). The γ and β hydrides used for magnetization and Mössbauer measurements were prepared with rapid cooling after eliminating the remaining hydrogen gas in the hydride capsule in order to avoid further hydrogenation at lower temperature. The number of absorbed hydrogen atoms was determined from gravimetric increase. The magnetization measurement was performed by a vibrating sample magnetometer in magnetic field of 0.84 MA/m (10.6 kOe). Mössbauer measurement was carried out for the samples used in magnetization measurements by a conventional constant acceleration-type spectrometer with ^{57}Co in Rh source.

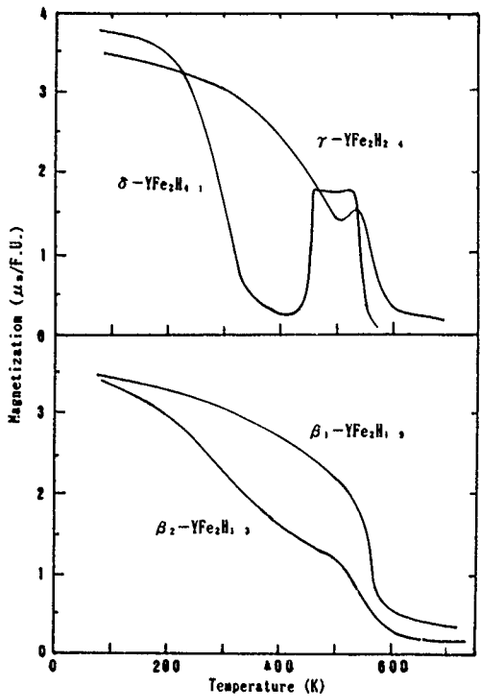

FIG. 1. Temperature dependencies of magnetization of δ hydride $YFe_2H_{4.1}$, γ hydride $YFe_2H_{2.4}$, β_1 hydride $YFe_2H_{1.9}$, and β_2 hydride $YFe_2H_{1.3}$ in H=0.84 MA/m (10.6 kOe). Anomalies near 500 K in δ and γ hydrides come from β hydride formed by desorption of hydrogen.

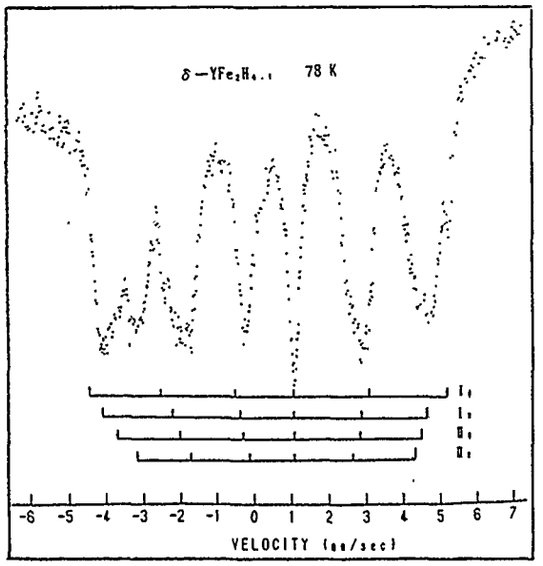

FIG. 2. Mössbauer spectrum of δ hydride $YFe_2H_{4.1}$ at 78 K, which is analyzed as the direction of magnetization is along [111].

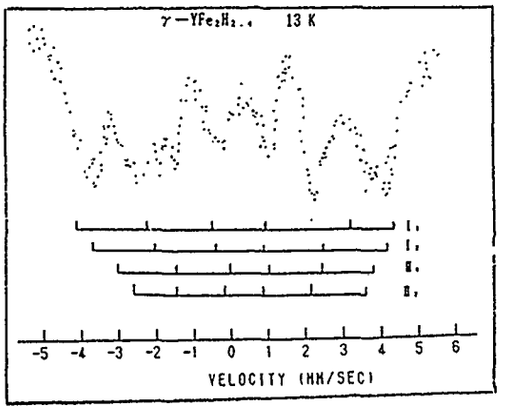

FIG. 3. Mössbauer spectrum of γ hydride $YFe_2H_{2.4}$ at 13 K, which is analyzed as the direction of magnetization is along the c axis.

III. RESULTS AND DISCUSSION

A. δ-hydride $YFe_2H_{4.1}$

The crystal structure of YFe_2 is $C15$ type with $a=0.737$ nm, and the magnetization and Curie temperature are $2.9\mu_B/YFe_2$ and $T_c=545$ K, respectively.

The δ hydride was prepared at 293 K. The crystal structure is an orthorhombic $C15$-type structure with $a=0.798$ nm, $b=0.783$ nm, and $c=0.807$ nm. The magnetization at 0 K estimated by extrapolation of the thermomagnetic curve is $3.8\mu_B$/f.u. (formula unit, YFe_2H_x) and the Curie temperature is 310 K [Fig. 1(a)].

TABLE I. Hyperfine fields H_i, quadrupole splittings ΔE, and isomer shifts.

Hydride and temperature	Spectrum	Hyperfine field H_i (kOe)	Quadrupole splitting ΔE (mm/s)	Isomer shift (mm/s)
δ-$YFe_2H_{4.1}$	I_1	307	0.09	0.39
78 K	I_2	288	−0.03	0.36
	II_1	260	0.09	0.40
	II_2	240	−0.03	0.45
γ-$YFe_2H_{2.4}$	I_1	275	−0.12	0.17
13 K	I_2	250	0.04	0.22
	II_1	221	−0.15	0.39
	II_2	195	0.05	0.14
β_1-$YFe_2H_{1.9}$	I_1	201	−0.30	−0.12

	I_2	230	0.30	0.03
	II	42		

The Mössbauer spectrum of $C15$-type compounds AFe_2 shows characteristic properties.[5,6] If the direction is [111], the Mössbauer spectrum of AFe_2 compounds is a superposition of two subspectra with the intensity ratio of 1/3 and the

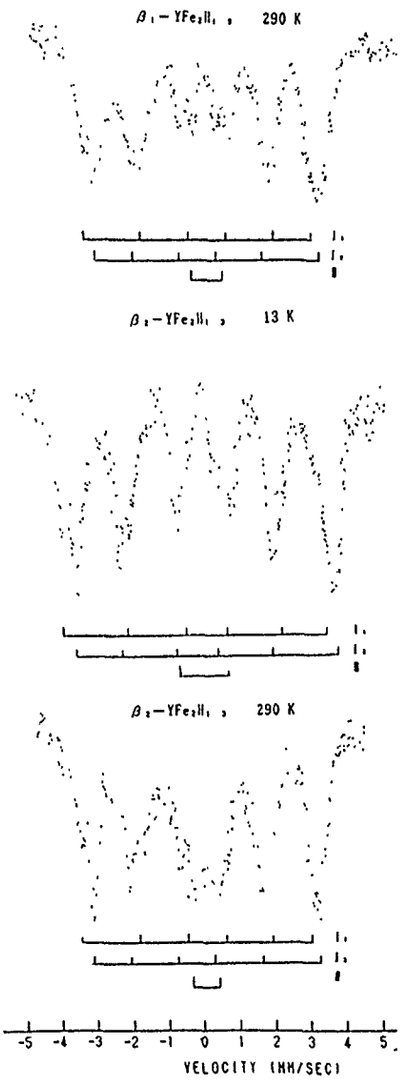

FIG. 4. Mössbauer spectra of β_1 hydride $YFe_2H_{1.9}$ at 290 K and β_2 hydride $YFe_2H_{1.3}$ at 290 and 13 K. The (I_1,I_2) are spectra when the direction of magnetization is in the c plane. The spectra (I_1,I_2) and II are interpreted to come from high- and low-magnetization phases.

ratio of quadrupole splitting of −3. The [110] direction of magnetization gives superposition of two subspectra with equal intensity and the ratio of quadrupole splitting of −1. The [100] direction gives a single spectrum.

The spectrum of δ-$YFe_2H_{4.1}$ may be a superposition of many subspe[illegible] because of the orthorhombic distortion. The spectrum at 7[illegible] K (Fig. 2) is analyzed as a superposition of two pairs of subspectra (I_1,I_2) and (II_1,II_2), which are observed when the direction of magnetization is along [111]. The Mössbauer parameters are listed in Table I.

B. γ-hydride $YFe_2H_{2.4}$

The γ-hydride $YFe_2H_{2.4}$ was prepared at 423 K. The x-ray-diffraction lines are indexed as a hexagonal structure of $a=0.566$ nm and $c=2.644$ nm. They are similar to, but not same as, those of rhombohedral ($R\bar{3}m$) $PuNi_3$-type $YCo_{2.9}$ (Ref. 7) and $YFe_{2.9}$.[8] The magnetization at 0 K estimated by extrapolation of the thermomagnetic curve is $3.5\mu_B/YFe_2H_{2.4}$ and the Curie temperature is about 500 K [Fig. 1(a)].

The iron atoms in rhombohedral YFe_3 form a tetrahedral network similar to those of YFe_2, and the c axis [001] and the a axis in c-plane [100] in hexagonal representation correspond to [111] and [110] directions in cubic structure, respectively. The spectrum at 13 K (Fig. 3) is analyzed as a superposition of two pairs of spectra, (I_1,I_2) and (II_1,II_2), which are observed when the direction of magnetization is along the c axis. The Mössbauer parameters are listed in Table I.

C. β_1 hydride $YFe_2H_{1.9}$ and β_2 hydride $YFe_2H_{1.3}$

The β_1 hydride $YFe_2H_{1.9}$ was formed at 500 K and the β_2 hydride $YFe_2H_{1.3}$ was formed at 523 K. The x-ray-diffraction lines of both hydrides are nearly the same and are indexed as a hexagonal structure of $a=0.514$ nm and $c=2.467$ nm for $YFe_2H_{1.9}$ and $a=0.514$ nm and $c=2.463$ nm for $YFe_2H_{1.3}$. They are similar to, but not same as, those of γ-$YFe_2H_{2.4}$, $YCo_{2.9}$, and $YFe_{2.9}$. The extrapolated values of magnetization at 0 K are $3.5\mu_B/YFe_2H_x$. The Curie temperatures of both hydrides are about 570 K, but the magnetization decrease of β_2 hydride occurred reversibly with heating and cooling between 200 and 400 K. Although the decrease suggests another ferromagnetic phase of lower Curie temperature, the x-ray-diffraction pattern at room temperature shows no other phase. Therefore, it is assumed that the magnetization decrease results from a transition between two magnetic phases of high and low magnetization with same structure.

The spectra of β_1 hydride $YFe_2H_{1.9}$ at 290 K and β_2 hydride $YFe_2H_{1.3}$ at 13 and 290 K are analyzed as a superposition of subspectra (I_1,I_2), and II (Fig. 4). The pair (I_1,I_2) are the spectra when the direction of magnetization is along the a axis in the c plane. The parameters are listed in Table I. The pair of subspectra (I_1,I_2) come from the high-magnetization phase, and the subspectrum II comes from the low-magnetization phase. The increase of relative intensity of subspectrum II with increasing temperature supports the transition from the high-magnetization phase to the low-magnetization phase. At present, it is not clear whether the two magnetic phase[illegible] exist separately or high and low spin states of iron atoms c[illegible]xist in the rhombohedral lattice. This is a problem for future study.

Longitudinal and transverse magnetoresistance and magnetoresistive anisotropy in ternary $(Pd_{1-x}Fe_x)_{95}Mn_5$ alloys

Z. Wang, H. P. Kunkel, and Gwyn Williams
Department of Physics, University of Manitoba, Winnipeg, Manitoba, Canada R3T 2N2

A summary of detailed measurements of the longitudinal and transverse magnetoresistance, and of the anisotropy in the magnetoresistance of ternary $(Pd_{1-x}Fe_x)_{95}Mn_5$ samples, is presented. While neither the longitudinal nor the transverse magnetoresistance saturate, these data suggest that the anisotropy (i.e., the difference) might become field independent in quite moderate fields. This feature enables a comparison to be made between this ternary system and binary PdFe, as a function of composition and temperature

I. INTRODUCTION

Unlike *Ni*Mn (Ref. 1) or *Pd*Mn,[2] ternary (*Pd*Fe)Mn remains as an example of a system in which initial indications of sequential paramagnetic to ferromagnetic to (transverse) spin-glass transitions have not been ruled out by subsequent detailed measurements. Early studies[3] of the zero-field ac susceptibility χ_{ac} in (Pd+0.35 at. % Fe)+5 at. % Mn revealed the characteristic rapid increase in this response with decreasing temperature near 10 K as the ferromagnetic ordering temperature T_c was approached from the higher-temperature paramagnetic phase; this was followed by an essentially temperature-independent plateau region (in which χ_{ac} was not limited by demagnetization factor constraints) terminated by a sharp fall in χ_{ac} with decreasing temperature near 4 K, which was interpreted as evidence that the system had entered a phase with spin-glass-like ordering of the transverse spin components. A more quantitative set of criteria for establishing possible phase boundaries has recently been applied to this system[4] which, in addition to providing estimates of the usual critical exponents near T_c, revealed the presence of an anomaly in the leading coefficient of the field-dependent response in the vicinity of the lower candidate transition. This latter anomaly, however, was weaker than predicted,[5] so that the critical nature of this second transition remains in question.

Below we present a summary of detailed measurements of the longitudinal and transverse magnetoresistivities of $(Pd_{1-x}Fe_x)_{95}Mn_5$. These measurements not only supplement detailed field and temperature χ_{ac} studies, but also enable a comparison of the behavior of this ternary system to be made with the extensively investigated and well-understood binary system *Pd*Fe.

II. EXPERIMENTAL DETAILS

Samples with nominal composition $(Pd_{1-x}Fe_x)_{95}Mn_5$ (x =0.35, 1.6, 1.8, 2.0, and 2.2 at. %) were prepared individually in an argon arc furnace from high-purity starting materials.[6] A well-established sequence of inverting, remelting, cold rolling, and annealing procedures was implemented to ensure homogeneity of the final samples,[7] which, for transport measurements, had typical dimensions 35×2×0.1 mm.[3] A low-frequency (37 Hz) ac method[8] was used to measure the magnetoresistivities which were carried out in both the longitudinal and transverse configurations at 4.2 and 1.5 K in applied fields up to 1 T, and in the longitudinal configuration alone at the same two temperatures in fields up to 8.5 T.

III. RESULTS AND DISCUSSION

Figures 1 and 2 reproduce the longitudinal (∥) and transverse (⊥) magnetoresistivities in the liquid-helium range on (Pd+2.2 at. % Fe)+5 at. % Mn and on Pd+2.2 at. % Fe. These figures not only allow a direct comparison between the binary and ternary systems, but also demonstrate clearly the difficulties encountered in attempting to analyze the data on the ternary system quantitatively, as discussed below. As reported previously[7] and confirmed in Fig. 2, although frequently referred to as a soft ferromagnet, applied fields ($\mu_0 H_a$) in excess of 1 T are necessary to produce full saturation in dilute *Pd*Fe, in agreement with magnetization measurements;[9] in Fig. 2 $\rho_\parallel(H_a)$ at both 1.5 and 4.2 K can be seen to increase rapidly at low field (a result linked to domain effects) while above 0.1–0.2 T, $\rho_\parallel$ decreases slightly with increasing field indicating incomplete saturation. The behavior of $\rho_\perp$ is similar. In both orientations this higher-field slope increases with increasing temperature, as expected. Despite the presence of this weak noncollinear spin component the spontaneous resistive anisotropy (SRA), defined as

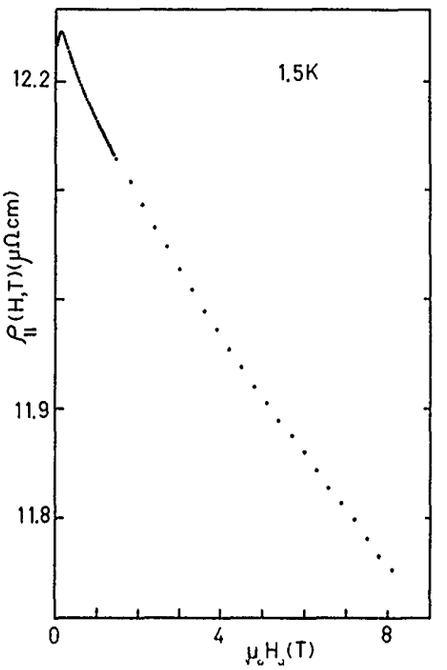

FIG. 3. The longitudinal magnetoresistance of the (Pd 2.2 at. % Fe) 5 at. % Mn sample vs applied field at 1.5 K, for an extended range of field.

$$\frac{\Delta\rho}{\rho_0}=\left(\frac{3(\rho_{\parallel}-\rho_{\perp})}{(\rho_{\parallel}+2\rho_{\perp})}\right)_{B\to 0} \tag{1}$$

can be estimated with reasonable accuracy as $\Delta\rho(H_a)=\rho_{\parallel}(H_a)-\rho_{\perp}(H_a)$ appears to become field independent above $\mu_0 H_a \simeq 0.5$ T [Fig. 2(c)], a field well below that necessary to achieve technical saturation. A similar result has been reported for amorphous *FeZr*.[10] As discussed previously[7,10] valid arguments exist to base the extrapolations implicit in Eq. (1) on the induction[11] B [$B=\mu_0(H_a+M)-NM$, M being the magnetization and N the appropriate demagnetization factor] rather than H_a, but the use of the former rather than the latter proves unnecessary here because the magnetization is small at these compositions and the higher-field variation of the resistivity is weak[7] (as confirmed in Fig. 2).

By contrast the behavior of the ternary sample at 1.5 K shown in Fig. 1 is dominated by a strong negative component in both orientations. This result is particularly striking since ac susceptibility measurements on Pd+2.2 at. % Fe yield[7] $T_c=81$ K whereas in ternary (Pd+2.2 at. % Fe)+5 at. % Mn T_c is similarly estimated at 48 K; thus, the 4.2 K data on the binary sample and the 1.5 K data on the ternary alloy were collected at essentially the same reduced temperature (T/T_c). These data on the ternary sample indicate unequivocally the presence of substantial spin noncollinearity (far in excess of that present in the corresponding binary alloy); nevertheless, the anisotropy in the magnetoresistance behaves in a similar manner to that in the binary system (apparently saturating in low field), and this forms the basis for subsequent analysis.

The extent of this noncollinearity is further demonstrated by the data reproduced in Fig. 3; in the longitudinal configuration the magnetoresistance continues to decrease in applied fields up to 8.5 T at 1.5 K, with little sign of saturation. Indeed, the fractional rate of change in resistivity ($1/\rho_0$) ($d\rho_{\parallel}/dH_a$) is nearly an order of magnitude larger at 8.5 T and 1.5 K in the ternary system than in the binary system at 1 T and 4.2 K.

The presence of such noncollinearity complicates estimates for the SRA through its influence on the field dependence of the resistivity. Figure 1(b) demonstrates the effects of replotting the data in Fig. 1(a) against the induction B, the latter being estimated with considerable care for the reasons outlined below. The induction was calculated by using directly, or scaling where necessary, previously published magnetization data (such as those of Sato *et al.*[12]) in conjunction with the corresponding demagnetizing factors, $N_{\parallel}$ and $N_{\perp}$. The latter were found by evaluating the appropriate elliptic integrals using the carefully measured dimensions of each sample. These dimensions were specifically chosen so that $N_{\perp}\simeq\mu_0$ [thus, there is essentially no difference between $\rho_{\perp}(H_a)$ and $\rho_{\perp}(B)$ in Fig. 1] while $N_{\parallel}\simeq 5\times 10^{-4}\, N_{\perp}$, so that $M(\mu_0-N_{\parallel})\simeq\mu_0 M=0.2$ T. This leads to a significant shift between $\rho_{\parallel}(H_a)$ and $\rho_{\parallel}(B)$, and while this shift plays an important role in estimates for the SRA, its reliability is determined by that of the available magnetization data (a property normally accurately measureable) not on estimates for the demagnetization factors (due to the sample geometry adopted). Figure 1(c) shows a plot of the ratio $\Delta\rho/\rho_0$ from Eq. (1) against the induction B; this ratio increases rapidly as B increases, before appearing to saturate for $B\simeq 0.4$ T despite the fact that neither $\rho_{\parallel}(B)$ or $\rho_{\perp}(B)$ show any indication of saturating; we suggest this approach to saturation in the ratio $\Delta\rho/\rho_0$ enables the SRA to be estimated in the manner shown, as indeed does the behavior of $\Delta\rho/\rho_0$ vs H_a in the binary sample [Fig. 2(c)]. In the binary system, of course, both $\rho_{\parallel}(H_a)$ and $\rho_{\perp}(H_a)$ show evidence of approach to saturation individually. It could certainly be argued that measurements

at higher fields might reveal a change in the field derivative of the SRA in the ternary system; such an argument, however, could equally well be applied to binary *Pd*Fe and amorphous *Fe*Zr. Interestingly the anisotropy $[\rho_{\parallel}(B) - \rho_{\perp}(B)]_{B\to 0}$ so estimated is approximately twice as large in the ternary sample compared with the binary alloy, but due to a fourfold increase in the residual resistivity ρ_0, the SRA is estimated to be twice as large in the binary system.

The results discussed above are typical for the composition range studied, viz., $(Pd_{1-x}Fe_x)_{95}Mn_5$ and $Pd_{1-x}Fe_x$ ($0.35 \leqslant x \leqslant 2.2$ at. % Fe), as summarized in Table I.

IV. CONCLUSIONS

Both the longitudinal and transverse magnetoresistivities of $(Pd_{1-x}Fe_x)_{95}Mn_5$ provide unequivocal evidence of noncollinearity in the impurity spins at temperatures as low as 3% of the ferromagnetic ordering temperature. Despite these complications, the SRA appears to saturate in low fields which, we suggest, enables estimates for the SRA to be made. Similar results have been reported in other systems,[7,10] although the noncollinearity is admittedly weaker in them, the apparent saturation of the SRA being attributed to the fact that while the high-field slope of the magnetization curves reveals noncollinearity on a global scale, both the magnetoresistivity and SRA reflect changes on length scales on the order of the conduction-electron mean free path (a scale over which the noncollinearity may not be so marked). As demonstrated by Fig. 1, this is clearly not the case in $(Pd_{1-x}Fe_x)_{95}Mn_5$. Currently there is no theoretical guidance available for interpreting the SRA in noncollinear systems; we have recently[13] applied an Ising model to successfully reproduce the characteristics of the SRA in the immediate vicinity of T_c in a number of ferromagnetic systems, however, the very nature of this model precludes its application to reentrant systems in which the noncollinearity arises from transverse spin-glass order combined with longitudinal ferromagnetic alignment. Furthermore, if indeed the spin configuration in $(Pd_{1-x}Fe_x)_{95}Mn_5$ is of this latter type then measurements in high fields (certainly those high enough to achieve technical saturation) should be avoided since they would disrupt the intrinsic spin polarization characteristic of the ground state. The situation is analogous to measuring the nonlinear magnetization of spin glasses; the balance that needs to be achieved is one in which the applied field is not large enough to significantly alter the ground-state configuration yet does reveal any "incipient" anisotropy/nonlinearity. The results reported here represent an initial attempt to understand aspects of this complicated problem. Such difficulties notwithstanding, the concentration dependence of the SRA in binary *Pd*Fe and *Pd*Mn has been interpreted previously[14] as indicating the absence of an orbital moment at the impurity sites in these systems, and the magnitude and composition dependence of the SRA in the ternary system (summarized in Table I) would, not surprisingly, lead to a similar conclusion for it.

Formation and magnetic properties of $Y_2(Fe_{0.8}Ga_{0.2})_{17}C_x$ compounds

Fang-Wei Wang, Lin-Shu Kong, Lei Cao, Ming Hu, Bao-Gen Shen, and Jian-Gao Zhao
State Key Laboratory of Magnetism, Institute of Physics, Chinese Academy of Sciences, Beijing 100080, People's Republic of China

The alloys $Y_2(Fe_{0.8}Ga_{0.2})_{17}C_x$ (x=0–2.5) with the rhombohedral Th_2Zn_{17} phase were prepared by arc melting. The lattice parameters and the unit-cell volumes derived from x-ray-diffraction measurements increase linearly with the carbon content x. The Curie temperature T_c increases at first with increasing carbon concentration x, shows a maximum value of 558 K at about x=1.0, then decreases with x. The saturation magnetization at 1.5 K and the Fe magnetic moment have a slight change with the interstitial carbon content. The dilution of Fe by nonmagnetic Ga decreases the saturation magnetization and the Fe magnetic moment.

I. INTRODUCTION

Intermetallic compounds of the R_2Fe_{17}(R denotes rare earth) have attracted much attention recently because they can dissolve large amounts of interstitial nitrogen and carbon by the solid-gas reaction,[1,2] which can enhance their magnetic properties considerably. The $Sm_2Fe_{17}N_x$ compound with excellent intrinsic magnetic properties[1–3] is a hopeful candidate for new permanent magnets. It is to be regretted that these nitrides and carbides are unstable at high temperatures. Early in 1988, de Mooij and Buschow[4] reported on the ternary $R_2Fe_{17}C_x$ compounds by means of arc melting, but the interstitial carbon concentration is much lower and the intrinsic magnetic properties are unfit for permanent magnets. Last year, Shen *et al.*[5–7] produced $R_2Fe_{17}C_x$ compounds with high carbon concentration which are stable at 1100 °C by melt spinning. However, it is difficult to gain a single 2:17-type phase carbide with high carbon if R is a light rare earth. Therefore, by substituting for Fe in $R_2Fe_{17}C_x$, we try to search for a path to gain high-carbon compounds with a single 2:17-type phase. We have reported some results of the $R_2(Fe,Ga)_{17}C_x$ compounds prepared by arc melting.[8,9] In this article the structure and magnetic properties of $Y_2(Fe_{0.8}Ga_{0.2})_{17}C_x$ compounds are reported.

II. EXPERIMENT

The samples of compositions $Y_2(Fe_{0.8}Ga_{0.2})_{17}C_x$ (x=0, 0.5, 1.0, 1.5, 2.0, 2.5) were prepared by arc melting the appropriate amounts of Y, Fe, Ga, and Fe-C alloys in a high-purity argon atmosphere. The elements used were at least 99.9% pure. The ingots were melted several times to ensure homogeneity. Phase components and lattice parameters of the samples were determined by x-ray diffraction using Co$K\alpha$ radiation. Curie temperatures were derived from the temperature dependence of ac susceptibility in a field of less than 1 Oe. Saturation magnetizations were measured by an extracting sample magnetometer in a field of 70 kOe at 1.5 K.

III. RESULTS AND DISCUSSION

X-ray-diffraction measurements on $Y_2(Fe_{0.8}Ga_{0.2})_{17}C_x$ (x=0–2.5) ingots that were produced by arc melting show a single rhombohedral Th_2Zn_{17} phase (Fig. 1). We deduce from the x-ray-diffraction patterns that there are not any amounts of α-Fe in any compounds. According to our previous work, alloys with compositions $Y_2Fe_{17}C_x$ (x=0–2.5) prepared by arc melting formed a single 2:17-type phase only for x=0–1.0. Some amounts of α-Fe exist as an impurity phase when

2.5	8.723	12.607	830.82	519	25.3	1.86

$x>1.0$; the amount of α-Fe increases with the carbon content. If a single phase is wanted for the higher carbon concentrations, melt spinning must be adopted.[6] Thus, it can be seen that Ga substituted for Fe makes it easy to construct a single 2:17 phase with high carbon concentration. The structure of compounds $Y_2(Fe_{0.8}Ga_{0.2})_{17}C_x$ (x=0, 0.5) turns to Th_2Zn_{17} type from hexagonal Th_2Ni_{17} type for Y_2Fe_{17} and $Y_2Fe_{17}C_{0.5}$. The lattice constants a,c and the unit-cell volumes v of $Y_2(Fe_{0.8}Ga_{0.2})_{17}C_x$ deduced from x-ray-diffraction measurements are listed in Table I. They increase linearly with the carbon content and the interstitial carbon extends the lattice constant a more obviously than the lattice constant c (Fig. 2). Comparing $Y_2(Fe_{0.8}Ga_{0.2})_{17}C_x$ with $Y_2Fe_{17}C_x$,[6] it can be found that carbon has less effect on the lattice parameters of $Y_2(Fe_{0.8}Ga_{0.2})_{17}C_x$, and Ga substituted for Fe expands the unit-cell volume considerably so that there exists more space in the unit cell. It may be the reason why the high carbides of $Y_2(Fe_{0.8}Ga_{0.2})_{17}C_x$ can be obtained easily, and why the carbon has less effect on the lattice parameters of $Y_2(Fe_{0.8}Ga_{0.2})_{17}C_x$.

The concentration dependence of the Curie temperature T_c of the $Y_2(Fe_{0.8}Ga_{0.2})_{17}C_x$ compounds is shown in Fig. 3. T_c increases at first with carbon content x, and shows a maximum value of 558 K at about x=1.0, then decreases with increasing x. T_c does not increase monotonously with increasing carbon concentration although the unit-cell volume is expanded linearly. In other words, the expansion of the unit-cell volume cannot cause continuous increase of T_c in the $Y_2(Fe_{0.8}Ga_{0.2})_{17}C_x$ series. T_c of $Y_2(Fe_{0.8}Ga_{0.2})_{17}$ is enhanced remarkably about 220 K over Y_2Fe_{17}. In the theory of the mean field, it is commonly accepted that the Curie temperature of rare-earth iron compounds is determined by the Fe-Fe, R-Fe, and R-R interactions. The Fe-Fe interaction is dominant, and the R-R interaction can be neglected relative to the R-Fe interaction and the Fe-Fe interaction. As result of this, the interstitial carbon in $Y_2Fe_{17}C_x$ improves the Fe-Fe interaction considerably; but, in $Y_2(Fe_{0.8}Ga_{0.2})_{17}C_x$ it only raises a little of the Fe-Fe interaction in a carbon content range x from 0 to 1.0, then reduces the Fe-Fe interaction at higher carbon concentrations.

The saturation magnetization M_s of $Y_2(Fe_{0.8}Ga_{0.2})_{17}C_x$ compounds is summarized in Table I. We find that the addition of interstitial carbon has a slight effect on M_s. Because yttrium, gallium, and carbon are nonmagnetic elements, the magnetic moment per Fe atom μ_{Fe} in $Y_2(Fe_{0.8}Ga_{0.2})_{17}C_x$ can be obtained according to $\mu_s=0.8\times17\mu_{Fe}$ (listed in Table I) and is constant about $1.81\pm0.03\mu_B$. So, the Fe magnetic moment is approximately independent of the carbon concentration. These results have been obtained before for compounds $R_2Fe_{17}C_x$.[5,6] The dilution of Fe by nonmagnetic Ga decreases the number of Fe atoms and varies the Fe atom environment. It probably causes the saturation magnetization and the Fe magnetic moment to decrease.

Alloys with the composition $Nd_2(Fe,Ti)_{19}$ can exist in two crystal structures depending on the preparation technique. Melt-spun material has a hexagonal $TbCu_7$-type structure ($a=4.902$ Å, $c=4.248$ Å) for a range of quenching speeds. Alloys prepared by arc melting, annealing at 1373 K and then water quenching have a complex monoclinic structure derived from a $TbCu_7$ superlattice ($a=10.644$ Å, $b=8.585$ Å, $c=9.755$ Å, $\beta=96.92°$) and related to those of other intermetallics such as tetragonal $Nd(Fe,Ti)_{12}$ and rhombohedral Nd_2Fe_{17}. Magnetic ordering temperatures for annealed (monoclinic) and melt-spun (hexagonal) $Nd_2(Fe,Ti)_{19}$ are 411 and 454 K, respectively. ^{57}Fe Mössbauer spectroscopy at 295 K demonstrates that the local environments of the Fe atoms in the two structural modifications of $Nd_2(Fe,Ti)_{19}$ are similar. The average ^{57}Fe magnetic hyperfine fields at 295 K for the monoclinic and hexagonal $Nd_2(Fe,Ti)_{19}$ are 20.8 and 22.3 T, corresponding to average Fe magnetic moments of 1.33 and 1.43μ_B, respectively.

I. INTRODUCTION

Collocott *et al.*[1] recently identified a ternary phase, with a nominal composition $Nd_2(Fe,Ti)_{19}$ (2:19) close to that of the well-established $NdFe_{11}Ti$ phase with the tetragonal $ThMn_{12}$-type structure. The crystal structure of this new phase is complex and x-ray diffraction patterns of arc-melted and annealed samples were tentatively indexed on a hexagonal $TbCu_7$-type (1:7) superlattice structure with lattice parameters, $a_{2:19}=2a_{1:7}=9.88$ Å and $c_{2:19}=4c_{1:7}=16.96$ Å.[1]

There have been many reports on the presence of a phase with similar composition to that of $Nd_2(Fe,Ti)_{19}$ in the Sm-Fe-Ti and Nd-Fe-Ti ternary alloy systems. Neiva *et al.*[2] reported the formation of $Sm(Fe,Ti)_9$ with a hexagonal $TbCu_7$ structure at 1273 K, and also Hirosawa *et al.*[3] observed the formation of a $Nd(Fe,Ti)_9$ phase based on the same $TbCu_7$ structure. A Ti-stabilized $NdFe_7$ has been reported by Jang and Stadelmaier[4] in as-cast alloys, and by Navarathna *et al.*[5] in sputtered films. The formation of the $TbCu_7$ structure has also been reported in melt-spun samples, with Saito, Takahashi, and Wakiyama[6] and Ohashi, Osugi, and Tawara[7] observing a change from the $ThMn_{12}$ structure to the $TbCu_7$ structure in $SmFe_{11}Ti$ with increasing quench rate. Similarly, Katter, Wecker, and Schultz[8] observed a change from the rhombohedral Th_2Zn_{17} structure to the hexagonal $TbCu_7$ structure in rapidly quenched binary Sm-Fe alloys.

This article presents magnetic and structural data on $Nd_2(Fe,Ti)_{19}$ produced by high-temperature annealing and by rapid quenching.

II. EXPERIMENTAL PROCEDURE

Single-phase alloys of $Nd_2(Fe,Ti)_{19}$ were prepared from Nd, Fe, and Ti of ≥99.9% purity by argon arc melting followed by annealing at 1373 K for 72 h under an argon atmosphere in sealed quartz tubes, and then water quenching. Melt-spun samples were prepared on a steel wheel in a helium atmosphere. Samples were characterized by x-ray diffraction using Cu$K\alpha$ radiation, optical metallography, differential scanning calorimetry (DSC), and scanning electron microscopy using a JEOL 35CF equipped for backscattered electron imaging and energy-dispersive x-ray microanalysis. Magnetization measurements were carried out using a Quantum Design superconducting quantum interference device (SQUID) magnetometer. ^{57}Fe Mössbauer spectra were acquired at room temperature (295 K) using a constant acceleration, transmission spectrometer with a ^{57}Co**Rh** source and calibrated with an α-Fe foil.

III. RESULTS AND DISCUSSION

Single-phase samples of $Nd_2(Fe,Ti)_{19}$ can be prepared by arc melting and annealing for a range of Ti contents according to the formula $Nd_{9.4}Fe_{90.6-x}Ti_x$ with ($3.8 \leq x \leq 5.3$). No significant compositional range for Nd was detected. The samples reported here contain 4.1 at. % Ti.

Melt-spun samples of $Nd_2(Fe,Ti)_{19}$ have the hexagonal $TbCu_7$ structure [Fig. 1(a)] with lattice parameters $a=4.902$ Å and $c=4.248$ Å over a range of wheel speeds from 5 to 30 m/s and contain less than 2% of α-Fe. Arc-melted samples also contain approximately 30% of the 1:7 phase prior to annealing.

Alloys prepared by arc melting and annealing at 1373 K exhibit a more complex structure. The x-ray diffraction data, shown in Fig. 1(b), which had originally been indexed[1] on a $2\times a$ and $4\times c$ superlattice of hexagonal $TbCu_7$ type has been reindexed using the Visser code[9] on the basis of a monoclinic cell with lattice parameters $a=10.644$ Å, $b=8.585$ Å, $c=9.755$ Å, and $\beta=96.92°$. Calculated and measured line positions and indices are shown in Table I for this structure. The relationship of the monoclinic $Nd_2(Fe,Ti)_{19}$ structure to

[a]Unaccounted line.

$TbCu_7$ is best illustrated by reference to Fig. 2, which shows the a-c plane of hexagonal $TbCu_7$. The lattice parameters of the outlined cell are $a=10.685$ Å ($b_{2\cdot19}\approx\sqrt{3}a_{1.7}$), $c=9.809$ Å, and $\beta=96.56°$, all of which are very close to the measured values for monoclinic $Nd_2(Fe,Ti)_{19}$. In the absence of single-crystal x-ray data or of a full profile refinement of the powder x-ray data, our identification of the annealed $Nd_2(Fe,Ti)_{19}$ structure as monoclinic and based upon a superlattice of hexagonal $TbCu_7$ must remain provisional. A cell derived from an even larger $TbCu_7$ superlattice is possible. However, it is probable that the structure of annealed $Nd_2(Fe,Ti)_{19}$ is related to that of melt-spun $Nd_2(Fe,Ti)_{19}$ (i.e., $TbCu_7$) by an ordering of the atoms on the $TbCu_7$ sites, and a minor distortion of the hexagonal lattice. Therefore, it is also related to other rare-earth transition-metal structures such as Th_2Zn_{17}, Th_2Ni_{17}, and $ThMn_{12}$.

Figure 3 shows magnetization data for isotropic polycrystalline samples of annealed and melt-spun $Nd_2(Fe,Ti)_{19}$ in applied fields of 0.1 and 5 T. Curie temperatures derived from low-field magnetization data are 411 K (annealed) and 454 K (melt spun), in agreement with the values measured by DSC.

Mössbauer spectra for the two structural modifications of $Nd_2(Fe,Ti)_{19}$ are shown in Fig. 4. It is obvious from the data that the local environment of the Fe atoms in the two structures is similar. In the case of annealed $Nd_2(Fe,Ti)_{19}$ a fit using five subspectra of sextets proved satisfactory,[10] while for the melt-spun sample the data were fitted by a distribution of hyperfine fields using the program of LeCäer and Dubois.[11] The average hyperfine field at room temperature for the melt-spun material (22.3 T) is higher than for annealed samples (20.8 T), in line with the difference in their Curie temperatures.

IV. CONCLUSION

We have shown by x-ray diffraction that alloys of $Nd_2(Fe,Ti)_{19}$ prepared by melt spinning, and by arc melting

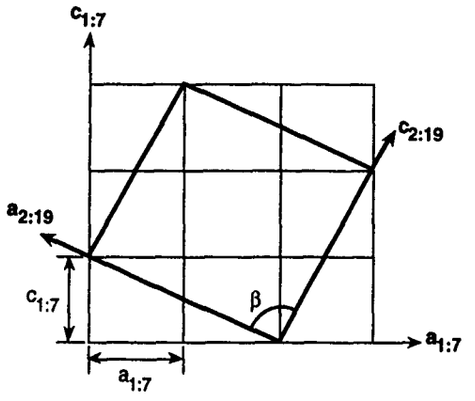

FIG. 2. Crystallographic relationship in the a-c plane between the unit cell of monoclinic $Nd_2(Fe,Ti)_{19}$ and the hexagonal $TbCu_7$ superlattice.

and annealing crystallize in two distinct structures. Of the two structural modifications, the melt-spun material with the hexagonal $TbCu_7$-type (a=4.902 Å, c=4.248 Å) structure is the simplest. The structure of arc-melted and annealed samples is more complex than the $2\times a$ and $4\times c$ superlattice of the $TbCu_7$ type proposed in our earlier report,[1] and even the monoclinic structure reported here (a=10.644 Å, b=8.585 Å, c=9.755 Å, and β=96.92°) must only be regarded as provisional until single-crystal x-ray data become available.

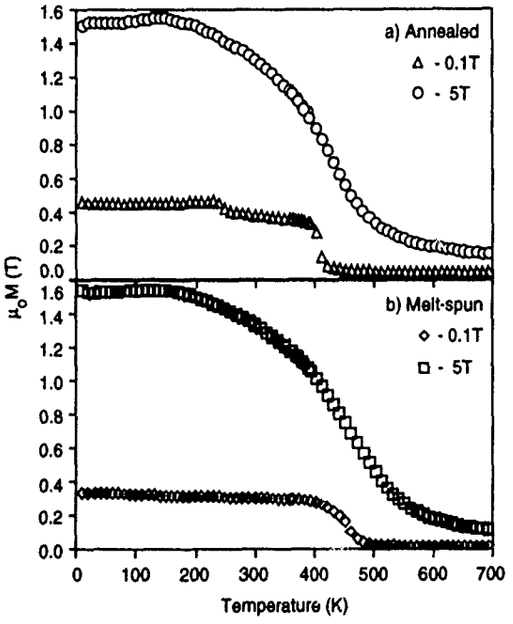

FIG. 3. Magnetization curves for (a) annealed and (b) melt-spun $Nd_2(Fe,Ti)_{19}$ at 0.1 and 5 T.

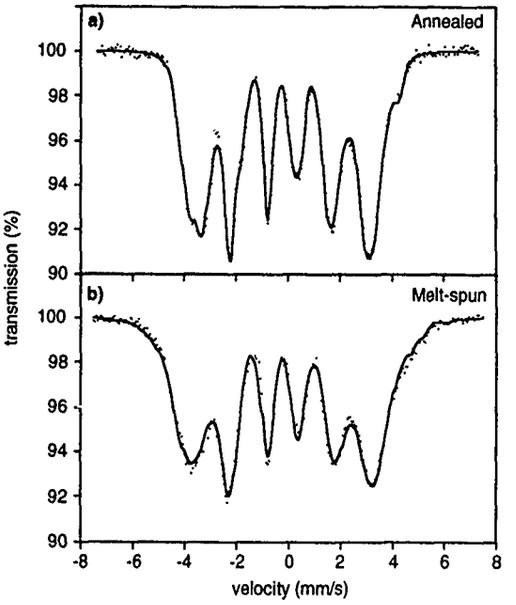

FIG. 4. Mössbauer spectra at 295 K for (a) annealed and (b) melt-spun $Nd_2(Fe,Ti)_{19}$.

Mössbauer spectra of melt-spun, and arc-melted and annealed samples demonstrate that the local environments of the Fe atoms are similar. The average ^{57}Fe hyperfine field of 20.8 T for annealed and 22.3 T for melt-spun material corresponds to average Fe magnetic moments of 1.33 and 1.43μ_B, respectively. The larger hyperfine field of the melt-spun material can be attributed to its higher Curie temperature.

The possibility of ferrimagnetic coupling between the magnetic moments of the light-rare-earth (Nd, Pr) ions and of the transition-metal (Fe) ions in $Nd_6Ga_3Fe_{11}$- and $Pr_6Ga_3Fe_{11}$-based compounds is deduced from the high-field magnetization curves measured at 4.2 K on magnetically aligned and on free-powder samples and from the temperature dependence of the magnetization. The ferrimagnetic coupling is very weak: at 4.2 K, the rare-earth moments and the transition-metal moments can be forced to ferromagnetic alignment by application of an external magnetic field of about 4 T. Generally, in intermetallic compounds, the magnetic coupling is ferromagnetic between light-rare-earth and transition-metal ions and ferrimagnetic between heavy-rare-earth and transition-metal ions. The present results suggest that in some crystal structures ferrimagnetic coupling also may exist in the compounds formed by light-rare-earth and transition-metal elements.

I. INTRODUCTION

The compounds $Nd_6Ga_3Fe_{11}$ and $Pr_6Ga_3Fe_{11}$ crystallize in the $La_6Ga_3Co_{11}$-type of structure with space group $I4/mcm$.[1] The crystal structure of $La_6Ga_3Co_{11}$ is shown in Fig. 1. The rare-earth atoms occupy two different crystallographic sites, $La1$ and $La2$. The Ga atoms occupy one site and share another site with Co. It can be seen from Fig. 1 that the crystal entails a stacking of layers of Co, rare-earth, and Ga atoms.

Magnetization transitions at low field strengths have been found at low temperatures in the $R_6Ga_3Fe_{11}$ compounds with R=Nd, Pr, Sm.[2] A previous investigation[3] has shown that the transition fields in $Nd_6Ga_3Fe_{11}$ and $Pr_6Ga_3Fe_{11}$ almost do not change when B is substituted for Ga; however, the magnetic anisotropy of $Nd_6Ga_3Fe_{11}$ is influenced remarkably, leading to a spin-reorientation transition in $Nd_6Ga_{2.5}B_{0.5}Fe_{11}$ at about 130 K.[3] These results suggest that the low-field transitions are not connected with the magnetic anisotropy. The aim of the present work is to obtain information about the origin of these transitions in $Nd_6Ga_3Fe_{11}$ and $Pr_6Ga_3Fe_{11}$.

II. EXPERIMENTAL PROCEDURE

The compounds $Nd_6Ga_{3-x}B_xFe_{11}$ and $Pr_6Ga_{3-x}B_xFe_{11}$ ($x=0$, 0.5) were prepared by melting together appropriate amounts of pure Nd, Pr, Ga, Fe, Fe-B alloy (20% B) in an arc furnace in a purified-argon atmosphere. To reach homogeneity, the ingots were inverted and melted twice. Wrapped in Mo foil, the as-cast ingots were annealed at 700 °C for 2 weeks in argon atmosphere. By x-ray diffraction, the annealed samples were found to possess the $La_6Ga_3Co_{11}$-type structure and to contain small amounts of α-Fe.

Magnetically aligned samples were prepared by mixing fine powder with a resin-doped epoxy solution at room temperature and by letting the mixture solidify in a mold with a cylindrical hole in an external magnetic field of 0.8 T. High-field magnetization curves at 4.2 K were measured in the high-field installation at the University of Amsterdam with the field applied parallel and perpendicular to the alignment direction of the samples. The free-powder magnetization was measured on samples consisting of fine powder particles which could freely rotate in the sample holder under the influence of the applied external field. The temperature dependence of the magnetization was measured on free-powder samples between 4.2 and 260 K in a field of 3 T in an extracting-sample magnetometer.

III. RESULTS AND DISCUSSION

The magnetization curves of $Nd_6Ga_3Fe_{11}$ and $Nd_6Ga_{2.5}B_{0.5}Fe_{11}$, measured parallel and perpendicular to the alignment direction, are shown in Fig. 2. In the dotted magnetization curves recorded with increasing field, the transitions earlier reported[3] to occur in low fields (below 5 T) are vaguely distinguishable, but they are very clearly visible in the dM/dB curves shown in Fig. 3. In the perpendicular

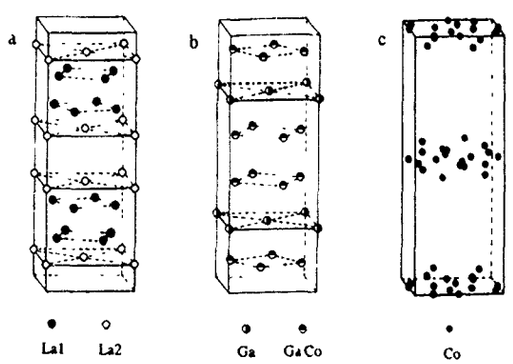

FIG. 1. Crystal structure of $La_6Ga_3Co_{11}$.

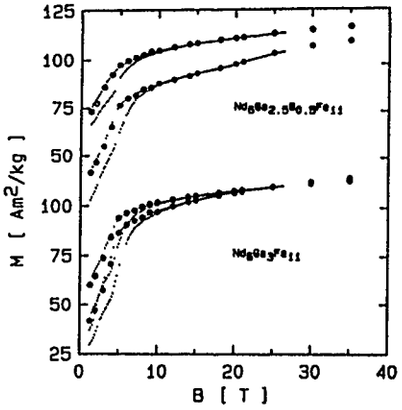

FIG. 2. Magnetization curves at 4.2 K of $Nd_6Ga_3Fe_{11}$-based compounds for the field applied parallel (O) and perpendicular (●) to the alignment direction. The dotted lines correspond to data obtained by means of a triangular continuous-field pulse in which the field increases linearly with time up to 26 T and after that decreases linearly.

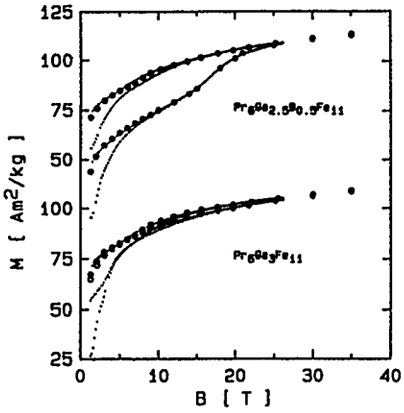

FIG. 4. Magnetization curves at 4.2 K of $Pr_6Ga_3Fe_{11}$-based compounds for the field applied parallel (O) and perpendicular (●) to the alignment direction. The dotted lines correspond to data obtained by means of a triangular-field pulse in which the field increases linearly with time up to 26 T and after that decreases linearly.

magnetization of $Nd_6Ga_{2.5}B_{0.5}Fe_{11}$ there is also a transition around 20 T. It is also seen in Fig. 3 that the critical fields of the low-field transitions hardly depend on the substitution of B for Ga. However, the magnetic anisotropy of $Nd_6Ga_3Fe_{11}$ is considerably enhanced upon substitution of B for Ga.

In $Pr_6Ga_3Fe_{11}$ (Fig. 4), the magnetic anisotropy is very small (<5 T), the parallel and perpendicular magnetization curves coinciding in relatively low fields. Similar to $Nd_6Ga_3Fe_{11}$, the substitution of B for Ga results in a higher magnetic anisotropy. Also in $Pr_6Ga_3Fe_{11}$ and $Pr_6Ga_{2.5}B_{0.5}Fe_{11}$, transitions are found at low fields in both the parallel and the perpendicular magnetization curves (Fig. 5). The critical fields of these transitions are again nearly independent of B substitution, as in the case of the $Nd_6Ga_3Fe_{11}$-based compounds. For $Pr_6Ga_{2.5}B_{0.5}Fe_{11}$, additional transitions are found both in the parallel magnetization curve (at 9 T) and in the perpendicular magnetization curve (at 17 T). All magnetization curves of both the $Nd_6Ga_3Fe_{11}$- and the $Pr_6Ga_3Fe_{11}$-based compounds display a high differential susceptibility even in the highest applied fields indicating a noncollinear structure to be present. Assuming that the rare-earth moments and the Fe moments are nearly parallel at 35 T and that Nd and Pr have the free-ion moment values of $3.20\mu_B$ and $3.27\mu_B$, respectively, we can derive for both $Nd_6Ga_3Fe_{11}$ and $Pr_6Ga_3Fe_{11}$ an Fe moment of about $1.7\mu_B$ from the values of the parallel magnetization at 35 T. This value for the Fe moment is in good agreement with Mössbauer results.[2]

The experimental results presented above show that substitution of B for Ga in $Nd_6Ga_3Fe_{11}$ and $Pr_6Ga_3Fe_{11}$ hardly affects the low-field transitions in these compounds. In the Nd compounds, the transition fields are slightly higher than in the Pr compounds. Of substantial interest is the fact that

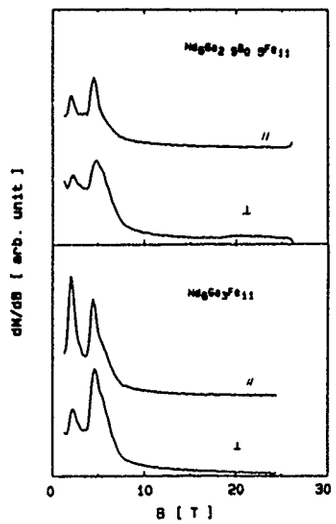

FIG. 3. Field dependence of dM/dB of $Nd_6Ga_3Fe_{11}$-based compounds at 4.2 K for the increasing-field part of the continuous-field 26 T pulse.

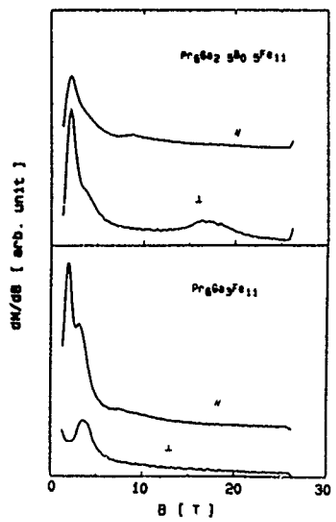

FIG. 5. Field dependence of dM/dB of $Pr_6Ga_3Fe_{11}$-based compounds at 4.2 K for the increasing-field part of the continuous-field 26 T pulse.

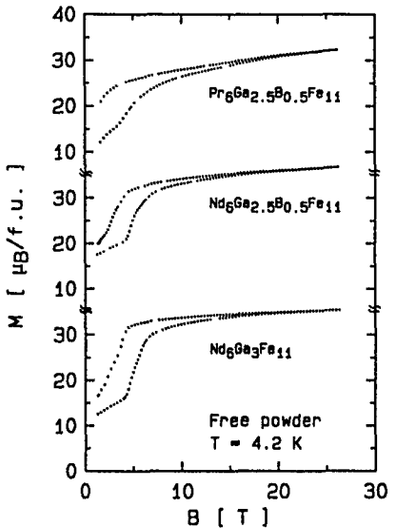

FIG. 6. Free-powder magnetization of $R_6Ga_{2.5}B_{0.5}Fe_{11}$ (R=Nd, Pr) compounds at 4.2 K.

the transitions are observed in both the parallel and perpendicular magnetization curves. Because there are at least two transitions in each magnetization curve, it is unlikely that all these transitions are first-order magnetization transitions (FOMP) as observed in $Nd_2Fe_{14}B$.[4] Even more important in this respect is the fact that the transitions appear in both the parallel and the perpendicular magnetization curves. In the case of FOMP transitions one would also have the contradiction that the anisotropy fields of the compounds are strongly enhanced by substitution, whereas the critical fields of the low-field transitions do not change. These low-field transitions are therefore not to be associated with the overall anisotropy of the compounds.

To further investigate the nature of the observed transitions we performed free-powder magnetization measurements on $Nd_6Ga_3Fe_{11}$, $Nd_6Ga_{2.5}B_{0.5}Fe_{11}$, and $Pr_6Ga_{2.5}B_{0.5}Fe_{11}$ with the idea that transitions originating from discontinuous rotation of the total magnetization vector as occurs in a FOMP should not be observable in free-powder magnetization curves. Figure 6 shows that the magnetization jumps at about 20 and 17 T in $Nd_6Ga_{2.5}B_{0.5}Fe_{11}$ (Figs. 2 and 3) and $Pr_6Ga_{2.5}B_{0.5}Fe_{11}$ (Figs. 4 and 5), respectively, have completely disappeared in the free-powder magnetization proving these transitions to be of the FOMP type. Only at low fields are transitions observed in the free-powder data, which are of different origin and may be associated

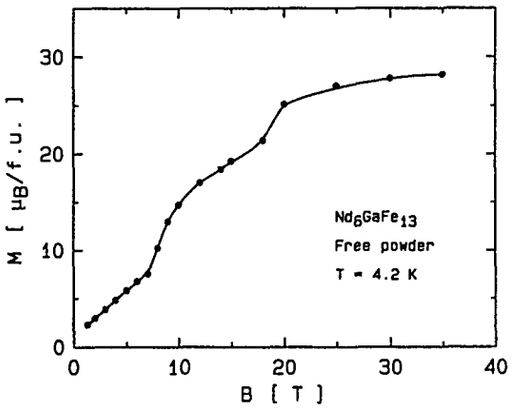

FIG. 7. Free-powder magnetization curve at 4.2 K of Nd_6GaFe_{13}. The line drawn is a guide to the eye.

with transitions from a ferrimagnetic spin structure to a ferromagnetic spin structure.

In order to obtain more information about the possible type of ferrimagnetic spin structure in these compounds, we measured the low-temperature magnetization of compounds of the type $Nd_6M_{3-x}Fe_{11+x}$ (M=Al or Ga) and found[5] that the transition fields strongly increase when Ga or Al are replaced by Fe. As an example, the result for $Nd_6Fe_{13}Ga$ is shown in Fig. 7. The substituted Fe atoms can be expected to occupy the Co positions in the GaCo layers in Fig 1(b), which separate the R and the Co layers. In this case, the substituted Fe ions will very likely influence the strength of the interaction between the moments in the R and the Fe layers. The result in Fig. 7 shows that this interaction is negative, which makes it tempting to conclude that in these compounds the Nd-Fe and the Pr-Fe interaction may be of the ferrimagnetic type. This would be the first example of compounds in which the moment configuration deviates from the ferromagnetic alignment of light-rare-earth moments with respect to the transition-metal moments, which has been explained by Campbell.[6]

Magnetic properties of a novel Pr-Fe-Ti phase

Hong-Shuo Li, Suharyana, J. M. Cadogan, and G. J. Bowden
School of Physics, The University of New South Wales, Kensington, NSW 2033, Australia

Jian-Min Xu, S. X. Dou, and H. K. Liu
School of Materials Science and Engineering, The University of New South Wales, Kensington, NSW 2033, Australia

In a systematic study of the $(Pr_{1-x}Ti_x)Fe_5$ alloy series, the $(Pr_{0.65}Ti_{0.35})Fe_5$ alloy has been found to have a dominant phase with either the rhombohedral Th_2Zn_{17} structure or the newly discovered $Nd_2(Fe,Ti)_{19}$ (S. J. Collocott, R. K. Day, J. B. Dunlop, and R. L. Davis, in Proceedings of the Seventh International Symposium on Magnetic Anisotropy and Coercivity in *R-T* Alloys, Canberra, July 1992, p. 437) structure, depending on the annealing procedure. Powder-x-ray-diffraction patterns and scanning electron microscopy show that the sample annealed at a temperature of 850 °C followed by 1000 °C has the 2:17 structure whereas annealing at 1000 °C directly leads to the new 2:19 structure. Energy-dispersive x-ray analysis yields Pr:Fe:Ti ratios of 10.7:86.2:3.1 for the $Pr_2(Fe,Ti)_{17}$ phase and 9.2:85.9:4.9 for the $Pr_2(Fe,Ti)_{19}$ phase. ^{57}Fe Mössbauer spectroscopy (at 295 K) gives values for the average ^{57}Fe hyperfine field of 15.7 T for the 2:17 phase and 17.5 T for the 2:19 phase, respectively.

I. INTRODUCTION

The discovery of the new $Nd_2(Fe,Ti)_{19}$ phase,[1] which is an intermediate phase between the well-known $Nd_2(Fe,Ti)_{17}$ and $Nd(Fe,Ti)_{12}$ phases, opens up an alternative choice for potential use as nitride permanent magnets similar to $Sm_2Fe_{17}N_x$.[2] Magnetic studies showed that both the magnetization and Curie temperature of the new 2:19 phase are very similar to those of the 2:17 phase.[1,3] From a consideration of the dumb-bell replacement sequence, we have shown in a previous article[4] that the 2:19 phase has a monoclinic structure[3] derived from the orthorhombic $ScFe_6Ga_6$ structure.[5,6] Both the $Nd_2(Fe,Ti)_{17}$ and $Nd(Fe,Ti)_{12}$ structures are formed by the replacement of a fraction of the Ca sites in the hexagonal $CaCu_5$ structure with transition-metal dumbbells. This process may be illustrated by the formula

$$R_{1-x}(2T)_xT_5 \rightarrow RT_y,$$

with (i) the 2:17 structure corresponding to $x=1/3$ and (ii) the 1:12 structure corresponding to $x=1/2$. For the new 2:19 structure, we deduced a value of $x=2/5$, which is between 1/3 and 1/2. In this way, we revealed a possible structure chain for the $CaCu_5$-related structures; namely 1:5, 1:7, 2:17, 2:19,..., 1:12.[4]

In this article we report results from our systematic study of the Pr-Fe-Ti phase diagram. In particular, we report the formation of the new $Pr_2(Fe,Ti)_{19}$ phase and also preliminary results from a study of the magnetic properties of this new compound by ^{57}Fe Mössbauer spectroscopy.

II. EXPERIMENTAL METHODS

A series of $(Pr_{1-x}Ti_x)Fe_5$ samples with $x=0.1$, 0.2, 0.25, 0.3, 0.35, 0.4, and 0.5 were prepared by arc melting in an argon atmosphere. All samples were subsequently annealed at different temperatures in sealed quartz tubes under argon. The samples were wrapped in tantalum foil for the annealing process. They were characterized by (i) powder-x-ray diffraction (XRD) using Cu$K\alpha$ radiation and (ii) scanning electron microscopy (SEM) with energy-dispersive x-ray analysis (EDAX). ^{57}Fe Mössbauer spectroscopy was carried out at 295 K in a standard transmission geometry using a ^{57}Co*Rh* source. The spectrometer was calibrated with an α-Fe foil.

III. RESULTS

XRD, SEM, and Mössbauer analyses show that all the as-cast samples contain large amounts, ~30%, of α-Fe(Ti), which virtually disappear after annealing at 800 or 1000 °C for 3 days. Only the $(Pr_{0.65}Ti_{0.35})Fe_5$ samples show the existence of the new 2:19 phase, which we study in detail in the remainder of this article. Results for the remainder of the series will be presented elsewhere.

In Fig. 1 we show the SEM micrographs of the $(Pr_{0.65}Ti_{0.35})Fe_5$ samples: (a) annealed at 850 °C/3 days followed by 1000 °C/3 days and (b) at 1000 °C/3 days; we denote these two samples as samples A and B, respectively. For sample A, the dominant phase is 2:17 with a Pr:Fe:Ti ratio of 10.7:86.2:3.1 [Fig. 1(a)]. For sample B, the dominant phase is the new 2:19 structure with a Pr:Fe:Ti ratio of 9.2:85.9:4.9 [Fig. 1(b)]. Both samples contain small amounts of α-Fe(Ti) impurity.

These SEM/EDAX results were confirmed by the powder XRD data as shown in Fig. 2. The XRD pattern of sample A shows the typical reflections of the rhombohedral Th_2Zn_{17} structure [Fig. 2(a)], while the XRD pattern of sample B gives a 2:19 structure, in which there is a characteristic peak located at ~39.7° [Fig. 2(b)] as observed in the XRD pattern of the $Nd_2(Fe,Ti)_{19}$ phase.[1,3]

Figure 3 shows the ^{57}Fe Mössbauer spectra collected at 295 K for sample A [Fig. 3(a)] and sample B [Fig. 3(b)]. Our analysis of these two spectra employed three magnetically split sextets with variable linewidths. Inclusion of extra subspectra in the fitting procedure has little effect on the average hyperfine field value. It is reasonable to believe that the $Pr_2(Fe,Ti)_{19}$ phase should have multiple Fe sites since the x-ray-diffraction study indicates a quite complex crystal structure.[1,3] As mentioned earlier, the 2-19 phase is an inter-

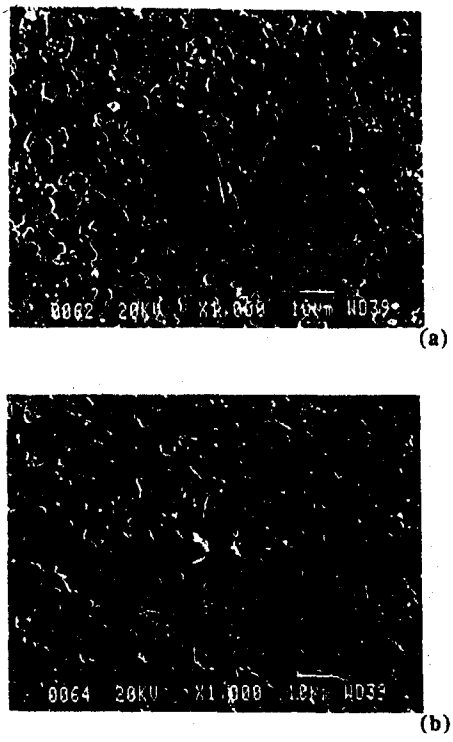

FIG. 1. SEM micrographs of $(Pr_{0.65}Ti_{0.35})Fe_5$: (a) sample A, annealed at 850 °C for 3 days followed by 1000 °C for 3 days; and (b) sample B, annealed at 1000 °C for 3 days.

mediate phase between well-known 2-17 and 1-12 phases; these two phases all have three or more Fe sites. The theoretical fits are represented by solid lines in Fig. 3; these fits yield an average ^{57}Fe hyperfine field of 15.7 T for the

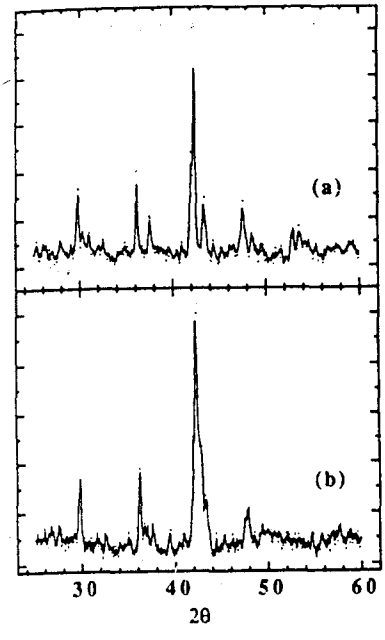

FIG. 2. Powder-x-ray-diffraction patterns (Cu$K\alpha$) of $(Pr_{0.65}Ti_{0.35})Fe_5$: (a) sample A and (b) sample B (same as in Fig. 1).

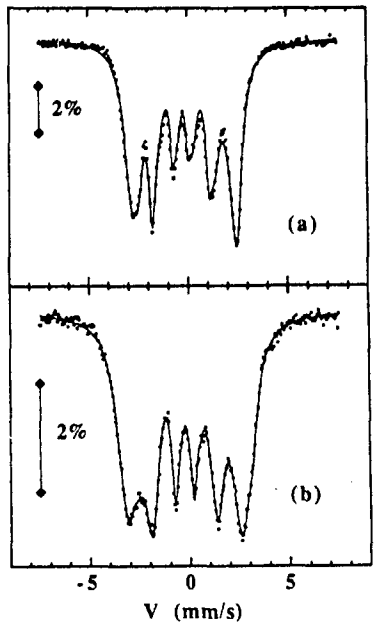

FIG. 3. ^{57}Fe Mössbauer spectra (at 295 K) of $(Pr_{0.65}Ti_{0.35})Fe_5$: (a) sample A and (b) sample B (same as in Fig. 1). Solid lines represent the theoretical fits.

$Pr_2(Fe,Ti)_{17}$ phase and 17.5 T for the $Pr_2(Fe,Ti)_{19}$ phase, respectively. The difference in the magnitude of the average hyperfine field between the 2:17 and 2:19 Pr-Fe-Ti phases is 1.8 T, compared to the corresponding value of 2.3 T in the Nd-Fe-Ti system (18.9 T for the 2:17 phase and 21.2 T for the 2:19 phase).[4]

IV. CONCLUSION

By using a combination of SEM/EDAX, powder-x-ray diffraction, and ^{57}Fe Mössbauer spectroscopy we have investigated the formation of a new ternary intermetallic phase in the Fe-rich corner of the Pr-Fe-Ti phase diagram, namely $Pr_2(Fe,Ti)_{19}$, with a structure derived from the orthorhombic $ScFe_6Ga_6$ structure. Mössbauer data show a distinguishable difference in magnitude of the average ^{57}Fe hyperfine field (at 295 K) of the 2:17 (15.7 T) and 2:19 (17.5 T) phases.

Magnetic properties of $Gd(Fe_{1-x}Co_x)_9Ti_2$ alloys

Suharyana, J. M. Cadogan, Hong-Shuo Li, and G. J. Bowden
School of Physics, The University of New South Wales, P.O. Box 1, Kensington, NSW 2033, Australia

Four samples of $Gd(Fe_{1-x}Co_x)_9Ti_2$ with $x=0.0$, 0.1, 0.2, and 0.3 were prepared by conventional arc melting followed by annealing at 1000 °C for 3 days. Powder-x-ray-diffraction patterns of these samples show that all of the samples have a dominant phase with the tetragonal $CeMn_6Ni_5$ structure. Traces of $TiFe_2$ are also present. ^{57}Fe Mössbauer spectra have been collected at 80 and 295 K. X-ray-diffraction patterns and Mössbauer spectra on magnetically aligned samples indicate that the easy axis of magnetization is the crystallographic c axis. The Curie temperature increases monotonically with increasing cobalt concentration. The average hyperfine field at 80 K reaches a maximum of 26.8(5) T for $x\approx0.2$.

I. INTRODUCTION

Rare-earth (R) transition-metal (T) intermetallic compounds, denoted as RT_{11}, with the tetragonal $CeMn_6Ni_5$ structure have been the subject of several investigations.[1-5] In particular, it has been shown[1] that the series of intermetallic compounds $GdFe_{9-x}Co_xTi_2$ crystallize in the tetragonal $CeMn_6Ni_5$ structure with the space group $P4/mbm$.[6] The Curie temperature T_c of the $GdFe_{9-x}Co_xTi_2$ compounds for $x=0$, 1, and 3 has also been determined[1] and it was found that the T_c increased monotonically with Co concentration, from 280 to 450 K.

A special study has also been made of the tetragonal $ThMn_{12}$ phase in $GdFe_{12-x}Ti_x$ compounds with $x=1$ and 1.5,[2] and Sm-Fe-Ti-Nb alloys in the atomic ratio of 14.5/75.0/9.5/1.0.[3] Even though the emphasis was on the 1-12 structure, the formation of a secondary 1-11 phase, with the $CeMn_6Ni_5$ structure, in annealed samples of both as-cast and melt-spun samples, was observed. A $CeMn_6Ni_5$ 1-11 phase has also been reported in the Sm-Fe-Ti system near the tie line Sm_2Fe_{17}-$TiFe_2$.[4] Finally, the $CeMn_6Ni_5$ structure has also been observed in $YFe_{11-x}Ti_x$ alloys,[5] when $x=2$.

In this paper, we report ^{57}Fe Mössbauer experiments on both magnetically aligned and random powder samples of $Gd(Fe_{1-x}Co_x)_9Ti_2$. It is shown, both by Mössbauer spectroscopy and x-ray diffraction (XRD), that the direction of easy magnetization lies along the c axis, at least for $x>0$. It is also found that the average ^{57}Fe magnetic hyperfine field in $Gd(Fe_{1-x}Co_x)_9Ti_2$ reaches a maximum when $x=0.2$, in accord with expectations based on the Slater–Pauling curve for Fe/Co alloys.

II. EXPERIMENTAL DETAILS

The samples of $Gd(Fe_{1-x}Co_x)_9Ti_2$ with $x=0.0$, 0.1, 0.2, and 0.3 were prepared by arc melting, followed by annealing at 1000 °C for 3 days. Powder XRD patterns were obtained using a Siemens diffractometer with Cu$K\alpha$ radiation. The samples comprise a dominant phase with the tetragonal $CeMn_6Ni_5$ structure, but with traces of $TiFe_2$. The ^{57}Fe Mössbauer spectra were collected at 80 and 295 K using a constant acceleration transmission spectrometer, with a $^{57}CoRh$ source. The low-temperature Mössbauer spectra were obtained using an Oxford Instruments CF506A continuous flow cryostat and an ITC-4 temperature controller (±0.1 K). The spectrometer was calibrated using an α-Fe foil. The magnetically aligned samples were prepared by mixing fine powder with epoxy resin and subsequently allowing the mixture to set in an applied magnetic field of 2.0 T at 295 K. For the Mössbauer experiments on aligned samples, the γ-ray direction was parallel to the direction of magnetic alignment. Curie temperatures were determined using ac susceptibility measurements with a frequency of 87 Hz. In addition, ac susceptibility measurements were also carried out in the temperature range 77–295 K, but no signs of magnetization reorientations were observed.

III. RESULTS

Typical XRD patterns on a random powder and a magnetically aligned samples of $Gd(Fe_{1-x}Co_x)_9Ti_2$ for $x=0.3$ can be seen in Figs. 1(a) and 1(b), respectively. Similar results were obtained for $x=0.1$ and 0.2. For $x=0$ the Curie temperature T_c lies below room temperature, thereby precluding measurements on aligned samples. The main reflec-

0.3	8.222	4.866	423	21.3	25.1

tion peaks were indexed according to the tetragonal $CeMn_6Ni_5$ structure, but with traces of the hexagonal Laves phase $TiFe_2$. From a comparison of the random powder and aligned x-ray patterns, it is clear that the easy axis of magnetization is the crystallographic c axis of the tetragonal $CeMn_6Ni_5$ structure. Only the (002) reflection is important in the magnetically aligned sample. In Table I we give the lattice parameters as a function of the Co concentration. Also included in Table I are the Curie temperatures determined by ac susceptibility measurements, which rise monotonically with increasing Co concentration.

The ^{57}Fe Mössbauer spectra at 295 K obtained using polycrystalline powder samples can be seen in Fig. 2(a). The spectra were fitted with (i) four magnetically split sextets and (ii) a quadrupole doublet for the $TiFe_2$ contaminant. The $TiFe_2$ Laves phase appears in a rather wide compositional range, 26.9–35.4 at. % Ti.[7] The measured quadrupole splitting was found to be 0.35 mm/s, which is somewhat lc ." than the value of 0.4 mm/s for pure crystalline $TiFe_2$.[8]

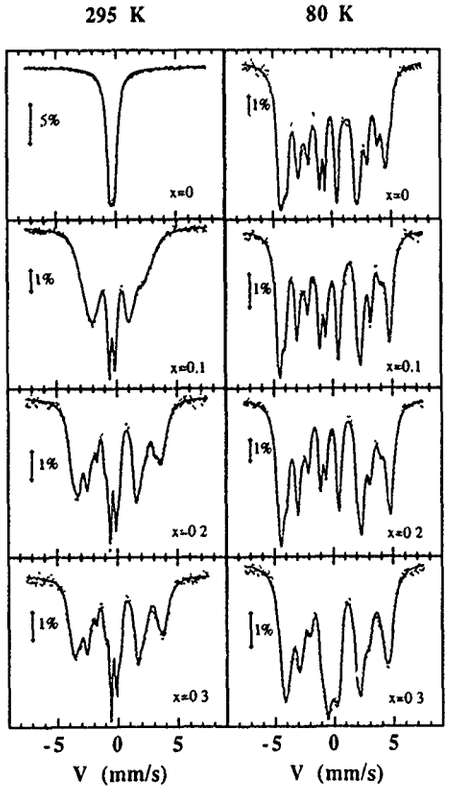

FIG. 2. ^{57}Fe Mossbauer spectra for random powder samples of $Gd(Fe_{1-x}Co_x)_9Ti_2$, where $x=0.0$, 0.1, 0 2, and 0 3 at (a) 80 K and (b) 295 K.

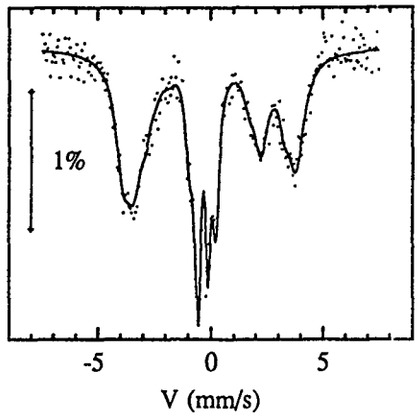

FIG. 3. ^{57}Fe Mössbauer spectra for a magnetically aligned sample of $Gd(Fe_{0\,7}Co_{0\,3})_9Ti_2$ at 295 K.

Because of the considerable broadening of the hyperfine field distribution, caused by the Fe/Co occupations of the nearest-neighbor shells, the linewidths of the outer, midle, and inner lines of the magnetically split spectra were varied independently. In practice, the area of the Mössbauer spectrum associated with the contaminant $TiFe_2$ was found to be $\approx$15%. The ^{57}Fe Mössbauer spectra at 80 K can be seen in Fig. 2(b). The situation is now slightly more complicated because the $TiFe_2$ impurity phase is magnetically split below 280 K.[7] At 80 K we find the magnetic hyperfine field of $TiFe_2$ in our compounds to be $\approx$7 T, which is in reasonable agreement with that determined by other workers.[9,10]

The average ^{57}Fe magnetic hyperfine field as a function of the Co concentration can be seen in Table I. This reveals that at 80 K the magnetic hyperfine field reaches a maximum when $x\approx0.2$. This is in reasonable agreement with expectations based on the Slater–Pauling curve for Fe-Co alloys.[11,12] Similar behavior has been observed in the $Y(Fe_{1-x}Co_x)_2$,[13] $Y(Fe_{1-x}Co_x)_3$, and $Dy(Fe_{1-x}Co_x)_3$ (Ref. 14) intermetallic compounds. This observation suggests that the magnitudes of both the Fe magnetic moments and hyperfine fields are determined, primarily, by the $3d$ bands associated with the Fe/Co sublattices.

In Fig. 3 the ^{57}Fe Mössbauer spectrum of a magnetically aligned $Gd(Fe_{0\,7}Co_{0\,3})_9Ti_2$ sample at 295 K can be seen. The solid line represents a theoretical fit, obtained using a variable angle θ, between the c axis and the direction of incident γ rays. The computed value of θ was found to be 21.0°, which strongly supports our conclusion based on the x-ray data, shown in Fig. 1(b). Thus, the easy direction of magnetization is the crystallographic c axis of the tetragonal $CeMn_6Ni_5$ structure. Since Gd^{3+} is in S state, the magnetocrystalline anisotropy of compounds under investigation must be determined by the properties of the Fe/Co sublattices.

IV. CONCLUSIONS

Both powder-x-ray diffraction and ^{57}Fe Mössbauer experiments on magnetically aligned samples show that the

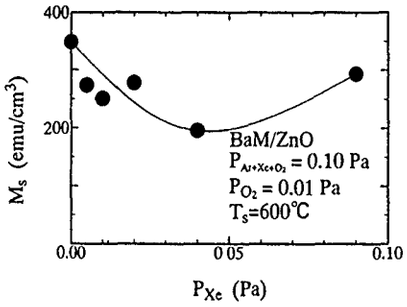

FIG. 5. Dependencies of saturation magnetization M_s on Xe pressure P_{Xe}.

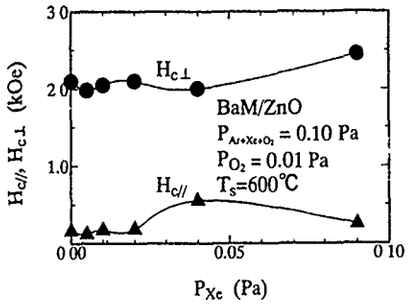

FIG. 6. Dependencies of perpendicular and in-plane coercivities $H_{c\perp}$ and $H_{c\parallel}$ on Xe gas pressure P_{Xe}.

arrive at the substrate after a few collisions with atoms of the working gas. The Fe, O, and even Ba atoms sputtered by Xe ions can arrive at the substrate with relatively high kinetic energy, enough to form BaM ferrite crystallites with good c-axis orientation. Therefore, the values of $\Delta\theta_{50}$ for both BaM layers deposited at P_{Ar+O_2} and P_{Xe+O_2} of 0.1 Pa were smaller and almost the same.

At P_{Xe} of 0.04 Pa, the sputtering phenomena and the collision of sputtered particles with the working gas seemed to be more complicated. There may be apparent differences in kinetic energies among deposited particles. Although the atoms sputtered by heavier Xe ions and collided with Ar or Xe atoms seem likely to possess relatively high energy and make a long walk on the substrate, the atoms sputtered by lighter Ar ions and collided with heavier Xe atoms seem likely to possess insufficient energy for a random walk on the substrate. Therefore, $\Delta\theta_{50}$ of the BaM layer deposited in mixed gases at P_{Xe} of 0.04 Pa might take a larger value than those at P_{Xe} of 0.00 and 0.09 Pa. It also seems that this nonuniformity of kinetic energy of deposited particles causes a very rough and nonuniform surface morphology for the films deposited in a mixture gases as seen in Figs. 3(c) and 3(d).

C. Magnetic characteristics

Figure 5 shows the P_{Xe} dependencies of the saturation magnetization M_s of the BaM layer. M_s of the BaM layer deposited at P_{Xe} of 0.00 Pa took the maximum value of 350 emu/cm^3 and was not so different from the bulk M_s of 380 emu/cm^3. M_s decreased with increase of P_{Xe} up to 0.04 Pa and took the minimum value of 196 emu/cm^3 at P_{Xe} of 0.04 Pa, of which the value was as relatively large as 293 emu/cm^3 at P_{Xe} of 0.09 Pa. These dependencies seemed to have a relationship distinctly close to the layer morphology and $\Delta\theta_{50}$ of films as seen in Figs. 3 and 4.

Figure 6 shows the P_{Xe} dependencies of the perpendicular and in-plane coercivities $H_{c\perp}$ and $H_{c\parallel}$, respectively. Although $H_{c\perp}$ was almost constant at about 2.0 kOe, $H_{c\parallel}$ took the maximum value of 0.6 kOe at P_{Xe} of 0.04 Pa. Since $H_{c\parallel}$ corresponds apparently to $\Delta\theta_{50}$, such a large $H_{c\parallel}$ at P_{Xe} of 0.04 Pa was attributed to the degradation of crystallinity implied by larger $\Delta\theta_{50}$ at P_{Xe} of 0.04 Pa as seen in Fig. 4.

IV. CONCLUSION

BaM ferrite layers were deposited on a ZnO underlayer at T_s of 600 °C at P_{Ar+Xe} of 0.09 Pa and O_2 at P_{O_2} of 0.01 Pa. The obtained results are as follows.

(i) BaM layers deposited at P_{Xe} of 0.09 Pa revealed a smooth surface appearance and excellent crystallinity with $\Delta\theta_{50}$ of 4°. In addition, they exhibited good magnetic characteristics such as M_s and $H_{c\perp}$ and $H_{c\parallel}$ of about 293 emu/cm^3 and 2.0 and 0.3 kOe, respectively.

(ii) BaM layers deposited in the mixed gas at P_{Ar}, P_{Xe}, and P_{O_2} of 0.05, 0.04, and 0.01 Pa, respectively, had rough surface texture and worse crystallinity with $\Delta\theta_{50}$ of 8.7°. They exhibited smaller M_s and higher $H_{c\parallel}$ of 196 emu/cm^3 and 0.6 kOe, respectively.

It seems to be possible to deposit the BaM layer with good crystallinity and magnetic characteristics on a ZnO underlayer using a mixture of O_2 and Xe instead of Ar as the sputtering gas.

Magnetic resonance in PdFe alloys near T_c

A. N. Medina, V. S. Oliveira, and F. G. Gandra

Magnetic resonance results in $Pd_{1-x}Fe_x$, with various Fe concentrations, are reported. The samples were prepared in the form of foils, 200 and 100 μm thick, and Fe concentrations of 0.2, 0.5, 1.0, and 1.5 at. %. The experiments were carried out at low temperature, close to the T_c of each alloy. For the more concentrated alloys and magnetic field perpendicular to the foil, more than one line is observed. The anomalies in the resonance spectrum are interpreted in terms of the existing giant moments in these alloys.

I. INTRODUCTION

$Pd_{1-x}Fe_x$ is ferromagnetic at low temperature, the Curie temperature $T_c(x)$, depending on Fe concentration. In an early magnetic resonance experiment,[1] made at temperatures between 1.5 and 25 K, a single line was observed for $x \leq 0.5$, and with the g value close to 2.18. No anomaly in the spectra was reported.

In our experiments, using samples of the same shape, we found extra resonance lines for Fe concentrations larger than 0.5%. It was also observed for low-concentration samples that the spectra are distorted. To investigate the origin of these lines, we observed the resonance as a function of sample thickness, Fe concentration, and for temperatures close to $T_c(x)$.

It is well known that Fe impurities dissolved in highly exchange-enhanced materials such as Pd induce giant moments due to the propagating polarization in the highly polarizable host.[2] Since the coupling of the Fe moment to this magnetic cloud is strong, one expects that the resonance spectrum may be different from that of isolated Fe atoms in, say, an insulating cubic material. Also, this complex metallic system requires a specific adaptation of the usual resonance theory. Although aware that Fe moments here are not localized in the same sense of a rare earth, we assume the resonance theory for local moments apply. The existence of polarized clusters, which follow the dynamics of the central Fe moment, will be included as an effective "anisotropy." Due to the shape of the samples, we derive parallel and perpendicular expressions for the field for resonance.

II. EXPERIMENTAL PROCEDURES

The samples were arc melted under argon atmosphere using 99.9% Fe and 99.99% Pd. The button was cold rolled to 200 μm and the thinner samples for the same concentration were obtained from this foil. All samples were annealed in argon at 810 °C for 3 days before the experiments.

The magnetic resonance experiments were carried out in a home-made homodine spectrometer with 3 mW microwave power in X band (9.34 GHz) and field modulation of 40 Oe peak to peak at 10 kHz. The samples were attached to the cold finger of the temperature variation system using thermal paste and Teflon tape. There was no contribution of the base line to the spectra at low temperature because the signal of the sample is very intense.

III. EXPERIMENTAL DATA AND ANALYSIS

The magnetic resonance spectra of $Pd_{1-x}Fe_x$ foils of 200 μm thickness and several concentrations are shown in Fig. 1. Clearly the spectrum is composed of more than one line, in particular for concentrations above 0.5%. This observation induces a natural question about the existence of extra phases.

Since Fe is quite soluble in Pd, thermal annealing[3] removes any existent sample inhomogeneity and other metallic phases such as Pd_3Fe. It remains to exclude other materials such as insulating oxides. To check this point the sample is reduced to powder, obtained from the same button. The result is a perfect Dysonian line, characteristic for metals, thus excluding the existence of oxides.

It is known that the lamination process can originate some degree of orientation of the foils. To find out the influence of the resulting (110) orientation of the foil on the resonance results, spectra were obtained for a 200 μm slab, cut

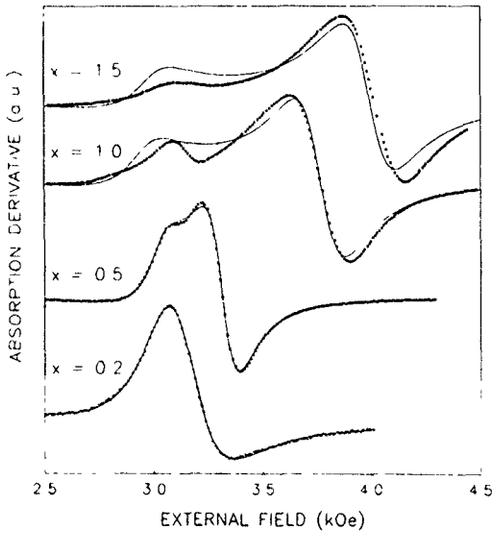

FIG. 1 Pd:Fe(x), x=0.2%, 0.5%, 1%, 1.5% resonance spectra at 7 K and 9.343 GHz of 200 μm foils with external field perpendicular to the surface. Dots indicate experiment and line indicates calculation.

 0021-8979/94/75(10)/7125/3/$6.00 © 1994 American Institute of Physics

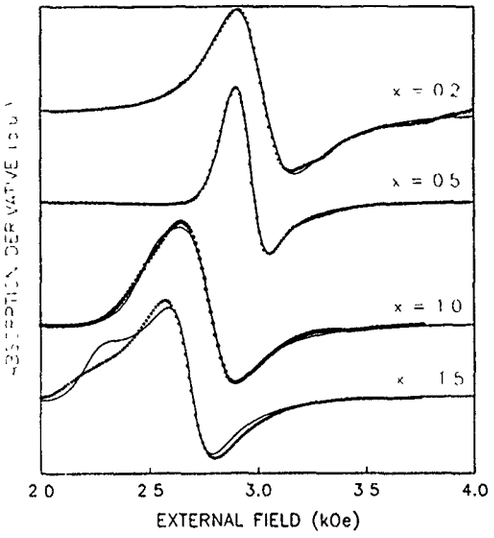

FIG. 2. Pd:Fe(x), x=0.2%, 0.5%, 1%, 1.5% resonance spectra at 7 K and 9.343 GHz of 200 μm foils with external field parallel to the surface. Dots indicate experiment and line indicates calculation.

from the 1% button, using a 0.2-mm-thick diamond saw. The result as compared to Fig. 1 indicated the same spectrum, thus discarding the influence of orientation, since the button was completely nonoriented.

In Figs. 1 and 2 we show the spectra for 200 μm foils, for several concentrations, parallel and perpendicular external field orientation, at 7 K. The lower-field line shows less variation as compared to the high-field one when Fe concentration is changed.

A possible interpretation for this comes from the magnetization behavior. When Fe concentration is increased, $T_c(x)$ and M increase, the same occurring with the demagnetization field, thus shifting the position of the resonance line. Since the magnetization is not saturated, demagnetization is field dependent and consequently the two lines will not shift the same amount. For 0.2% and $T>T_c$ we observed one line with metallic shape but a field orientation dependence still persists.

The interpretation of our experimental spectra relies on two possibilities. The first one considers the existence of "good" moments, subjected to shape demagnetization and effective anisotropy field. The second contemplates long-range macroscopic ferromagnetic order. However, in usual ferromagnetic resonance one must fulfill special conditions[4] to observe this two-line scenario.

We adopt then a modified version of the first possibility, taking into account the existence of the giant moments. Then one introduces effective spins submitted to anisotropy, the origin of the latter being associated with the existence of giant moments. These giant moments induced in Pd by the Fe impurity, confined in these foils, and strongly coupled to the Fe moments, will hinder the free rotation of the Fe moments. It is then reasonable to describe this effect through an effective anisotropy induced by these large magnetic clusters. This anisotropy acts on the effective local magnetic moments in such a way as to produce a spectrum with two possible g values.

From now on we assume the usual theory for resonance phenomena, taking into account, however, that Dysonian line shapes exist with two g values: $g_\perp$ and $g_\parallel$. It is essential, however, to take into account that one has a polycrystalline sample, and thus a powder spectrum should be calculated. In principle, for temperatures larger than T_c we should get one distorted line, but corrections due to internal fields are necessary in both ordered and disordered magnetic phases.

The internal effective field for perpendicular [Eq. (1a)] and parallel [Eq. (1b)] orientations of the external field H to the foil are given by[5]

$$H_{\text{eff}}=(H-4\pi M_s+H_a), \tag{1a}$$

$$H_{\text{eff}}=\sqrt{H(H+4\pi M_s-H_a)}, \tag{1b}$$

where 4π is the demagnetization factor for the foil and H_a is the phenomenological effective anisotropy field attributed here to field inhomogeneities, surface effects, magnetocrystalline anisotropy, etc. M_s is the saturation magnetization, but since we are close to T_c, we use $M(H)$ instead. We assume that the alloy magnetization varies linearly with field, in the range from 0 to 4 kOe, such that $M=M_0+H\ dM/dH$. Since we are close to T_c only terms proportional to H are retained. Here, $M_0=0$ and dM/dH is a fitting parameter.

The intensity of the first derivative of the powder spectrum is given by[6]

$$Y'(H)=C\int_{H_\parallel}^{H_\perp} F'(H,H')\,\frac{[1+(H_\parallel/H')^2]}{[1-(H'/H_\perp)^2]}\,dH', \tag{2}$$

where C is the amplitude, $H_\parallel=h\nu/\mu_b g_\parallel$, $H_\perp=h\nu/\mu_b g_\perp$ with ν the microwave frequency and μ_b the Bohr magneton. $F'(H,H')$ is the field derivative of the metallic line shape

$$F(H,H')\propto M\,\frac{1+\alpha x}{(1+x^2)},\quad x=\frac{H_{\text{eff}}-H'}{\Delta H}. \tag{3}$$

In this expression, α is a dispersion parameter, ΔH is the linewidth, and the effective field H_{eff} is given by Eq. (1) using M in the limit of linear field dependence and negleting H_a. The field derivative of the line is

$$F'(H,H')\propto\left[-\frac{B}{\Delta H}\frac{H^2}{H_{\text{eff}}}\left(1-2\pi\frac{dM}{dH}\right)+\left(A-\frac{2\pi BH^2}{\Delta H H_{\text{eff}}}\frac{dM}{dH}\right)\right], \tag{4a}$$

$$F'(H,H')\propto\left[A+\frac{BH}{\Delta H}\left(4\pi\frac{dM}{dH}-1\right)\right], \tag{4b}$$

respectively, for H parallel and perpendicular to the foil, where $A=(1+\alpha x)/(1+x^2)$, $B=-dA/dx$. Expressions (4a) and (4b) are substituted in expression (2) to fit the experimental data with an overall amplitude C, ΔH, $H_\parallel$, $H_\perp$, α, and dM/dH as fitting parameters.

The results are shown in Table I and Figs. 1 and 2 show the theoretical curves. Considering the degree of complexity presented by Eq. (2), the fitting to the experimental data is quite good. For $x=0.2$, there is no clear evidence for an extra

TABLE I. Fitting parameters of the powder spectra for $T=7$ K and 200 μm. $g\pm5\%$, $\Delta H\pm10\%$. The symbols $\perp$ and $\parallel$ in the first column refer to the external field orientation to the sample surface.

Conc. at. %		g perp	$g\parallel$	ΔH (kOe)	dM/dH (10^{-4})
0.2	$\perp$	2.15	2.17	0.212	9
	$\parallel$	2.19	2.21	0.229	15
0.5	$\perp$	2.14	2.35	0.098	58
	$\parallel$	2.19	2.28	0.105	42
1.0	$\perp$	1.91	2.44	0.141	60
	$\parallel$	2.19	2.44	0.167	155
1.5	$\perp$	1.80	2.40	0.147	60
	$\parallel$	2.14	2.58	0.160	275

line and the $g_\perp$ and $g_\parallel$ values are very close to each other. We verify also that dM/dH is not large and with near values for both orientations. This fact seems reasonable since the working temperature is 7 K and T_c is about 4 K. For this sample, the linewidth as a function of temperature is linear, the g value close to 2.18. This behavior is appropriate for a paramagnet, but we should mention that the internal field is corrected by about 100 Oe due to the high susceptibility of the sample.

For higher concentrations, the difference between $g_\perp$ and $g_\parallel$ increases as concentration goes to 1.5%, showing that the anisotropy associated with the giant moment is also increasing. This is associated with the improvement of connectivity in the percolating and interacting magnetic clusters embedded in the foil-like sample.

The effective anisotropy field H_a is evaluated for $x\geq0.5\%$ in the following way: Considering that $H_a/H\ll1$ we note from Eqs. (1a) and (1b) that the correction to the internal field is very small for H parallel to the sample surface, so we assume that the correct g values are extracted from this configuration. H_a is then evaluated by the difference of the fields corresponding to $g_\perp$ for both configurations of the external field ($g_\parallel$ is not used here because it is more affected by error). The values for H_a are 70, 450, and 590 Oe, respectively, for 0.5%, 1%, and 1.5%. The obtained anisotropy fields are small as compared to the resonance field and increase with increasing Fe concentration. This results from the improved ferromagnetic properties of the samples.

In Fig. 3 we show the temperature dependence of the resonance spectra for $x=1\%$. When temperature increases g_{eff} decreases toward 2.1 and, for $T>T_c$ ($T_c\approx38$ K), the spectrum shows a single line.

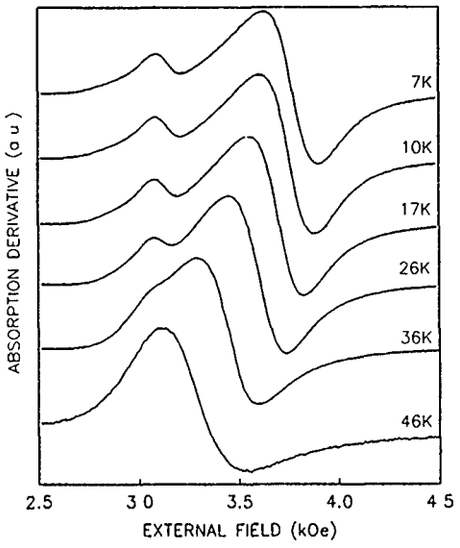

FIG. 3. Temperature dependence for Pd:Fe(1%), 200 μm, and external field perpendicular to sample surface.

IV. CONCLUSIONS

We have presented a very simple model for the resonance in PdFe alloys, characterized by the existence of giant moments. We define effective localized moments to describe the resonance spectrum. Also, anisotropy associated with the giant moment is responsible for slightly different g values, originating the powder spectrum.

Using the g shift for the $x=0.2\%$ and 1.5%, the ρJ product ratio is estimated to be 1.4. This is consistent with a higher coupling of the interacting clusters, qualitatively understood in terms of an effective spin, via an increasing product ρJ.

Effects of Co and Y substitution on magnetic properties of $CeFe_2$

Xianfeng Zhang and Naushad Ali
Department of Physics and Molecular Science Program, Southern Illinois University, Carbondale, Illinois 62901

$CeFe_2$ orders ferromagnetically (FM) below T_C=227 K; however, this FM state is inherently unstable and partial substitution of Fe by Co precipitates the instability of FM state and a ferromagnetic to antiferromagnetic (AFM) phase transition is observed at lower temperature. This second phase transition is a first-order phase transition. The dependence of T_C and T_N on the concentration of Co X for $Ce(Fe_{1-X}Co_X)_2$ is presented. For $Ce(Fe_{0.8}Co_{0.2})_2$, the FM transition is at T_C=160 K, and the AFM transition is at T_N=76 K. The entropy change associated with the FM to AFM phase transition has been determined from magnetization measurements and found to be primarily associated with a change in the electronic density of states at E_F. If one starts with $Ce(Fe_{0.8}Co_{0.2})_2$ and partially substitutes Ce by Y, it is found that T_N gradually decreases with Y concentration; and for Y concentration greater than 10%, the AFM phase disappears and FM phase is fully restored. The dependence of T_C and T_N on the concentration of Y Z is presented for $Ce_{1-Z}Y_Z(Fe_{0.8}Co_{0.2})_2$. It is suggested that the second transition (FM to AFM) is a result of the competition between exchange energy and magnetic anisotropy energy. The measurements of magnetization, ac susceptibility, resistivity, and thermal expansitivity are presented.

$CeFe_2$ is a ferromagnet that exhibits some anomalous magnetic properties such as a much lower Curie temperature (T_C=227 K) and a much lower magnetic moment per Fe atom ($1.15\mu_B$) than other compounds in the RFe_2 series (R denotes rare earth).[1] A number of investigations[2–4] suggests that the anomalous magnetic properties of $CeFe_2$ may be due to some transfer of the Ce $4f$ electrons to the Fe $3d$ band. This suggestion is supported by experimental data of electronic specific heat coefficients, which are 53 mJ K^{-2} mol^{-1} for $CeFe_2$,[5] and 21 mJ K^{-2} mol^{-1} for $CeCo_2$.[6]

The ferromagnetic state of $CeFe_2$ is inherently unstable. A small partial substitution of Fe by other elements such as Co, Al, and Ru precipitates the instability of ferromagnetic state and a ferromagnetic (FM) to antiferromagnetic (AFM) phase transition is observed at the temperature T_N, lower than T_C.[7–9] This second phase transition is a first-order phase transition in case of $Ce(Fe_{1-X}Co_X)_2$.[7] The magnetic ordering of $Ce(Fe_{1-X}Co_X)_2$ has been determined by Kennedy *et al.*[10] using neutron diffraction. The ac susceptibility results by Roy and Coles[11] show that the T_C moves up but T_N is suppressed with the increase in Y concentration in $Ce_{1-Z}Y_Z(Fe_{1-X}Al_X)_2$. They found that T_C increased to 235 K with Z=0.1 and went up further to 252 K for Z=0.15 in the case of X=0.035. The low-temperature transition is no longer present for X greater than 0.15.

According to the x-ray-diffraction studies by Nishihara, Tokumoto, and Yamaguchi,[12] there is a small volume change of 0.05% at T_N for the $Ce(Fe_{1-X}Al_X)_2$ system. Kennedy *et al.*[10] also reported a 0.05% cell volume change at T_N in the $Ce(Fe_{1-X}Co_X)_2$ system. The 0.05% volume change is too small to apply an exchange-inversion model to explain the FM-AFM transition observed here.

In this article we present the effect of partial substitution of Fe by Co and Ce by Y on magnetic properties of the $CeFe_2$. Two magnetic phase diagrams are presented for the $Ce(Fe_{1-X}Co_X)_2$ and for the $Ce_{1-Z}Y_Z(Fe_{0.8}Co_{0.2})_2$. The entropy change at the FM-AFM transition is determined for $Ce(Fe_{0.8}Co_{0.2})_2$ as a function of temperature. Some specific measurements presented here include magnetization, ac susceptibility, resistivity, and thermal expansion for the $Ce(Fe_{0.8}Co_{0.2})_2$.

The sample preparation and experimental details are described in Refs. 7 and 13.

The magnetization M and ac susceptibility χ_{ac} as a function of temperature for $Ce(Fe_{0.8}Co_{0.2})_2$ are presented in Figs. 1(a) and 1(b), respectively. It is evident that partial substitution of Fe by Co causes a sharp transition from FM to AFM. The temperature dependence of the electrical resistivity [Fig. 1(c)] also clearly shows this magnetic transition. A significant slope change in the resistivity at 162 K is identified as being due to a paramagnetic (PM)-FM transition which occurs at 160 K in the magnetization measurement. The abrupt rise of the resistivity at 75 K corresponds to FM-AFM tran-

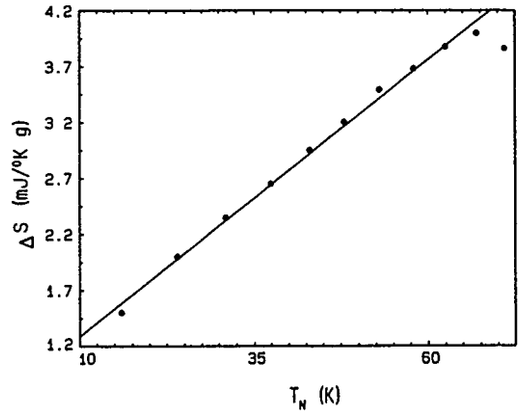

FIG. 4. Total entropy change ΔS as a function of temperature T for $Ce(Fe_{0.8}Co_{0.2})_2$ at the AFM-FM transition temperature.

sition. The result of thermal expansitivity for $Ce(Fe_{0.8}Co_{0.2})_2$ is presented in Fig. 1(d). We observe a slope change in $(\Delta L/L)$ at $T \approx 162$ K as shown in the insert of the Fig. 1(d) and a step change in $\Delta L/L$ around $T=75$ K. This result shows conclusively that the phase transition at 162 K is second order and the FM-AFM transition at 75 K is first order. Similar results are obtained for other samples.

Figure 2(a) shows the phase diagram for the system $Ce(Fe_{1-X}Co_X)_2$. The first transition temperature T_C decreases continuously as cobalt concentration increases for $X \leq 0.40$. Meanwhile, the second transition temperature T_N increases first with increasing X and then decreases after a maximum at 15% Co. For the Co concentration higher than 30%, no second transition has been observed down to the temperature of 4.2 K. Here the T_C and the T_N are defined as the temperatures at which the magnetization reaches the half-height of the on-set value.

Figure 3(a) shows magnetization versus temperature for $Ce_{1-Z}Y_Z(Fe_{0.8}Co_{0.2})_2$ with various Z values. The T_C increases while T_N decreases with the Z. For $Z=0.1$, there is

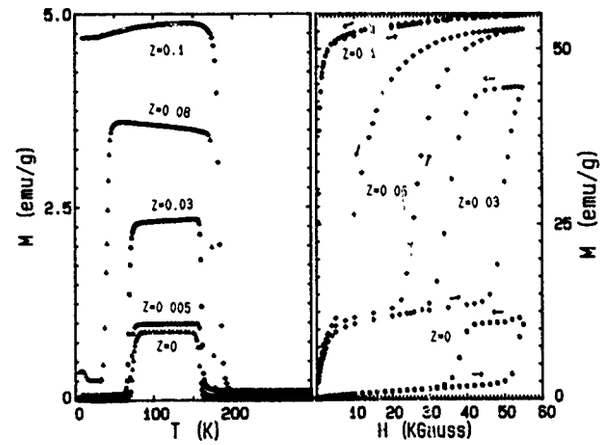

FIG. 3. (a) Magnetization M vs temperature T and (b) isothermal (at $T=10$ K) magnetization M vs applied magnetic field H for $Ce_{1-Z}Y_Z(Fe_{0.8}Co_{0.2})_2$ with various Z values.

no FM-AFM transition down to 5 K. A magnetic phase diagram for $Ce_{1-Z}Y_Z(Fe_{0.8}Co_{0.2})_2$ as a function of Y concentration is presented in Fig. 2(b). It is quite obvious that the partial substitution of Ce by Y in $Ce_{1-Z}Y_Z(Fe_{0.8}Co_{0.2})_2$ reduces the instability of the FM state; and for 10% Y substitution, a complete restoration of the FM state down to 5 K is achieved.

The results of isothermal (at $T=10$ K) magnetization as a function of applied magnetic field for various Y concentrations is presented in Fig. 3(b). The magnetization increases very sharply at a critical field data H_C (for $Z=0$, 0.03, and 0.06) with large field hysteresis. This sharp rise in magnetization at a critical field is associated with a field-induced AFM-FM first-order phase transition. We notice that the critical field decreases with increasing concentration of Y and it vanishes for 10% Y concentration.

The field-induced transition is also observed for all samples in the $Ce(Fe_{1-X}Co_X)_2$ system. The critical field H_C is plotted as a function of Co concentration X in Fig. 2(a) and as a function of Y concentration Z in Fig. 2(b). The H_C and T_N are closely associated with each other. In the system $Ce(Fe_{1-X}Co_X)_2$, the H_C and T_N show a maximum around the same X value of 0.15. In $Ce_{1-Z}Y_Z(Fe_{0.8}Co_{0.2})_2$, both H_C and T_N decrease monotonically with Y concentration. The field-induced transition and the magnetic hysteresis suggest the presence of magnetic anisotropy.[14] Therefore, it is likely that magnetic anisotropy is a very important factor in the development of the AFM phase. Furthermore, we would like to propose that the competition between the exchange interaction energy and the temperature-dependent magnetic anisotropy energy is responsible for the FM-AFM transition in the itinerant system $Ce(Fe_{1-X}Co_X)_2$.

In an itinerant electron system the exchange interaction energy is directly related with the electronic density of states at the Fermi level.[1] We now present the result of entropy change across the FM-AFM transition, which we hope will provide us with some information on the electronic band structure in $Ce(Fe_{1-X}Co_X)_2$.

Figure 4 presents the change in entropy as a function of temperature for $Ce(Fe_{0.8}Co_{0.2})_2$ calculated using the thermodynamic relationship $\Delta S_T = -\Delta M(\partial H/\partial T)_{T_n}$. ΔS_T is total

entropy change which consists of the lattice entropy change and electronic entropy change across the transition; ΔM is the magnetization change between the AFM state and the FM state at T_N; and $(\partial H/\partial T)_{T_N}$ is the derivative of the field dependence curve of the transition temperature T_N which can be calculated based on experimental data.[13]

The linearity of the entropy change with T_N suggests that it is the electronic entropy change that is primarily involved in the FM-AFM transition in our system because the electronic entropy can be written as $S_E=\int(C/T)dT=\gamma T$, where $C=\gamma T$ is used and γ is the electronic specific-heat coefficient. Since γ is proportional to the density of the electronic states at the Fermi surface, S_E is strongly influenced by the electronic band structure. At the FM-AFM transition, the electronic entropy change would be $\Delta S_E=(\gamma_{FM}-\gamma_{AFM})T_N$, where γ_{FM} and γ_{AFM} are the electronic specific-heat coefficients for FM and AFM states, respectively. The slope obtained from Fig. 4 is 10 mJ K^{-2} mol^{-1}. The value of $\gamma_{FM}-\gamma_{AFM}$ by Wada, Nishigori, and Shiga[15] is 13 mJ K^{-2} mol^{-1}. The two values are in good agreement. The above results indicate that the main contribution to the total entropy change at the FM-AFM transition for this system is due to the electronic entropy change. The positive value of ΔS_E means that the electronic density of states at the Fermi level in the FM state is higher than that in the AFM state.

The FM state in $CeFe_2$ is inherently unstable. This has been recently suggested by the neutron-diffraction studies by Kennedy and Coles[16] and Yang *et al.*[17] They observed an antiferromagnetic component developing below $T\approx 80$ K in $CeFe_2$. Wada and co-workers[15] measured the Co concentration dependence of the electronic specific-heat coefficient γ for $Ce(Fe_{1-X}Co_X)_2$. They found that the γ value has a minimum around $X=0.16$. Thus, we may conclude that Co substitution for Fe in $Ce(Fe_{1-X}Co_X)$ has two effects: One is to modify the exchange interaction energy via altering the electronic density of states at the Fermi level; and the other is to modify the magnetic anisotropy energy. Generally from our data, the former is suppressed and the latter is enhanced by the Co substitution. Both effects enhance the instability of the FM state and, thus, the FM-AFM transition is likely to occur.

Up to now no experimental γ data for $Ce_{1-Z}Y_ZFe_2$ have been reported. Khowash[18] calculated the electronic band structure for $CeFe_2$. His results show that Y substitution for Ce in $CeFe_2$ may increase the electronic density of states at the Fermi level if we assume the rigid-band model is applicable to $Ce_{1-Z}Y_ZFe_2$. On the other hand, our experimental results show that Y substitution for Ce suppresses the magnetic anisotropy. In contrast to the effects of the Co substitution for Fe, the Y substitution for Ce intensifies the stability of the FM state and, thus, prevents the FM-AFM transition.

In summary, the electronic band structure is modified at the FM-AFM transition in the $Ce(Fe_{1-X}Co_X)_2$ system. The FM phase has a higher electronic density of states at the Fermi level than the AFM phase. Co substitution for Fe in the $Ce(Fe_{1-X}Co_X)_2$ system intensifies the instability of FM phase. The Y substitution for Ce in the $Ce_{1-Z}Y_Z(Fe_{0.8}Co_{0.2})_2$ suppresses the magnetic anisotropy and gradually restores the stability of the FM phase. Finally, for 10% Y substitution for Ce, the stability of the FM phase is totally restored down to a temperature of 5 K. The competition between exchange interaction and the magnetic entropy is a possible mechanism for the FM-AFM transition observed in $CeFe_2$ and related pseudobinary compounds.

Preparation and magnetic properties of BaM films with excellent crystallinity by Xe sputtering

N. Matsushita, K. Noma, S. Nakagawa, and M. Naoe
Department of Physical Electronics, Tokyo Institute of Technology, 2-12-1 O-okayama, Meguro-ku, Tokyo 152, Japan

M-type barium ferrite ($BaFe_{12}O_{19}$) films were deposited on a ZnO underlayer by sputtering with mixture of Ar, Xe, and O_2 gases. P_{O_2} and P_{Ar+Xe} were set at 0.01 and 0.09 Pa, respectively, where P_{Xe} was changed from 0.00 to 0.09 Pa. The dependencies of surface morphology, $\langle D \rangle$, $\Delta\theta_{50}$, M_s, and $H_{c\perp}$ and $H_{c\parallel}$ on P_{Xe} were investigated. Both BaM layers deposited at P_{Xe} and P_{Ar} of 0.09 Pa possessed smooth surface and exhibited $\Delta\theta_{50}$, M_s, $H_{c\perp}$, and $H_{c\parallel}$ of about 4°, 300 emu/cm^3, 2.0 and 0.3 kOe, respectively. The BaM layer deposited at P_{Xe} of 0.04 Pa possessed a rough surface and exhibited $\Delta\theta_{50}$ and $H_{c\parallel}$ as large as about 9° and 0.6 kOe, respectively, and M_s as small as about 200 emu/cm^3.

I. INTRODUCTION

A magnetoplumbite type of Ba ferrite (BaM:$BaFe_{12}O_{19}$) has been intensively investigated due to its various attractive and useful properties for magnetic recording media and microwave filters, and so on.[1-7] In BaM ferrite, Ba ions occupy the same sites as oxygen ones in the R block where larger Ba^{2+} ions with a radius of 1.43 Å (see Fig. 2) should replace smaller O^{2-} ones with that of 1.32 Å. Therefore, it seems effective for the deposition of BaM ferrite films with good crystallinity that the Ba adatoms have a high kinetic energy for a sufficiently long walk on the substrate surface. However, since the atomic weight of Ba (137.3) is much heavier than that of Ar (40.0) as seen in Fig. 1, it is considered that Ba atoms ought to arrive at the substrate with a relatively low kinetic energy. Moreover, the Ar atoms recoiled by heavier Ba ions in targets might bombard the growing film with high kinetic energy during deposition and some of them not only may be incorporated into films as impurities, but also easily destroy the regularly packed lattice composed of lighter oxygen ions with a mass of 16.0. On the other hand, the atomic weight of Xe (131.3) is much heavier than that of O (16.0) and Fe (55.8), but is not so different from that of Ba. Therefore, Ba atoms as well as O and Fe ones seem to arrive at the substrate with relatively high kinetic energy for a sufficiently long walk and the number of the recoiled particles seems to decrease when Xe is used as the sputtering gas. It has also been found that ZnO underlayers are useful for the epitaxial growth of BaM layers as well as spinel ferrite layers.[7,8] Therefore, BaM layers were deposited on the ZnO underlayer in mixture of Ar, Xe, and O_2 gases by using the facing target sputtering (FTS) apparatus; then, the crystallographic and magnetic characteristics of the specimen films on the partial Xe pressure P_{Xe} were investigated.

II. EXPERIMENTS

A. FTS apparatus

Figure 2 shows the schematic representation of the FTS apparatus for multilayers used in this study. The dc glow discharge is performed using the facing targets as cathodes and the grounded chamber wall and shield rings as anodes. The magnetic field for confining the plasma was about 140 Oe at the point of the center line between targets. Since the substrate is placed outside of the confined plasma, the deposited films can avoid the bombardment of high-energy particles such as γ electrons and negative ions.[8] Moreover, since the highly ionized plasma is confined in a narrow space between targets, it can be maintained even at a very low working gas pressure below 0.1 Pa, the value of which is too low for a conventional sputtering system to generate the stable glow discharge.

B. Preparation of specimen films

Prior to the deposition of the BaM ferrite layer, the ZnO underlayer was deposited on a SiO_x/Si substrate. It is known that ZnO is composed of a densely packed structure of oxygen and since the distance between oxygen atoms in the densely packed plane of ZnO (3.24 Å) is not so different from that of $CoFe_2O_4$ with (111) orientation (2.96 Å) and BaM ferrite with c-axis orientation (2.95 Å), the ZnO underlayer is useful for the epitaxial growth of these ferrite layers.[7,9] The preparation conditions are listed in the right-hand-side column of Table I. The thickness of the ZnO layer was about 4500 Å for the deposition of 1 h. The crystallite size $\langle D \rangle$ and the dispersion degree of c-axis orientation $\Delta\theta_{50}$ of the ZnO underlayer were about 500 Å and smaller than 4°, respectively.

The preparation conditions for BaM ferrite layers are listed in the left-hand-side column of Table I. The disk plates 85 mm in diameter used as targets were sintered from the

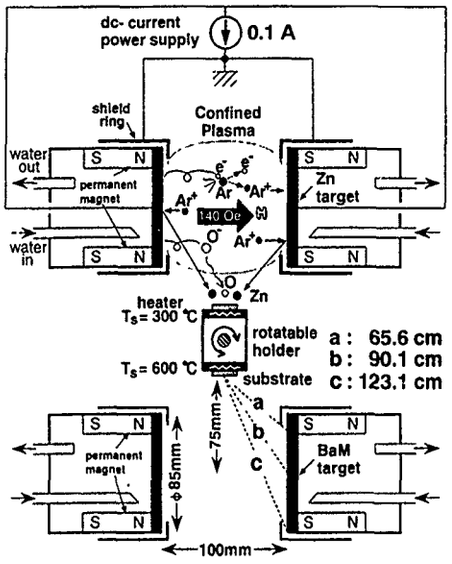

FIG. 2. Schematic representation of FTS apparatus for multilayers.

mixture of BaO and 5.5(Fe_2O_3) powders at 1350 °C in the air by a conventional dry method. The discharge current was set at 0.1 A and then the discharge voltage increased from 472 to 660 V with increase of P_{Xe} from 0.00 to 0.09 Pa.

III. RESULTS AND DISCUSSION

A. Composition and microstructure

The Ba and Fe content C_{Ba} and C_{Fe} was measured by using inductively coupled plasma spectrometry (ICPS). C_{Ba} normalized for C_{Fe} of 12 was about 0.9 at various P_{Xe} in the range between 0.00 and 0.09 Pa.

Figure 3 shows the scanning electron microscopy (SEM) photographs of the surface appearance of BaM layers deposited on a ZnO underlayer at P_{Xe} of (a) 0.00, (b) 0.01, (c) 0.04, and (d) 0.09 Pa. As seen in (a), the layer at P_{Xe} of 0.00 Pa revealed an almost smooth, dense, and uniform morphology, although very fine grains were slightly visible on the film surface; however, the surface smoothness was not obtained even when P_{Xe} was only 0.01 Pa as seen in (b). The layer deposited at P_{Xe} of 0.04 Pa revealed a very rough and nonuniform morphology as seen in (c). On the contrary, the layer at P_{Xe} of 0.09 Pa revealed a very smooth and flat morphology as seen in (d). These differences of surface morphologies between (a) and (c), or (d) and (c), seemed to have close relationships to the difference of the kinetic energy of deposited particles. These differences of energy of deposited particles cause the change of crystallographic and magnetic characteristics as seen in Secs. III B and III C.

TABLE I. Preparation conditions.

	BaM layer	ZnO underlayer
Target composition	$Ba_{1.0}Fe_{11.0}O_{19.0-x}$	Zn
Substrate	ZnO/SiO_x/Si	SiO_x/Si
Substrate temperature T_s	600 °C	300 °C
Residual pressure	8.0×10^{-5} Pa	
Total gas pressure $P_{Ar+Xe+O_2}$	0.10 Pa	0.26 Pa
Ar gas pressure P_{Ar}	0.09–0.00 Pa	0.13 Pa
Xe gas pressure P_{Xe}	0.00–0.09 Pa	···
O_2 gas pressure P_{O_2}	0.01 Pa	0.13 Pa

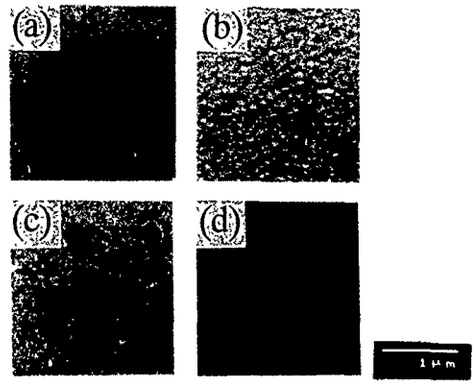

FIG. 3. SEM photographs for surfaces of BaM layers deposited at P_{Xe} of (a) 0.00, (b) 0.01, (c) 0.04, and (d) 0.09 Pa.

B. Crystallinity

Figure 4 snows the P_{Xe} dependencies of $\langle D\rangle$ and $\Delta\theta_{50}$ of the BaM layer. $\langle D\rangle$ slightly decreased and $\Delta\theta_{50}$ was as small as 3.7° at P_{Xe} of 0.09 Pa and took a maximum value of 8.7° at P_{Xe} of 0.04 Pa.

The P_{Xe} dependencies of $\Delta\theta_{50}$ seemed to have a relationship remarkably close to the sputtering phenomena at the target and the collision times of sputtered particles to working gas atoms during the flight from target to substrate. The mean free path of sputtered particles in the working gas at the pressure of 0.1 Pa is about 50 and 100 mm for Ba and Fe atoms with radius of 2.22 and 1.26 Å, respectively, as shown in Fig. 1. The distances a, b, and c, which correspond to the shortest, mean, and the longest distance from target to substrate center, were 65.6, 90.1, and 123.1 mm, respectively, as seen in Fig. 2. Therefore, the sputtered particles seem to

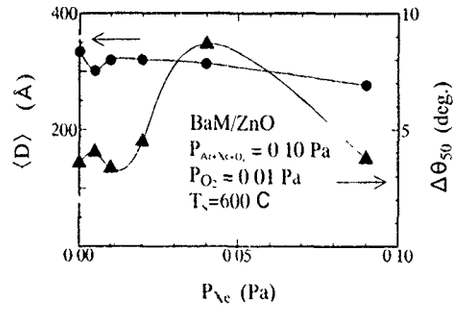

FIG. 4. Dependencies of crystallite size $\langle D\rangle$ and dispersion degree of c-axis orientation $\Delta\theta_{50}$ on Xe pressure P_{Xe}.

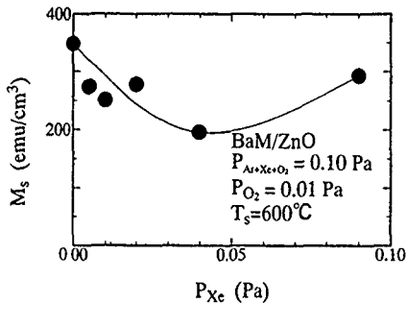

FIG. 5. Dependencies of saturation magnetization M_s on Xe pressure P_{Xe}.

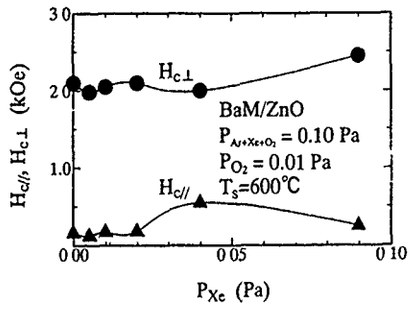

FIG. 6. Dependencies of perpendicular and in-plane coercivities $H_{c\perp}$ and $H_{c\parallel}$ on Xe gas pressure P_{Xe}.

arrive at the substrate after a few collisions with atoms of the working gas. The Fe, O, and even Ba atoms sputtered by Xe ions can arrive at the substrate with relatively high kinetic energy, enough to form BaM ferrite crystallites with good c-axis orientation. Therefore, the values of $\Delta\theta_{50}$ for both BaM layers deposited at P_{Ar+O_2} and P_{Xe+O_2} of 0.1 Pa were smaller and almost the same.

At P_{Xe} of 0.04 Pa, the sputtering phenomena and the collision of sputtered particles with the working gas seemed to be more complicated. There may be apparent differences in kinetic energies among deposited particles. Although the atoms sputtered by heavier Xe ions and collided with Ar or Xe atoms seem likely to possess relatively high energy and make a long walk on the substrate, the atoms sputtered by lighter Ar ions and collided with heavier Xe atoms seem likely to possess insufficient energy for a random walk on the substrate. Therefore, $\Delta\theta_{50}$ of the BaM layer deposited in mixed gases at P_{Xe} of 0.04 Pa might take a larger value than those at P_{Xe} of 0.00 and 0.09 Pa. It also seems that this nonuniformity of kinetic energy of deposited particles causes a very rough and nonuniform surface morphology for the films deposited in a mixture gases as seen in Figs. 3(c) and 3(d).

C. Magnetic characteristics

Figure 5 shows the P_{Xe} dependencies of the saturation magnetization M_s of the BaM layer. M_s of the BaM layer deposited at P_{Xe} of 0.00 Pa took the maximum value of 350 emu/cm^3 and was not so different from the bulk M_s of 380 emu/cm^3. M_s decreased with increase of P_{Xe} up to 0.04 Pa and took the minimum value of 196 emu/cm^3 at P_{Xe} of 0.04 Pa, of which the value was as relatively large as 293 emu/cm^3 at P_{Xe} of 0.09 Pa. These dependencies seemed to have a relationship distinctly close to the layer morphology and $\Delta\theta_{50}$ of films as seen in Figs. 3 and 4.

Figure 6 shows the P_{Xe} dependencies of the perpendicular and in-plane coercivities $H_{c\perp}$ and $H_{c\parallel}$, respectively. Although $H_{c\perp}$ was almost constant at about 2.0 kOe, $H_{c\parallel}$ took the maximum value of 0.6 kOe at P_{Xe} of 0.04 Pa. Since $H_{c\parallel}$ corresponds apparently to $\Delta\theta_{50}$, such a large $H_{c\parallel}$ at P_{Xe} of 0.04 Pa was attributed to the degradation of crystallinity implied by larger $\Delta\theta_{50}$ at P_{Xe} of 0.04 Pa as seen in Fig. 4.

IV. CONCLUSION

BaM ferrite layers were deposited on a ZnO underlayer at T_s of 600 °C at P_{Ar+Xe} of 0.09 Pa and O_2 at P_{O_2} of 0.01 Pa. The obtained results are as follows.

(i) BaM layers deposited at P_{Xe} of 0.09 Pa revealed a smooth surface appearance and excellent crystallinity with $\Delta\theta_{50}$ of 4°. In addition, they exhibited good magnetic characteristics such as M_s and $H_{c\perp}$ and $H_{c\parallel}$ of about 293 emu/cm^3 and 2.0 and 0.3 kOe, respectively.

(ii) BaM layers deposited in the mixed gas at P_{Ar}, P_{Xe}, and P_{O_2} of 0.05, 0.04, and 0.01 Pa, respectively, had rough surface texture and worse crystallinity with $\Delta\theta_{50}$ of 8.7°. They exhibited smaller M_s and higher $H_{c\parallel}$ of 196 emu/cm^3 and 0.6 kOe, respectively.

It seems to be possible to deposit the BaM layer with good crystallinity and magnetic characteristics on a ZnO underlayer using a mixture of O_2 and Xe instead of Ar as the sputtering gas.

Magnetic ordering in $UCoNiSi_2$ and $UCoCuSi_2$ studied by ac-susceptibility and neutron-diffraction measurements

Moshe Kuznietz, Haim Pinto, and Mordechai Melamud
Nuclear Research Centre–Negev, P.O. Box 9001, 84190 Beer-Sheva, Israel

Polycrystalline samples of intermediate solid solutions of the UM_2Si_2 compounds (M=Co,Ni,Cu), namely $UCoNiSi_2$ and $UCoCuSi_2$, were prepared and were found to have body-centered tetragonal $ThCr_2Si_2$-type crystallographic structure. In $UCoNiSi_2$ ac susceptibility indicates a single antiferromagnetic (AF) transition at $T_N=115\pm5$ K, confirmed by neutron-diffraction observation of the AF-*I* structure down to 10 K (with uranium moments of $1.6\pm0.2\mu_B$, along the tetragonal *c* axis). In $UCoCuSi_2$ ac susceptibility indicates ferromagnetic transition at $T_C=107\pm5$ K, and implies an AF transition at lower temperature, confirmed by the AF-*I* structure, observed in neutron diffraction below $T_0=95\pm5$ K down to 10 K (with uranium moments of $1.6\pm0.1\mu_B$, along the *c* axis). The magnetic properties are discussed in comparison with UM_2X_2 and $U(M,M')_2X_2$ materials (X=Si,Ge).

I. INTRODUCTION

The UM_2Si_2 compounds (M=Co,Ni,Cu) were studied previously[1,2] and found to have $ThCr_2Si_2$-type crystallographic structure. UCo_2Si_2 orders antiferromagnetically below 85 K into the AF-*I* structure (+ − + −) with a wave vector $\mathbf{k}=(0,0,1)$.[1] UNi_2Si_2 orders below 124 K into an incommensurate phase,[2] acquires AF-*I* structure below 103 K (Refs. 1 and 2) and ferrimagnetic (+ + −) structure with a wave vector $\mathbf{k}=(0,0,2/3)$ below 53 K.[1,2] UCu_2Si_2 orders ferromagnetically below 103 K.[1] The ordered moments are along the tetragonal axis, and are found only on uranium.[1,2]

Studying the $U(M,M')_2Si_2$ systems, we started with intermediate solid solutions $UMM'Si_2$. In $UNiCuSi_2$ ac susceptibility indicated[3–5] antiferromagnetic (AF) transition at $T_N=150\pm5$ and 155 ± 5 K, in two separately prepared samples, with four (or three) transitions below T_N with ferro/ferrimagnetic *F* character. Neutron diffraction on both materials showed[4,5] that apart from the AF transitions at T_N (150 ± 1 and 152 ± 2 K, respectively) to the AF-*I* structure (+ − + −), in accordance with the ac susceptibility, none of the *F* transitions was observed. The AF-*I* structure persists down to 1.7(1.5) K. Short-range magnetic order involving several consecutive ferromagnetic planes in the AF-*I* phase detected by ac susceptibility, and not by neutron diffraction, is proposed to explain the differences between these measurements. Following our studies of $UNiCuSi_2$, we have prepared polycrystalline samples of the other two intermediate solid solutions of the UM_2Si_2 compounds, namely $UCoNiSi_2$ and $UCoCuSi_2$, and present here their magnetic properties, measured by ac susceptibility and neutron diffraction.

II. EXPERIMENTAL DETAILS

Polycrystalline samples of the solid solutions $UCoNiSi_2$ and $UCoCuSi_2$ were prepared by arc melting stoichiometric amounts of the constituents in an argon atmosphere. The obtained buttons were annealed at 750 °C in vacuum for 120 h, and were subsequently crushed into fine powders and examined by x-ray diffraction at room temperature (RT=295 K) to determine their quality, as well as their crystallographic properties.

ac-susceptibility measurements on polycrystalline samples were done on $UCoNiSi_2$ (456 mg) down to 80 K (Ref. 3) and later down to 20 K, and on $UCoCuSi_2$ (348 mg) down to 80 K. The ac magnetic field was rather weak (<10 Oe). Calibration of the ac-susceptibility values was done for $UCoNiSi_2$ with a polycrystalline sample of Gd_2O_3 (300 mg), for which the χ_M value at 293 K is 51×10^{-3} emu/mol (with $\theta=-15$ K and $\mu_{eff}=7.9\mu_B$), and for $UCoCuSi_2$ with a polycrystalline sample of Ho_2O_3 (20 mg), for which the χ_M value at 293 K is 89×10^{-3} emu/mol (with $\theta=-14$ K and $\mu_{eff}=10.5\mu_B$). These measurements determined the temperatures and types of magnetic transitions in near-zero magnetic fields, as well as the paramagnetic properties of these materials.

Neutron-diffraction measurements on 20 g polycrystalline samples (in cylindrical aluminium containers) were done in the IRR-2 reactor, with the diffractometers KANDI-II (at $\lambda=2.453$ Å) for $UCoNiSi_2$ and KANDI-III (at $\lambda=2.40$ Å) for $UCoCuSi_2$. A DISPLEX (closed-cycle helium cooler made by Air Products, Inc.) was used for measurements at low temperatures (LT), down to 10 K, and the temperature was measured with Au(Fe)/Chromel thermocouple. These measurements determined the RT and LT crystallographic structure and LT magnetic structure of both materials.

III. RESULTS

At RT only $\{hkl\}$ reflections with $h+k+l$=even are observed by x-ray and neutron diffraction from both $UCoNiSi_2$ and $UCoCuSi_2$. These are consistent with the body-centered tetragonal $ThCr_2Si_2$-type crystallographic structure (space group $I4/mmm$). The RT structure parameters are obtained from least-squares fits of the observed integrated and calculated neutron-diffraction intensities, assuming random occupation of the (M,M′) site, yielding residuals $R=4.2\%$ and 3.7%, respectively. The RT lattice parameters (a,c) and derived tetragonal cell volume V, and the RT fitted position parameter (z) of the silicon atom, of $UCoNiSi_2$ and $UCoCuSi_2$, are given in Table I. The parameters are compared in Table I with the averages of previously published values of the same parameters in the UM_2Si_2 compounds[1,4] and in $UNiCuSi_2$.[3–5]

The temperature dependence of the molar ac susceptibility of $UCoNiSi_2$, in the temperature range 20–295 K, is shown in Fig. 1. A single transition to an antiferromagnetic state is observed at $T_N=115\pm5$ K, with a rather low $\chi_M=(6\pm1)\times10^{-3}$ emu/mol at the transition. The temperature dependence of the molar ac susceptibility of $UCoCuSi_2$ in the temperature range 80–295 K, is shown in Fig. 2. A rather strong susceptibility peak, corresponding to a ferromagnetic ordering, is observed at $T_C=107\pm5$ K, with a high $\chi_M=(165\pm5)\times10^{-3}$ emu/mol at the transition. The sharp decrease of the ac-susceptibility curve at its low-temperature side, uncommon to a ferromagnetic phase, suggests a second transition, to an AF phase.

Inverse molar susceptibility curves of $UCoNiSi_2$ and $UCoCuSi_2$ in their paramagnetic states are deduced from Figs. 1 and 2, respectively. The paramagnetic Curie temperature θ is obtained from the intersection of the linear part of such a curve (above 200 K) with the temperature axis.

$\mu_{\rm eff}$ (in μ_B) is obtained via the relation $(\chi_M)^{-1}=(2.83/\mu_{\rm eff})^2(T-\theta)$, where χ_M is given in emu/mol and $(T-\theta)$ is given in K. The values for θ and $\mu_{\rm eff}$ are listed in Table II, where they are compared with the respective values of $UNiCuSi_2$ (Refs. 3–5).

The LT neutron diffractograms of $UCoNiSi_2$ and $UCoCuSi_2$ (at 10 K) show additional reflections for which $h+k+l=$odd (such as {010},{012},{111}), indicating AF ordering of at least the uranium sublattice, with a wave vector $\mathbf{k}=(0,0,1)$ and alternate stacking $(+\ -)$ of ferromagnetic layers along the tetragonal axis (AF-I). The absence of $\{00l\}$ reflections with odd l points out to ordered magnetic moments along the tetragonal axis. The LT diffractograms are similar to those shown for UCo_2Ge_2 (Ref. 6) and $UNiCuSi_2$.[4,5]

The LT lattice parameters of $UCoNiSi_2$ and $UCoCuSi_2$ are obtained from least-squares fits of observed integrated and calculated intensities, with residuals $R=4.9\%$ and 3.7%, respectively. The LT fitted parameters (a,c,z) fall within the experimental error range of the RT values. The integrated intensities of the reflections with $h+k+l=$odd are in agreement with ordering of the uranium sublattice, with fitted (by the procedure of Ref. 6) ordered magnetic moments of $1.6\pm0.2\mu_B$ (Table II).

Temperature variation of the integrated intensity of the magnetic {010} reflection (Fig. 3) indicates that the AF-I structure exists in $UCoNiSi_2$ up to $T_N=115\pm5$ K [Fig. 3(a)], in accordance with the transition observed in the ac susceptibility (Fig. 1). In $UCoCuSi_2$ the AF-I structure persists up to $T_0=95\pm5$ K [Fig. 3(b)], while the ac-susceptibility curve (Fig. 2) points out a ferromagnetic transition at $T_C=107\pm5$ K. However, the poor statistical quality of the data in Fig. 3(b) does not allow us to confirm that T_C is indeed above T_0, as expected. Moreover, due to the small ordered magnetic moment close to T_C, our neutron diffraction measurements in the T_0 to T_C temperature range are unable to detect the ferromagnetism.

IV. DISCUSSION

The measured lattice parameters in $UCoNiSi_2$ and $UCoCuSi_2$ fall between the respective parameters of the end

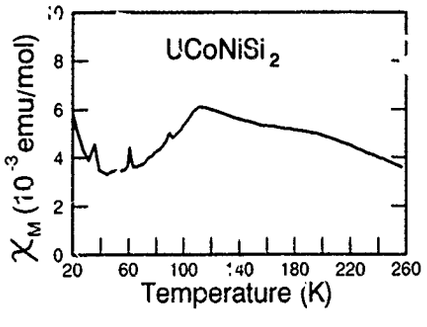

FIG. 1. Temperature dependence of the molar ac susceptibility in a polycrystalline sample of $UCoNiSi_2$ indicating antiferromagnetic ordering below $T_N=115\pm5$ K. The inverse molar susceptibility above 200 K leads to $\theta=-175\pm50$ K and $\mu_{\rm eff}=3.5\pm0.3\mu_B$

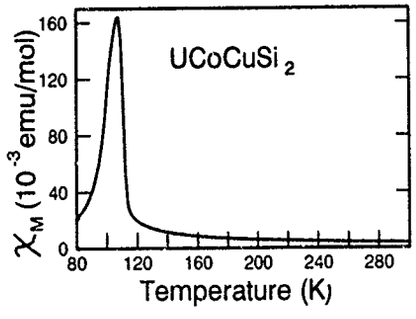

FIG. 2. Temperature dependence of the molar ac susceptibility in a polycrystalline sample of $UCoCuSi_2$ indicating initial ferromagnetic ordering below $T_C=107\pm5$ K, followed by a transition to an antiferromagnetic phase. The inverse molar susceptibility above 200 K leads to $\theta=+40\pm10$ K and $\mu_{\rm eff}=2.8\pm0.2\mu_B$

TABLE II. Paramagnetic values (μ_{eff} and θ), ordering (T_N or T_C) and transition (T_0) temperatures, magnetic structures, and uranium ordered magnetic moments m in the $UMM'Si_2$ solid solutions.

Material	μ_{eff} (μ_B)	θ (K)	$T_N(T_C)$ (K)	Order below $T_N(T_C)$	T_0 (K)	Order below T_0	m (10 K) (μ_B)
$UCoNiSi_2$	3.5±0.3[a]	−175±50[a]	115± 5[a]	AF-I	···	···	1.6±0.2
$UNiCuSi_2$	2.4±0.1[a]	+80± 5[a]	150±1[a,b]	AF-I[b]	···	···	2.2±0.2[b]
$UCoCuSi_2$	2.8±0.2	+40± 10	107± 5	ferro	95 ± 5	AF-I	1.6±0.1

[a] Reference 3. [b] Reference 4.

compounds UM_2Si_2 (Table I), in agreement with the Vegard (Zen) law. In the case of $UCoNiSi_2$ a and c have different trends, while in the case of $UCoCuSi_2$ both a and c have similar trends, with respect to the end compounds.

The effective paramagnetic moments μ_{eff} in $UCoNiSi_2$ and $UCoCuSi_2$ are higher than the moment in $UNiCuSi_2$ (Table II), but all are still within a reasonable $5f$ configuration. This is the case also for UNi_2Si_2 and UCu_2Si_2.[1] The μ_{eff} values ($\leq 3.5\mu_B$) of all these materials seem to be correlated with the occurrence of localized magnetic moments on uranium atoms only. As an exception, a high effective paramagnetic moment, $4.85\mu_B$, is reported for UCo_2Si_2,[1] implying a certain paramagnetic moment on the cobalt.[6]

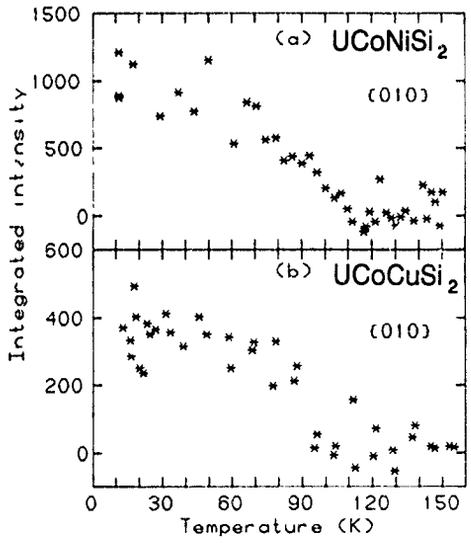

FIG. 3. Temperature dependence of the neutron-diffraction integrated intensity (above the background) of the magnetic {010} reflection: (a) in $UCoNiSi_2$, indicating $T_N=115\pm5$ K; (b) in $UCoCuSi_2$, indicating $T_0=95\pm5$ K. Each data point is an average of three consecutive scans of the {010} reflection, taken at increasing temperatures.

The additional small peaks on the ac-susceptibility curve of $UCoNiSi_2$ (see Fig. 1) are probably indicative of short-range-order transitions, but in a reduced extent when compared to the situation in $UNiCuSi_2$,[3-5] outlined above. The reduced regions of irregular ferromagnetic (or ferrimagnetic) short-range order in $UCoNiSi_2$ indicate increased stabilization of the AF-I structure in this material compared with $UNiCuSi_2$.

The paramagnetic Curie temperature θ varies from negative in $UCoNiSi_2$ to positive and close to T_C in $UCoCuSi_2$ (Table II). Based on the trend of these θ values we expect an oscillatory variation of θ with x in the corresponding $U(M_{1-x}M'_x)_2Si_2$ systems, similar to that reported for $U(Ni_{1-x}Cu_x)_2Ge_2$.[7]

The occurrence of two magnetic phases in $UCoCuSi_2$, ferromagnetic below $T_C=107\pm5$ K and AF-I below $T_0=95\pm5$ K down to 10 K, is different from the magnetic behavior of the $UCoNiSi_2$ and $UNiCuSi_2$. The latter have single magnetic phases, both AF-I, below $T_N=115\pm5$ and 150 ± 1 K, respectively.

The oscillatory variations of θ with x in the $U(M_{1-x}M'_x)_2Si_2$ systems, and the magnetic phase diagrams of these systems are expected to be correlated with the change in the number of conduction electrons (*RKKY*-like behavior), as discussed for the $U(Ni_{1-x}Cu_x)_2Ge_2$ system.[7]

Ferromagnetic ordering in dilute *Pd*Co alloys

R. E. Parra and A. C. Gonzalez
Centro de Fisica, Instituto Venezolano de Investigaciones Científicas, Apartado 21827, Caracas 1020A, Venezuela

The analysis of magnetization and neutron-scattering measurements shows that the ferromagnetic cloud in dilute *Pd*Co alloys has a size of $7.92\mu_B$, with a Co moment of $2.02\mu_B$, for a range of concentrations of $0.3 \leq c \leq 2.0$ at. % Co. Using the values obtained by our analysis of the data, the neutron scattering and the critical temperatures of ferromagnetism are reproduced using a localized magnetic moment model with a Heisenberg type of interaction between clouds and Monte Carlo simulation methods. The calculated neutron scattering shows a strong component of critical scattering in the unpolarized neutron; this component is the cause of the larger value of the ferromagnetic cloud ($\sim 10\mu_B$) that can be inferred from the neutron scattering. Agreement is also found between calculated critical temperatures and experimental T_c's at these values of concentrations.

I. INTRODUCTION

*Pd*Co alloys have always been treated as one of the most typical giant moment systems, along with *Pd*Fe alloys. The size of the giant moment has been taken as $\sim 10\mu_B$, based on magnetization measurements made by Bozorth *et al.*[1] in 1961 and on unpolarized diffuse neutron-scattering measurements made by Low and Holden[2] in 1966. Although there has been subsequent analyses of the mentioned data, and also new experimental data, until now there has been no agreement on the size of the magnetization cloud and on several other magnetic characteristics of these alloys. It is the purpose of this work to present our results on these matters, using a new approach by analyzing the available experimental data with a local moment model in order to predict some of the magnetic properties of these alloys.

II. MAGNETIC MOMENTS

In 1961, Bozorth *et al.*[1] published their magnetization measurements on *Pd*Co alloys. They found that ferromagnetism exists in compounds as dilute as 0.1 at. % Co. They also determined the average moment associated with each Co atom without making assumptions on whether the moment resides only on the Co atom, or partly on the Co with the rest of the moment scattered on the host atoms. The modern approach for this problem is to determine the individual average moment of the impurity and the magnetization cloud size [$M(0)$] by neutron scattering and to verify the latter by magnetization measurements.[3] $M(0)$ should be equal to $d\mu_{\rm sat}/dc$, where $\mu_{\rm sat}$ is the average magnetic moment of the alloy determined by magnetization measurements. Low and Holden[2] made unpolarized diffuse neutron-scattering measurements and determined the individual average moment of Co as $2.1 \pm 0.3\mu_B$. They also estimated that the giant moment size was about $10\mu_B$. Further analysis of the same data by Ododo[4] in 1985 showed the same value for the impurity moment but a smaller value for the giant moment. There are only unpolarized neutron measurements on *Pd*Co which, according to our analysis, have a nonelastic component in the scattering, therefore the $M(0)$ cannot be measured reliably at $K=0$, using this method. Moreover, there was no saturation in the available magnetization data.[3] The best way to obtain $M(0)$ was to determine the average individual moments from the neutron scattering (critical scattering does not affect the neutron scattering at large K), and using the appropiate magnetic form factors, and then to calculate $d\mu_{\rm sat}/dc$ using the fact that $\mu_{\rm sat}=c\mu_i+(1-c)\mu_h$. With this method we find that $M(0)$ is equal to $7.92 \pm 0.29\mu_B$ and that $\mu_{\rm Co}=2.02 \pm 0.03$. These values are in agreement, within the errors, with the results obtained by Ododo.[4]

III. MODEL AND CRITICAL TEMPERATURES

We use a magnetic environment model that has been used for other giant moment systems. We only present here the necessary formulas; the complete model can be found in Ref. 5.

The giant moment is formed by the exchange enhancement of the Pd atoms. This enhancement is verifiable in the susceptibility of Pd which in this model can be written as

$$\chi = \frac{\chi_0}{1-\Gamma}, \tag{1}$$

where Γ is an enhancement factor that has been determined as 0.947 ± 0.009, and χ_0 is the nonenhanced susceptibility.

In this model we assumed no interaction between the magnetic impurities (we assume they are sufficiently isolated) and that the inducer of the ferromagnetism is the interaction between polarization clouds. This interaction is given by

$$H = -\tfrac{1}{2}\sum_{\substack{i,j \\ i \neq j}} J_{ij}\mathbf{S}_i \cdot \mathbf{S}_j - \sum_i \mathbf{B}\cdot\mathbf{S}_i, \tag{2}$$

where $\mathbf{S}_i$ are the spins of the system, $\mathbf{B}$ is an external field, and J_{ij} are the exchange interactions between clouds. Using this interaction we determine, by Monte Carlo simulation, the critical temperatures of ferromagnetism from the maximum of $\tilde{\chi}$ which is given by

$$\tilde{\chi} = \frac{\langle (M - \langle M \rangle)^2 \rangle}{NkT}. \tag{3}$$

The quantity $\tilde{\chi}$ coincides with the susceptibility χ for infinite systems and is proportional to the fluctuation of the magni-

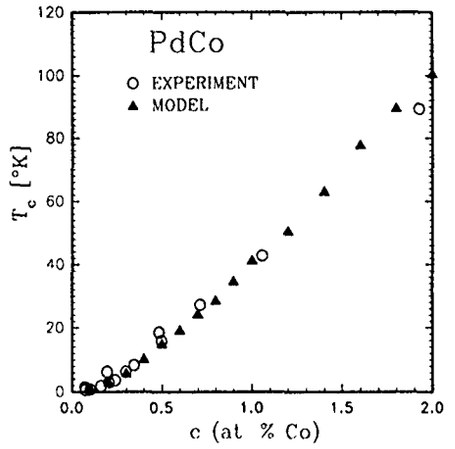

FIG. 1. Comparison of calculated critical temperatures of ferromagnetism with experimental values.

tude of the total moment. Critical temperatures were determined with 200 impurity spins in a fcc periodic lattice, with 2000 Monte Carlo steps per spin. The calculated temperatures are compared with experimental values in Fig. 1.

IV. NEUTRON SCATTERING

The diffuse unpolarized neutron scattering on *Pd*Co alloys shows forward peaks which would give larger magnetization clouds than the values obtained by Ododo[4] and by our analysis, for this concentration. This disagreement suggests the presence of a critical scattering contribution to the neutron measurements, which we decided to calculate. In order to do this, we used the following formula:[6]

$$T(\mathbf{K}) = \frac{1}{(0.27)^2 c(1-c)N}\frac{d\sigma}{d\Omega}$$

$$= |M(\mathbf{K})|^2\left((\langle\overline{\mathbf{S}^{\perp}}\rangle)^2 + \frac{1}{c(1-c)N} \times \sum_{ij} e^{i\mathbf{K}\cdot(\mathbf{r}_i-\mathbf{r}_j)}[\langle \mathbf{S}_i^{\perp}\cdot\mathbf{S}_j^{\perp}\rangle - (\langle\overline{\mathbf{S}^{\perp}}\rangle)^2]\right). \quad (4)$$

In this equation, $\mathbf{S}_i^{\perp}$ is the component of $\mathbf{S}_i$ perpendicular to $\mathbf{K}$, $\langle\,\rangle$ indicate thermal averages, the overhead bar indicates spatial averages, and $M(\mathbf{K})$ is the form factor of the magnetization cloud.

The Monte Carlo calculations were made, using the Hamiltonian given in Eq. (2), the same way as before but with a field $\mathbf{B}$ along the z axis assumed perpendicular to $\mathbf{K}$ and obeying the condition

$$\frac{kT}{N} \ll B \ll kT_c . \quad (5)$$

This relation guarantees that the total magnetic moment keeps its orientation and that the local field of each spin is unaffected by the field B. Under the conditions expressed above, we calculated the quantities $\langle S_i^z\rangle$, $\langle \mathbf{S}_i\cdot\mathbf{S}_j\rangle$, and $\langle S_i^z S_j^z\rangle$ from which we obtained

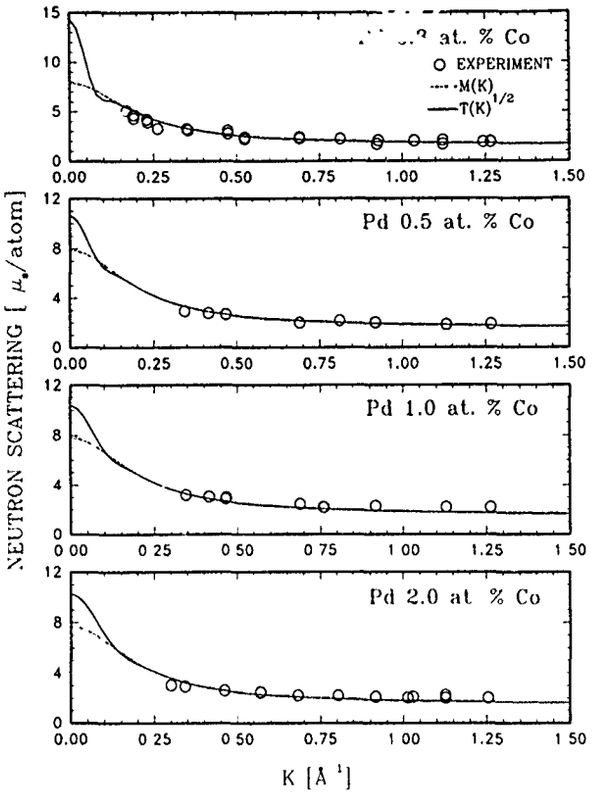

FIG. 2. Calculated neutron scattering compared with experimental values.

$$\langle \mathbf{S}_i^{\perp}\rangle = \langle S_i^z\rangle\hat{z}, \quad (6)$$

$$\langle \mathbf{S}_i^{\perp}\cdot\mathbf{S}_j^{\perp}\rangle = \tfrac{1}{2}(\langle S_i^z S_j^z\rangle + \langle \mathbf{S}_i\cdot\mathbf{S}_j\rangle). \quad (7)$$

Since the samples were polycrystalline, the spherically averaged diffuse scattering cross section was calculated as a function of wave vector $\mathbf{K}$. The calculation was performed at the temperature of the experiments. The results are shown in Fig. 2. $T(\mathbf{K})$ corresponds to a cross section normalized in order to be equal to $M(\mathbf{K})$ for large values of K; the diffuse cross section without normalization is below the experimental data, since it was calculated for a nonsaturated system. The calculated neutron scattering shows that there is a strong component of critical scattering in the unpolarized neutron data of Low and Holden;[2] this component is the cause of the larger value of the ferromagnetic cloud that can be inferred from the neutron scattering.

V. CONCLUSIONS

Our results indicate that *Pd*Co behaves as typical giant moment system, as expected. We find, however, that the magnetization cloud is not as large as has been reported earlier. This, we think, is reasonable because Co has a moment in a Pd host which is about one-third smaller than the moment of Fe in the same host. The cloud produced by Co must therefore be smaller and not of approximately the same value. The calculations of the critical temperatures and of the neutron scattering presented here and its verification against experimental values seem to confirm our conclusions.

Magnetic susceptibility of RCo_3B_2 (R=Y, Sm, Gd, and Dy)

H. Ido, M. Nanjo, and M. Yamada
Department of Applied Physics, Tohoku Gakuin University, Tagajo 985, Japan

The temperature dependence of magnetic susceptibility has been measured in a temperature region from about 100 to 500 K for the compounds RCo_3B_2 with R=Y, Sm, Gd, and Dy. Their magnetization curves at $T=5$ K have also been measured in a pulsed high field up to 170 kOe. YCo_3B_2 seems to have a Pauli paramagnetic nature down to $T=5$ K. In the paramagnetic temperature region, $SmCo_3B_2$ exhibits Van Vleck paramagnetism; however, $GdCo_3B_2$ and $DyCo_3B_2$ show Curie–Weiss character. The paramagnetic susceptibility for all compounds mentioned above is found to include a Pauli paramagnetic contribution from the Co sublattice. In the case of $GdCo_3B_2$ at $T=5$ K, the magnetic moment of $0.2\mu_B$/Co, which is antiparallel to the Gd moment, is considered to be induced by the exchange field from the Gd spin. A similar induced moment of $0.14\mu_B$/Co is also estimated in $DyCo_3B_2$. The Sm- and Dy-sublattice moments at $T=5$ K are smaller than the free-ion values, which can be explained by the crystal-field theory. A relatively large value of $B_2^0=7.0$ K for Dy^{3+} in $DyCo_3B_2$ can explain the experimental Dy^{3+} spontaneous moment and its increase by external field. The Sm moment in $SmCo_3B_2$ at $T=5$ K may be antiparallel to the induced Co-sublattice moment.

I. INTRODUCTION

The compounds RCo_3B_2 (R denotes rare earth) correspond to the case of $n=\infty$ of the compound systems expressed by the general formula $R_{n+1}Co_{3n+5}B_{2n}$ whose magnetic properties should reflect the systematic crystallographic change with n.[1-3] The above systems also include some possibility as a hard magnetic material.[4,5] Therefore, magnetic study for the above systems seems very important from fundamental as well as applied view points. Ballou, Burzo, and Pop[6] recently studied the magnetic properties of $(Gd_{1-x}Y_x)_2Co_7B_2$ compounds and pointed out that the Gd exchange field on the Co site significantly enhances the Co-sublattice moment. Similar suggestions have also presented by others.[7-10] In order to clarify the induced moment on the Co site and also the magnetic state of the rare-earth sublattice, this work focuses on the compounds RCo_3B_2 with R=Y, Sm, Gd, and Dy. The magnetic susceptibility in the paramagnetic region in addition to the magnetic moment at $T=0$ K have been measured and are discussed for the above compounds.

II. SAMPLE PREPARATION AND X-RAY ANALYSIS

Samples examined in this work have been prepared by melting raw materials of 99.9% purity in an arc furnace. Generally the melting was repeated several times to homogenize the ingots which were then annealed at 800 °C for 1 day. The crystal structure of the samples thus prepared has been confirmed to be of the $CeCo_3B_2$ type which is constructed by replacing the $2c$-site cobalts of the $CaCu_5$-type structure by boron atoms.[2,3] As seen in Table I, it is noted that the a axis of RCo_3B_2 remains almost unchanged; however, the c axis decreases significantly in comparison with those of the RCo_5 of the $CaCu_5$-type structure.

III. MAGNETIC MEASUREMENTS

In order to determine the magnetic moment per formula unit (μ_B/f.u.), magnetization curves of loose powder RCo_3B_2 with R=Y, Sm, Gd, and Dy have been measured at $T=5$ K in a pulsed field up to 170 kOe. In the case of YCo_3B_2, magnetization reached saturation at about 15 kOe, which gives a saturation moment of 0.6 emu/g or $0.032\mu_B$/f.u. This small value must be atributed to ferromagnetic impurity which has been confirmed in the YCo_3B_2 sample.[10] Therefore, the Co sublattice of YCo_3B_2 must be essentially in a nonmagnetic state at $T=5$ K.

Magnetization curves for RCo_3B_2 with R=Sm, Gd, and Dy are illustrated in Figs. 1 and 2, respectively.

Spontaneous magnetization of $SmCo_3B_2$ is obtained to be 1.94 emu/g or $0.12\mu_B$/f.u. by the linear extrapolation of the magnetization curve to zero field. The value of $0.12\mu_B$/f.u. is much smaller than the Sm free-ion moment.

The linear part of the magnetization curve gives a high-field susceptibility $X_{HF}=6.9\times10^{-6}$ emu/g, 4.5×10^{-4} μ_B/kOe. In the cases of $GdCo_3B_2$ and $DyCo_3B_2$, the magnetizations do not reach the free-ion moments. Both magnetization curves with increasing field in Fig. 2 begin to have a linear part at around 60 kOe. The linear part for $GdCo_3B_2$ seems to be the saturation, which gives $6.4\mu_B$/f.u., while the linear part for $DyCo_3B_2$ gives $8.2\mu_B$/f.u. by extrapolation to zero field and $8.9\mu_B$/f.u. at the maximum field

TABLE I Lattice constants (the values in parentheses are for RCo_5), Curie temperature, and magnetic moment per formula unit at $T=4.2$ or 5 K. Data from some references are also tabulated. The free ion moments $\mu_R{}^{3+}$ are also shown.

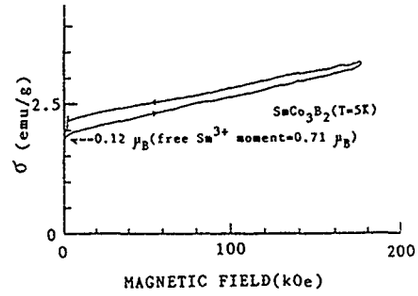

FIG. 1. Magnetization curve for loose powder of $SmCo_3B_2$ at $T=5$ K.

of 140 kOe. The specimens in this measurment are loose powder but may have some friction among powder particles; in addition, the pulsed field is used, so we regard only the linear part of the magnetization curve as an intrinsic magnetization process. The magnetic data are summarized in Table I.

Paramagnetic susceptibility has been measured for RCo_3B_2 in the temperature range from about 100 to 500 K. To remove the contribution from ferromagnetic impurities in the samples, we generally measured first a lot of thermomagnetic curves under various external magnetic fields up to 8 kOe, and then constructed magnetization curves from them at various temperatures above room temperature. In the temperature region below room temperature, magnetization curves have been measured in fields up to 12 kOe. The paramagnetic susceptibility has been determined from the linear part of each magnetization curve. Spontaneous moment contributed from the impurity in the case of $DyCo_3B_2$ has been determined to be 0.13 emu/g at room temperature.

In the case of YCo_3B_2, the ferromagnetic impurity prevents us from determining the intrinsic magnetic susceptibility which is very small compared with those of $GdCo_3B_2$ and $DyCo_3B_2$. The temperature dependence of magnetization mainly due to the temperature dependence of magnetization

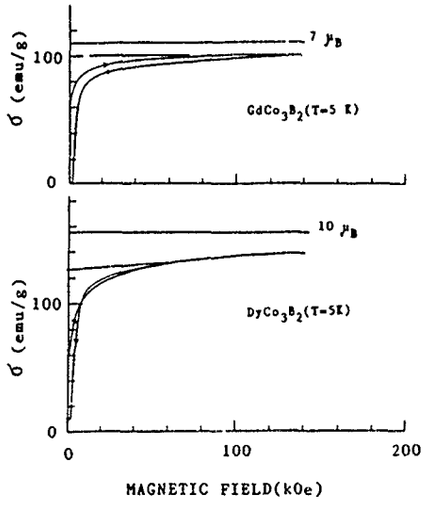

FIG. 2. Magnetization curves for loose powder of $GdCo_3B_2$ and $DyCo_3B_2$.

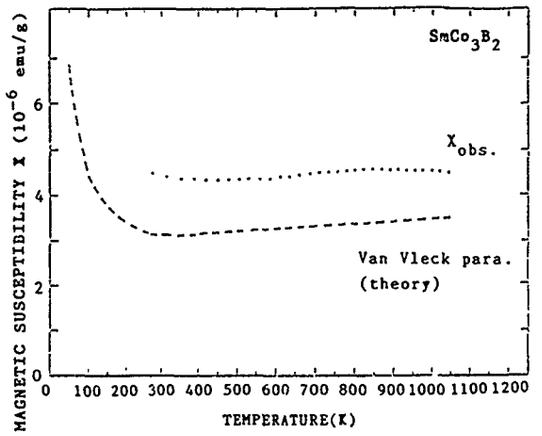

FIG. 3. Temperature dependence of magnetic susceptibility for $SmCo_3B_2$ powder.

of YCo_3B_2 in a constant magnetic field has been found to be almost independent of temperature in a wide range of temperatures, which also implies that YCo_3B_2 is essentially Pauli paramagnetic (see also Ref. 10).

The sample of $SmCo_3B_2$ is fortunately found not to contain ferromagnetic impurity with T_C higher than room temperature, so the temperature dependence of susceptibility has been easily determined as shown in Fig. 3. In the cases of $GdCo_3B_2$ and $DyCo_3B_2$, their intrinsic magnetic susceptibilities have been determined by the method mentioned above. The data are shown in Fig. 4. These data deviate slightly from the Curie–Weiss law in the high-temperature region. The linear parts in the low-temperature region give 7.95 and $11.4\mu_B$/f.u. for the effective moments of $GdCo_3B_2$ and $DyCo_3B_2$, respectively. The former agrees well with the Gd^{3+} effective moment, however the latter is a little larger than the free Dy^{3+} value of $10.65\mu_B$. The paramagnetic Curie points agree fairly well with the ferromagnetic Curie temperatures listed in Table I

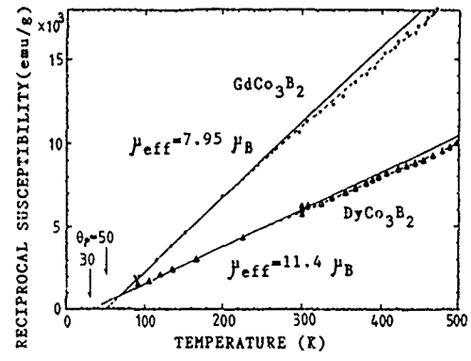

FIG. 4. Calculated magnetic moment m of Dy^{3+} at $T=0$ K as a function of $x=\mu_B(H_m+2H)/D$. H_m: molecular field; H:external field; $D=3B_2^0$.

IV. DISCUSSION OF THE RESULTS

As seen in Table I, the moment of the $0.01\mu_B$/Co atom for YCo_3B_2 suggests nonmagnetic Co sublattice. As discussed in our previous article,[3] the B atoms in the $R_{n+1}Co_{3n+5}B_{2n}$ systems have been considered to donate their valence electrons to the Co sublattice, which results in the nonmagnetic state of the Co sublattice. The moment of $SmCo_3B_2$, $0.12\mu_B$/f.u., at $T=5$ K suggests the influence of excited multiplets. The large high-field susceptibility of 6.9×10^{-6} emu/g in Fig. 1 must be explained mainly by the excited multiplets effect and partly by the Pauli paramagnetic Co sublattice. The saturation moment of $6.4\mu_B$/f.u. for $GdCo_3B_2$ seems to be the most reliable value. The $-0.6\mu_B$ extra moment in comparison with $7.0\mu_B$ of a free Gd^{3+} moment must be attributed to the Co-sublattice negative polarization which is $0.2\mu_B$/Co atom.[6,9] The large spin of the Gd atom ($S=7/2$) gives a strong exchange field to the Co $3d$ electrons. This result contrasts with the $0.6\mu_B$ extra moment parallel to the Gd moment in pure Gd metal at $T=0$ K.[12] The induced moment of the $0.2\mu_B$/Co atom is smaller than $0.49\mu_B$/Co estimated by Ballou and co-workers[6] for $Gd_2Co_7B_3$ or $0.3\mu_B$/Co estimated for $GdCo_4B$ by Pedziwiatr *et al.*[7] and Burzo *et al.*[8] Since the B atoms in the $R_{n+1}Co_{3n+5}B_{2n}$ systems donate their valence electrons to the Co sublattice[3] like $RCo_{5-y}Al_y$,[13] the Co $3d$ band in RCo_3B_2 compounds must be nearly filled and distorted; therefore, the disagreement mentioned above is not surprising. Similar analysis is applied to the data for $DyCo_3B_2$. The Dy atom has the same spin of 5/2 as that of the Sm atom. If the exchange field on the Co site is proportional to the rare-earth spin, the Co polarization in $DyCo_3B_2$ as well as in $SmCo_3B_2$ is calculated on the basis of the data for $GdCo_3B_2$ to be $0.43\mu_B$/f.u. or $0.14\mu_B$/Co atom.

Therefore, the $8.2\mu_B$/f.u. of $DyCo_3B_2$ and $0.12\mu_B$/f.u. of $SmCo_3B_2$ lead to $8.63\mu_B$/Dy and $0.31\mu_B$/Sm which are antiparallel to the induced Co moment. The latter case is especially noteworthy because the R moment is generally parallel to the moment of $3d$ metal atoms. The intrinsic Dy^{3+} spontaneous moment of $8.63\mu_B$ is now discussed by the crystal-field theory. We express the Hamiltonian for $DyCo_3B_2$ in a simple form by the following:

$$\mathcal{H}=DJ_z^2+2(g_J-1)J_x\mu_BH_m, \tag{1}$$

where the first term in the right-hand side is the crystal field due to only A_2^0, the second the exchange interaction between Dy ions with the molecular field H_m which is in the c plane, $D=3B_2^0$, and the other notations are usual ones.

Solving the 16×16 determinant, we determined the ground-state wave function and then calculated the Dy^{3+} moment, $-g_JJ_x\mu_B=m\mu_B$ at $T=0$ K as a function of $x=\mu_BH_m/D$.

The calculated result is shown in Fig. 5. When an external field H is applied, the H_m must be replaced by (H_m+2H). Point A in Fig. 4 gives a spontaneous Dy moment of $8.63\mu_B$, which results in $\mu_BH_m/D=0.70$. The molecular field μ_BH_m/k is estimated to be 14.7 K or $H_m=219$ kOe from $T_C=27$ K, therefore $D=3B_2^0$ is obtained to be 21.0 K or $B_2^0=7.0$ K, which is in good agreement with $B_2^0=6.37$ K

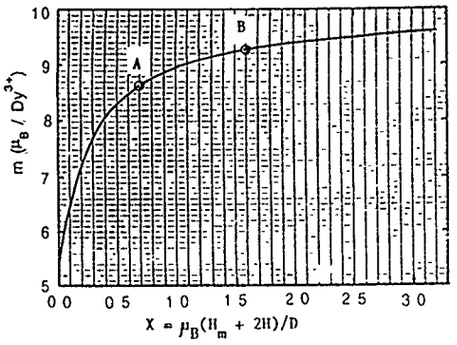

FIG. 5. Temperature dependence of reciprocal magnetic susceptibility for $GdCo_3B_2$ and $DyCo_3B_2$.

estimated from the Mössbauer spectrum by Malik and co-workers.[9] On the other hand, the maximum field in Fig. 3 is 140 kOe, which is comparable to the H_m. The summation of the two fields gives $\mu_B(Hm+2H)/D=1.60$, therefore $9.25\mu_B$ is expected for the Dy moment as seen from point B in Fig. 4. This expected value agrees very well with the experimental one, the intrinsic Dy moment of $9.33\mu_B$, which is the summation of $8.9\mu_B$/f.u. at $H=140$ kOe and the Co-induced moment of $0.43\mu_B$.

In the paramagnetic temperature region, $SmCo_3B_2$ behaves like the Van Vleck paramagnetism. The dashed line is calculated by taking the excited multiplets of $J=7/2$ and 9/2 into account, and also by using $\lambda/k=350$ K for the LS coupling constant. Therefore, the difference between the observed and calculated curves in Fig. 3 corresponds to the Pauli paramagnetic susceptibility contributed by the Co sublattice, $X_{Co}=1.1\times10^{-6}$ emu/g. This Co contribution also appears in the magnetic susceptibilities of $GdCo_3B_2$ and $DyCo_3B_2$. The deviations from the Curie–Weiss law are seen in Fig. 4. Rough estimation of X_{Co} from those deviations is about 2×10^{-6} emu/g for $GdCo_3B_2$ and about 4×10^{-6} emu/g for $DyCo_3B_2$, which agree approximately with the X_{Co} for $SmCo_3B_2$.

^{139}La nuclear quadrupole resonance and relaxation measurements, aimed at the study of static magnetic properties and of the dynamical generalized susceptibility in $La_2Cu_{1-x}Zn_xO_4$, upon substitution of Zn^{2+} ($S=0$) for Cu^{2+} ($S=1/2$) inducing a spin vacancy in the antiferromagnetic matrix, are presented. From the doublet resulting from the mixed Zeeman-quadrupolar eigenstates, it is shown how the sublattice magnetization is only slightly x dependent, while its temperature dependence changes with respect to pure La_2CuO_4. The relaxation rates show moderate (compared to the case of itinerant spin vacancies, as in $La_{2-x}Sr_xCuO_4$) effects, which are related to the decrease of the correlation length and to the modifications induced in the spin-wave spectrum.

I. INTRODUCTION

The study of the effects of Zn for Cu substitution in La_2CuO_4 is motivated by the connections with the mechanism of superconductivity in cuprates, which is known to occur on the verge of antiferromagnetic (AF) order. The Zn doping of La_2CuO_4 decreases the Néel temperature, with the removal of a Cu^{2+} spin from the AF matrix, a situation somewhat equivalent to the spin vacancy induced by Sr doping, the relevant difference being that in this latter case the vacancy is itinerant. Zn doping has effects stronger than the conventional magnetic dilution. In fact, for two-dimensional (2D) Heisenberg AF on square lattice theoretical treatments,[1] and experimental findings,[2] indicate that the initial suppression rate

$$A=\frac{-1}{T_N(0)}\lim_{x\to 0}\frac{dT_N(x)}{dx} \tag{1}$$

should be π, while the AF order should persist up to the percolation threshold $x\approx 0.41$. In $La_2Cu_{1-x}Zn_xO_4$, A seems larger and for $x\approx 0.11$ T_N is already close to zero.[3] The Cu magnetic moment and the magnetic exchange also stay practically constant for $x\leq 0.1$. Thus, one is led to the conclusion[3] that novel microscopic features, such as effects on the electronic states, occur in $La_2Cu_{1-x}Zn_xO_4$.

A useful tool to study the microscopic magnetic properties in doped La_2CuO_4 is ^{139}La nuclear quadrupole resonance (NQR) and spin-lattice relaxation. A variety of experiments[4] provided enlightning insights, particularly in $La_{2-x}Sr_xCuO_4$. In this article the results obtained in $La_2Cu_{1-x}Zn_xO_4$ are reported. The NQR spectra are used to derive the Cu sublattice magnetization $\langle\mu\rangle$ and its x and temperature dependence. The relaxation rates are interpreted in terms of magnetic excitations and of the modifications induced by the spin vacancy in the magnons spectrum.

II. EXPERIMENT

The Zn-doped La_2CuO_4 samples have been prepared by solid-state reactions in air, with annealing of the pellets for 24–48 h at 1050 °C. Particular attention has been devoted to the problem of extra oxygen, which is known[5] to cause a strong depression of T_N, particularly in Zn-doped YBCO.[6,7] Measurements were first carried out in as-grown samples. Then a set of samples at various x was kept for 24 h at various temperatures from 600 to 900 °C in N_2 atmosphere. T_N was found to increase progressively, supporting the conclusion[8] that the effect of interstitial oxygen simply adds on to one due to the magnetic vacancies. In the thermally treated samples, where for $x=0$ one has $T_N=315$ K (close to the highest T_N achieved in La_2CuO_4), still some evidence of small amounts of extra oxygen, undetected by thermogravimetry measurements, was noticed from La NQR relaxation at $T\geq 300$ K.

The ^{139}La NQR spectra have been obtained with standard pulse techniques, from the echo envelope, by sweeping the frequency at moderate intensity of the radio-frequency field. The field at the La site was derived from the resonance lines originated from the mixed Zeeman-quadrupolar eigenstates of the $\pm 1/2\leftrightarrow\pm 3/2$ NQR line.[9] In particular, the shift δ of the doublet at higher frequency with respect to the quadrupole frequency ν_Q, obtained from the $(\pm 5/2\leftrightarrow\pm 7/2)$ doublet, was measured. Since the asymmetry parameter of the electric-field gradient is small,[9] δ is practically proportional to the effective field $|h|$ at the La site. Then, in the limit $T\to 0$, one has

$$\frac{\langle\mu_{Cu}(x,0)\rangle}{\langle\mu_{Cu}(0,0)\rangle}=\frac{|h(x,0)|}{|h(0,0)|}=\frac{\delta(x,0)}{\delta(0,0)}. \tag{2}$$

The temperature dependence of $\langle\mu_{Cu}(x,T)\rangle$ was obtained from $|h(x,T)|$ in the assumption that the proportionality constant is temperature independent, which is the case when no modifications in the magnetic lattice occur. The field was derived from $\delta(x,T)$, through direct diagonalization of the matrix involving the Zeeman-perturbed quadrupole levels.

The ^{139}La NQR relaxation rate W has been obtained from the recovery, after saturation, of the echo signal of the $\pm 5/2\leftrightarrow\pm 7/2$ line. One has[4]

$$2W=\frac{\gamma^2}{2}\int\langle h_+(0)h_-(t)\rangle e^{-i3\omega_Q t}\,dt$$

$$\approx\frac{\gamma^2}{2\pi^2}(h_{\rm eff})^2\frac{kT}{N}\sum_q\chi_q(0)J_q(3\omega_Q), \tag{3}$$

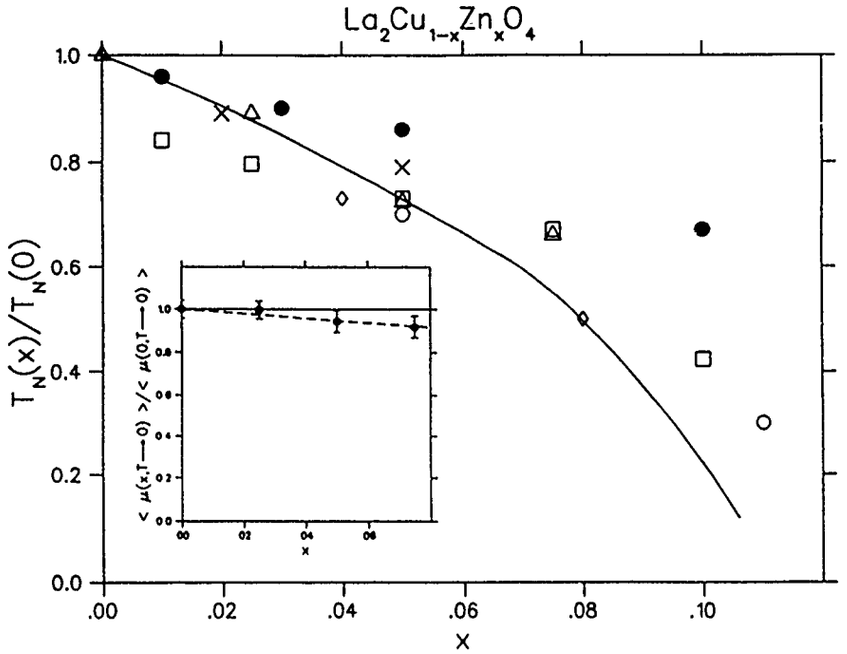

FIG. 1. x dependent of the Néel temperature and of the Cu sublattice magnetization $\langle\mu(x,T\rightarrow 0)\rangle$ (inset) in $La_2Cu_{1-x}Zn_xO_4$ after thermal treatment. [For the as-grown sample an analogous behavior is observed with $T_N(x=0)=225$ K, instead of $T_N(x=0)=315$ K of the thermally treated sample.] Representative data obtained by other authors with different techniques are also shown: (◇) susceptibility, Ref. 10; (□) susceptibility and μ SR, Ref. 11; (●) susceptibility, Ref. 5; (×) neutron scattering, Ref. 8; (○) dc susceptibility, Ref. 12; (△) present work. The solid and the dashed lines are the best-fit behaviors predicted by Acquarone and Paiusco (Ref. 3) in correspondence to a model of metallic AF.

where h_{eff} is an effective field, mediated over the Brillouin zone and close to the value of the static field $|h|\simeq 10^3$ G found in La_2CuO_4 at the lowest temperature.

III. RESULTS AND DISCUSSION

The Néel temperatures (obtained from the condition $\delta\rightarrow 0$ and from the concurrent peaks in the relaxation rate and/or in the dephasing time of the echo signals) and the x dependence of the sublattice magnetization are shown in Fig. 1. From our data the factor A [Eq. (1)] turns out close to 5.5. The x dependence of T_N appears well fitted by the theoretical behavior[3] of a metallic AF.

In Fig. 2 the temperature dependence of the sublattice magnetization is shown. For $x=2.5\%$ the behavior of $\langle\mu_{\text{Cu}}(T)\rangle$ is close to the one for weakly itinerant AF (solid line), while at $x=7.5\%$ the data are better described by the behavior of the order parameter in 2D systems. For $(T/T_N)\ll 1$ one can try to analyze the decrease of $\langle\mu\rangle$ in terms of the law $1-AT^{\alpha}$, expected to result from spin-wave excitations. One derives $\alpha\simeq 1.95$ and $A=1.4\times 10^{-5}\,K^{-1.95}$, a large value implying rapid decrease of the sublattice magnetization.

In Fig. 3 the ^{139}La NQR relaxation rates are reported and compared with the behavior in pure La_2CuO_4. In the AF phases W decrease rapidly with decreasing temperature, as expected for the Raman two-magnon relaxation process.[14,15] This can be interpreted in terms of an effective spectral density in the rf range which is negligible when the excitations are AF spin waves. Then, for 3D isotropic AF, one would have

$$J_{\text{eff}}=[4/(2\pi)^3\omega_{\text{exch}}](T/T_{\text{exch}})^3,$$

with ω_{exch} Heisenberg exchange frequency. However, estimates on the basis of this expression yield W considerably smaller than the experimental results. Even though a spin-

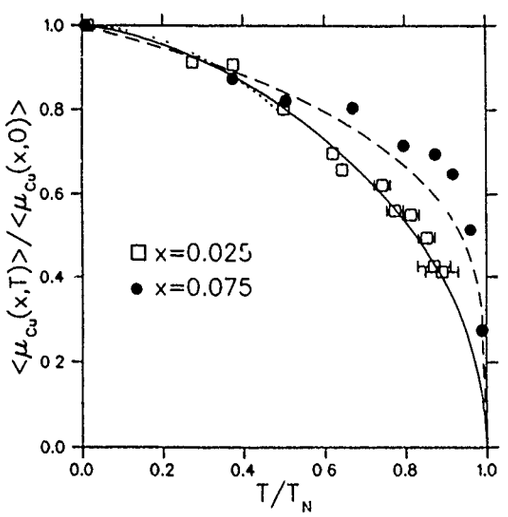

FIG. 2. Normalized temperature dependence of the Cu sublattice magnetization in $La_2Cu_{1-x}Zn_xO_4$. The solid line is the theoretical behavior predicted for a weekly itinerant AF (see Ref. 9) and fits rather well our data for $x=0$ (and those of Refs. 9 and 13 in pure La_2CuO_4, practically coincident with ours). The dashed line is the function $\langle\mu_{\text{Cu}}\rangle\propto(T_N-T)^{1/4}$, of the form expected for the order parameter in low-dimensional systems. The dotted line corresponds to the function $(\langle\mu(0)\rangle-\langle\mu(T)\rangle)/\langle\mu(0)\rangle=AT^{\alpha}$ with $\alpha=1.95$ and $A=1.4\times 10^{-5}\,K^{-1.95}$.

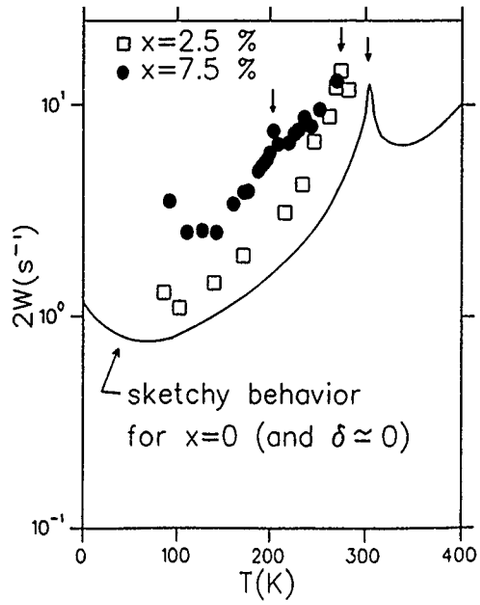

FIG. 3. ^{139}La NQR relaxation rates $2W$ in $La_2Cu_{1-x}Zn_xO_4$, for $x=0.025$ and $x=0.075$ as a function of temperature, and comparison with the sketched behavior (solid line) in $La_2CuO_{4+\delta}$ with $\delta\simeq 0$. Some amount of extra stoichiometric oxygen δ, hardly detected in thermogravimetric measurements, is evidenced by the contribution to the relaxation occurring for $T\geq 250$ K and associated with quadrupolar mechanism, possibly through oxygen diffusion. The arrows mark the Néel temperatures indicated by the NQR spectra.

wave spectrum appropriate to 2D La_2CuO_4 is used,[16] agreement is not found, as already observed for Cu relaxation.[17,18]

In nominally pure La_2CuO_4 for T around T_N and particularly in the presence of AF disorder as in Zn-doped compounds, modifications in the conventional spin-wave spectrum can be expected.[19] In particular, if $\xi\simeq a/\sqrt{x}$ is the 2D magnetic correlation length, propagating spin waves can exist only for wave vector q larger than ξ^{-1} and one has regions of magnetization density short-range ordered in space which relax with a time scale related to ξ^{-1}. To discuss these effects we model the spectral density in Eq. (3) in the form

$$J_q(\omega)=\frac{1}{2\pi}\left(\frac{\Gamma_{SF}}{(\omega-\omega_q)^2+\Gamma_{SF}}+\frac{\Gamma_{SF}}{(\omega+\omega_q)^2+\Gamma_{SF}}\right), \quad (4)$$

suggested[18] in the interpretation of neutron scattering in 2D AFs. Γ_{SF} heuristically describes the relaxational dynamics associated with the AF disorder or with finite size effects. By taking into account that in Eq. (3) $\chi(q,0)\propto|S_q|^2$ is only slightly q and x dependent[3,8] and thus $kT\chi(q,0)\approx S(S+1)/3$, we can discuss the W's in terms of the spectral density

$$J_{\rm eff}(\omega\approx 0)=\frac{1}{N}\sum_q J_q(3\omega_Q\approx 0).$$

2D integration with $\omega_q=(c^2q^2+\Delta^2)^{1/2}$ yields

$$J_{\rm eff}\approx\frac{1}{2\Gamma_{SF}}\left(\frac{\Gamma_{SF}}{\Gamma_{SW}}\right)^2\ln\frac{\Gamma_{SW}^2+\Delta^2+\Gamma_{SF}^2}{\Gamma_{SF}^2+\Delta^2}, \quad (5)$$

where $\Gamma_{SW}=cq_m(q_m\approx\pi/a$, maximum wave vector) is a typical spin-wave frequency that for order-of-magnitude estimates one can take as $\Gamma_{SW}\approx\omega_{exch}\sim 2\times10^{14}$ rad/s. In the light of Eq. (5), $J_{\rm eff}$ is expected to increase with x, in correspondence with the increased number of modes contributing to the central component. Furthermore, the decrease of the spin-wave velocity c with x^3 implies a decrease of Γ_{SW} and an increase in W, in agreement with the trend in Fig. 3.

Finally, we observe that in $La_2Cu_{1-x}Zn_xO_4$ the relaxation is affected by doping to a much smaller extent than the one due to itinerant spin vacancies, as in $La_{2-x}Sr_xCuO_4$,[4] or $Cu_{1-x}Li_xO_4$,[18] consistent with the predictions derived for the Zhang–Rice singlet in the framework of the t-J model.

^{35}Cl nuclear-magnetic-resonance (NMR) and relaxation measurements have been performed in a $Sr_2CuO_2Cl_2$ single crystal as a function of orientation between the external magnetic field $\mathbf{H}_0$ and the tetragonal **c** axis. The onset is found of an anisotropic inhomogeneous broadening of the NMR line without paramagnetic shift starting below about 320 K. The broadening is strongly temperature dependent and it increases with increasing $\mathbf{H}_0$. The relaxation rate T_1^{-1}, on the other hand, diverges at $T_N \simeq 260$ K in agreement with previous results in powder sample. It is suggested that the observed broadening is due to the onset at $T > T_N$ of a spontaneous nonzero thermal average of the Cu^{2+} moment lying in the a-b plane.

I. INTRODUCTION

$Sr_2CuO_2Cl_2$ is a layered perovskite with the body-centered-tetragonal K_2NiF_4 structure.[1] Neutron-diffraction,[2] magnetic susceptibility,[2] and μsR (Ref. 3) studies have shown that $Sr_2CuO_2Cl_2$ orders magnetically with three-dimensional (3D) antiferromagnetic (AF) structure and an effective Cu^{2+} moment similar to the one in La_2CuO_4, well known as a parent compound of a series of high-T_c superconductors. The Cu^{2+} $S=1/2$ magnetic moments order in 3D, below $T_N \simeq 260$ K, along the [110] crystal direction, without the out-of-plane canting observed instead in La_2CuO_4 and related to the tetragonal to orthorombic transition. Therefore, $Sr_2CuO_2Cl_2$ appears to be a good prototype of a 2D $S=1/2$ Heisenberg system.

A previous ^{35}Cl nuclear-magnetic-resonance (NMR) study in powder sample[4] revealed a divergence of the nuclear spin-lattice relaxation rate (NSLR) with a sharp, magnetic-field-independent peak occurring at $T \equiv T_N = 260 \pm 0.5$ K for $T \rightarrow T_N^+$. The critical behavior of the NSLR was interpreted in terms of strongly correlated 2D Cu^{2+} spin fluctuations. In the same study it was noted that the full width at half-intensity (FWHI) of the ^{35}Cl NMR line exibited pretransitional broadening. The important message of the broadening is that it may indicate the occurrence of a nonzero thermal average of the Cu^{2+} moment even above T_N. In order to investigate this effect we present here the results of the ^{35}Cl NMR spectra as a function of the temperature in a single crystal.

II. EXPERIMENT

The single crystal consisted is a thin slab about 1 mm thick and 5×10 mm^2 wide with the **c** axis perpendicular to the plane of the slab. Some measurements were performed on a stack of about ten small slabs in order to increase the signal-to-noise ratio. At the temperatures where strong anisotropy of the line is present the measurements in the stack were found to be affected by misalignment effects.

The $I=3/2$, ^{35}Cl NMR measurements were carried out with a Fourier transform (FT) pulse spectrometer at two values of the external magnetic field: 5.9 and 2.3 T. The symmetry of the electric-field gradient tensor at the Cl site is axial with the principal axis in the **c** direction. In this case one expects a central line transition $(+1/2 \leftrightarrow -1/2)$ and symmetric satellite transitions $(\pm 3/2 \leftrightarrow \pm 1/2)$ displaced in frequency by an amount which depends upon the angle between $\mathbf{H}_0$ and **c**.

Due to the small signal-to-noise ratio in the single crystal, the satellite lines could not be clearly detected. However, an estimate of $\nu_Q \leqslant 0.5$ MHz was inferred from the second-order shift of the central line. The measurements of the magnetic effects were performed on the central line transition only, for the two orientations $\mathbf{H}_0 \| \mathbf{c}$ and $\mathbf{H}_0 \perp \mathbf{c}$ for which the satellite lines are shifted by an amount greater than the linewidth. The NMR spectra were obtained by FT of half of the echo signal following a two-pulse sequence (pulse width around 5–6 μs). For the wider lines the spectrum was obtained by the frequency-swept echo intensity method. A few preliminary measurements of spin-lattice relaxation rate (NSLR) were performed by saturating the central line with a radio-frequency pulse sequence as described previously.[4]

III. RESULTS

The 3D Néel temperature was estimated from the peak in the ^{35}Cl NSRL shown in Fig. 1. Since the signal in the single crystal had an insufficient signal-to-noise ratio for reliable systematic relaxation measurements, particularly at low field H_0, the measurements were carried out in the stack of single crystals. The NSLR is close to the values in the powder sample[4] with a maximum at a slightly higher temperature ($T_N = 260 \pm 0.5$ K for the powder, $T_N = 265 \pm 3$ K for the stack of single crystals). No difference in the NSLR is detected within experimental error for the two magnetic-field orientations and for the two values of H_0. A more precise

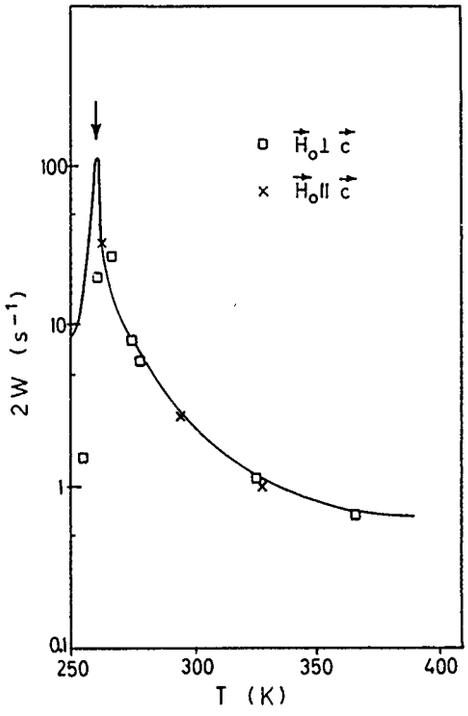

FIG. 1. ^{35}Cl nuclear spin lattice relaxation rate $2W$ as a function of temperature for a stack of single crystals, at H_0=5.9 T, for $\mathbf{H}_0\|\mathbf{c}$ and $\mathbf{H}_0\perp\mathbf{c}$. The solid line reports the behavior of $2W$ observed in the powder sample (Ref. 4), with T_N indicated by the arrow. An analogous behavior of the W vs T was observed at H_0=2.3 T (data not reported).

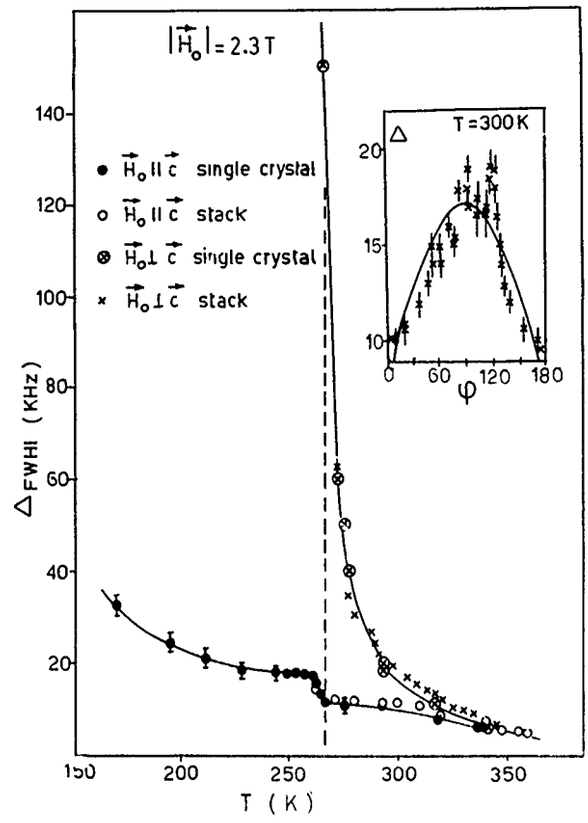

FIG. 2. ^{35}Cl NMR linewidth (full width at half-intensity) as a function of temperature for $\mathbf{H}_0\|\mathbf{c}$ and $\mathbf{H}_0\perp\mathbf{c}$ at $|\mathbf{H}_0|$=2.3 T. (The solid lines are guides for the eye.) The dashed line indicates the Néel temperature as derived from the NSLR (Fig. 1). In the inset the angular dependence of Δ_{FWHI} at T=300 K is reported (the solid line is the function Δ=8+9 sin ϕ kHz, ϕ being the angle between c and $\mathbf{H}_0$).

study of the critical spin dynamics through NSLR measurements has to wait for the availability of a larger single crystal.

The data for the linewidth as a function of temperature, magnetic-field intensity, and orientation of the crystalline **c** axis with respect to the external magnetic field are shown in Figs. 2 and 3. The remarkable result here is represented by the onset of a strongly anisotropic inhomogeneous broadening, for both field values, starting at $T\approx320$ K. It is noted that for $\mathbf{H}_0\|\mathbf{c}$ there is only a small broadening while for $\mathbf{H}_0\perp\mathbf{c}$ the broadening below T_N exceeds 150 kHz. For $T<T_N$ the signal-to-noise ratio becomes too small to allow for reliable linewidth measurements. It should be stressed that for both orientations, no average shift of the center of the line with respect to the ^{35}Cl Larmor frequency could be evidenced.

IV. DISCUSSION

Let us first analyze the data in the 3D ordered phase below T_N. The lack of a detectable shift combined with the strongly anisotropic broadening is an unusual occurrence in a magnetically ordered single crystal. However, in the present case it is consistent with a dominant ^{35}Cl-Cu^{2+} nuclear-electron dipolar interaction and with the reported magnetic AF lattice structure with the Cu^{2+} magnetic moment along the equivalent [110] directions.[2] The dipolar local field due to a moment $\boldsymbol{\mu}$ at position $\mathbf{r}$ with respect to a nucleus at the origin is

$$\mathbf{h}_d=\frac{\boldsymbol{\mu}}{r^3}-\frac{3(\boldsymbol{\mu}\cdot\mathbf{r})\cdot\mathbf{r}}{r^5}. \tag{1}$$

Thus, for $\mathbf{H}_0\|\mathbf{c}$, the contribution of the Cu^{2+} nearest-neighbor magnetic moment at a given apical Cl site has a zero projection along the quantization axis **H**. On the contrary, for $\mathbf{H}_0\perp\mathbf{c}$, the projection of the dipolar field yields $h_d^z=(\mu/r^3)\cos\alpha$ where α is the angle between $\boldsymbol{\mu}$ and **H**. For fixed a,b axis there are two possible magnetic domains and four possible angles α yielding four lines symmetrically shifted with respect to the Larmor frequency. Since our single slab might have more than one orientation with different (**ab**) directions the superposition of several four-line spectra are expected to give rise to an unresolved broadening without average shift. The dipolar field at the Cl site due to the dominant first Cu^{2+} neighbor contribution is 133 G for $\mu=0.34\mu_B$ and is directed perpendicular to the c axis. The complete dipolar sum evaluated for the AF arrangement described above yields a value of 115 G,[4] with a direction still perpendicular to the c axis. Thus, in the presence of AF order and considering only dipolar local fields one expects a broadening which depends on the angle ϕ between **H** and **c** as

$$\Delta H(\phi)=\Delta H_{\|}+C|\sin\phi|, \tag{2}$$

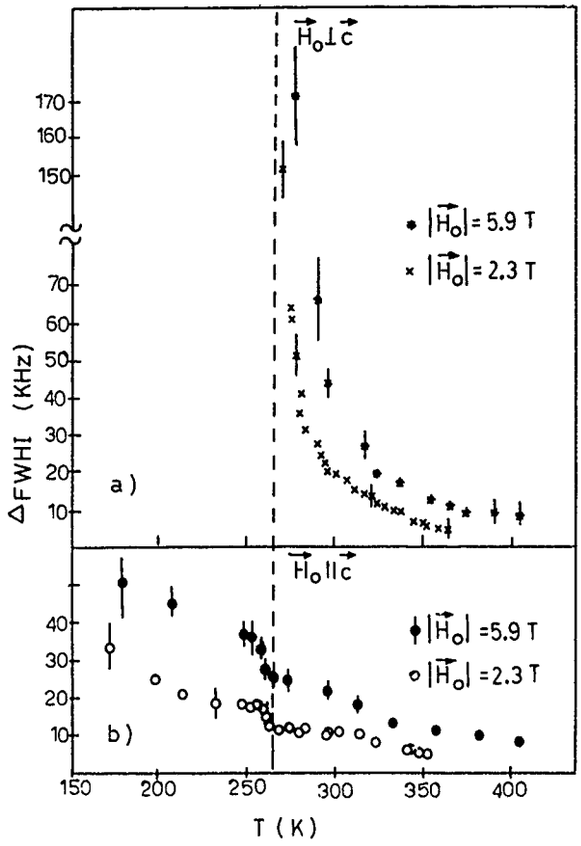

FIG. 3. ^{35}Cl NMR linewidth for (a) $\mathbf{H}_0 \perp \mathbf{c}$ and (b) $\mathbf{H}_0 \| \mathbf{c}$ as a function of temperature for two values of $|\mathbf{H}_0|$. The dashed line indicates the Néel temperature. Typical error bars are indicated.

where $\Delta H_{\|}$ is the NMR linewidth for $\mathbf{H}_0 \| \mathbf{c}$ and C $C = \sqrt{\langle (h_d^z)^2 \rangle}$ is the rms value of the distribution of the dipolar field component along the quantization axis $\mathbf{H}_0$ due to the distribution of angles α.

The above considerations allow one to interpret the most striking result of the present study, i.e., the large anisotropic broadening of the NMR line above T_N. In fact, if the system were paramagnetic above T_N, one would expect a paramagnetic shift of the center of the NMR line of the order of magnitude of the broadening or more. Furthermore the dipolar shift due to the first Cu^{2+} neighbor should be larger for $\mathbf{H}_0 \| \mathbf{c}$ and of opposite sign than the one for $\mathbf{H}_0 \perp \mathbf{c}$ [see Eq. (1)]. Thus, the only plausible explanation for the broadening without shift occurring above T_N is the onset at $T \leq 320$ K of a static 2D order characterized by a local spontaneous moment $\langle \mu \rangle \neq 0$ lying in the a-b plane. In this case the local field at the ^{35}Cl site could be similar to the one predicted above for the AF 3D ordering since it is largely dominated by the first next-nearest-neighbor contribution. In fact, the rotation pattern for the linewidth at $T = 300$ K $> T_N$ shown in the inset of Fig. 2 can be fitted with the behavior of Eq. (2). For $T = 300$ K one finds $\Delta H_{\|} \simeq 8$ kHz and $C \simeq 9$ kHz. The value of the intrinsic linewidth can be estimated from the linear extrapolation at $H_0 = 0$ of the linewidth at any temperature and for both orientations. The value so found is $\Delta H^0 = 4 \pm 1$ kHz. The experimental value of $\Delta H_{\|}$ is temperature dependent and larger then the intrinsic width ΔH^0 for $T < 350$ K (see Fig. 2). The difference is too large to be due to misalignment effects. Thus, we conclude that the broadening for $\mathbf{H}_0 \| \mathbf{c}$ is due to the dipolar field of more distant Cu^{2+} moments not included in the simple model discussed above. The critical increase of the linewidth indicates that $\langle \mu \rangle$ increases rapidly as the 3D ordering temperature T_N is approached from above. While the anisotropy of the broadening can be explained in terms of the different effect of the dipolar fields for $\mathbf{H}_0 \| \mathbf{c}$ and $\mathbf{H}_0 \perp \mathbf{c}$ (as discussed above for $T < T_N$) the size of the constant C in Eq. (2) is too large to be explained only by the direct dipolar field at the Cl site and one should invoke a contribution due to nuclear-electron pseudodipolar interaction. Furthermore, the practically linear field dependence (see Figs. 2 and 3) of the broadening above T_N indicates that the static 2D effects are unconventional. It is noted that the field-dependent broadening cannot be due to the demagnetization effects which are negligible here, nor to random paramagnetic impurities which whould not give rise to anisotropy. Also, the quadrupole broadening would have the opposite field dependence.

One is led to the tentative conclusion that there is a spontaneous average local moment $\langle \mu \rangle$ lying in the a-b plane, which arises above T_N and it is both temperature and field dependent. On the other hand, the fact that the NSLR still has a peak at T_N as in the powder sample indicates that the thermodynamic slowing down of the Cu^{2+} spin fluctuations is driven by the 3D transition. It should be pointed out that in the previous susceptibility measurements[2] a distinct slope discontinuity was seen in $\chi_{\|}$ at $T \simeq 310$ K and it was ascribed to the onset of 3D order at T_N, arguing that the value higher than $T_N = 251$ K found by neutron scattering was due to the different sample employed. In the light of the present measurements it is conceivable that the effect observed at 310 K on the susceptibility is due to the onset of local 2D order as described here.

Effects of Co and Y substitution on magnetic properties of $CeFe_2$

Xianfeng Zhang and Naushad Ali
Department of Physics and Molecular Science Program, Southern Illinois University, Carbondale, Illinois 62901

$CeFe_2$ orders ferromagnetically (FM) below T_C=227 K; however, this FM state is inherently unstable and partial substitution of Fe by Co precipitates the instability of FM state and a ferromagnetic to antiferromagnetic (AFM) phase transition is observed at lower temperature. This second phase transition is a first-order phase transition. The dependence of T_C and T_N on the concentration of Co X for $Ce(Fe_{1-X}Co_X)_2$ is presented. For $Ce(Fe_{0.8}Co_{0.2})_2$, the FM transition is at T_C=160 K, and the AFM transition is at T_N=76 K. The entropy change associated with the FM to AFM phase transition has been determined from magnetization measurements and found to be primarily associated with a change in the electronic density of states at E_F. If one starts with $Ce(Fe_{0.8}Co_{0.2})_2$ and partially substitutes Ce by Y, it is found that T_N gradually decreases with Y concentration; and for Y concentration greater than 10%, the AFM phase disappears and FM phase is fully restored. The dependence of T_C and T_N on the concentration of Y Z is presented for $Ce_{1-Z}Y_Z(Fe_{0.8}Co_{0.2})_2$. It is suggested that the second transition (FM to AFM) is a result of the competition between exchange energy and magnetic anisotropy energy. The measurements of magnetization, ac susceptibility, resistivity, and thermal expansitivity are presented.

$CeFe_2$ is a ferromagnet that exhibits some anomalous magnetic properties such as a much lower Curie temperature (T_C=227 K) and a much lower magnetic moment per Fe atom ($1.15\mu_B$) than other compounds in the RFe_2 series (R denotes rare earth).[1] A number of investigations[2–4] suggests that the anomalous magnetic properties of $CeFe_2$ may be due to some transfer of the Ce $4f$ electrons to the Fe $3d$ band. This suggestion is supported by experimental data of electronic specific heat coefficients, which are 53 mJ K^{-2} mol^{-1} for $CeFe_2$,[5] and 21 mJ K^{-2} mol^{-1} for $CeCo_2$.[6]

The ferromagnetic state of $CeFe_2$ is inherently unstable. A small partial substitution of Fe by other elements such as Co, Al, and Ru precipitates the instability of ferromagnetic state and a ferromagnetic (FM) to antiferromagnetic (AFM) phase transition is observed at the temperature T_N, lower than T_C.[7–9] This second phase transition is a first-order phase transition in case of $Ce(Fe_{1-X}Co_X)_2$.[7] The magnetic ordering of $Ce(Fe_{1-X}Co_X)_2$ has been determined by Kennedy *et al.*[10] using neutron diffraction. The ac susceptibility results by Roy and Coles[11] show that the T_C moves up but T_N is suppressed with the increase in Y concentration in $Ce_{1-Z}Y_Z(Fe_{1-X}Al_X)_2$. They found that T_C increased to 235 K with Z=0.1 and went up further to 252 K for Z=0.15 in the case of X=0.035. The low-temperature transition is no longer present for X greater than 0.15.

According to the x-ray-diffraction studies by Nishihara, Tokumoto, and Yamaguchi,[12] there is a small volume change of 0.05% at T_N for the $Ce(Fe_{1-X}Al_X)_2$ system. Kennedy *et al.*[10] also reported a 0.05% cell volume change at T_N in the $Ce(Fe_{1-X}Co_X)_2$ system. The 0.05% volume change is too small to apply an exchange-inversion model to explain the FM-AFM transition observed here.

In this article we present the effect of partial substitution of Fe by Co and Ce by Y on magnetic properties of the $CeFe_2$. Two magnetic phase diagrams are presented for the $Ce(Fe_{1-X}Co_X)_2$ and for the $Ce_{1-Z}Y_Z(Fe_{0.8}Co_{0.2})_2$. The entropy change at the FM-AFM transition is determined for $Ce(Fe_{0.8}Co_{0.2})_2$ as a function of temperature. Some specific measurements presented here include magnetization, ac susceptibility, resistivity, and thermal expansion for the $Ce(Fe_{0.8}Co_{0.2})_2$.

The sample preparation and experimental details are described in Refs. 7 and 13.

The magnetization M and ac susceptibility χ_{ac} as a function of temperature for $Ce(Fe_{0.8}Co_{0.2})_2$ are presented in Figs. 1(a) and 1(b), respectively. It is evident that partial substitution of Fe by Co causes a sharp transition from FM to AFM. The temperature dependence of the electrical resistivity [Fig. 1(c)] also clearly shows this magnetic transition. A significant slope change in the resistivity at 162 K is identified as being due to a paramagnetic (PM)-FM transition which occurs at 160 K in the magnetization measurement. The abrupt rise of the resistivity at 75 K corresponds to FM-AFM tran-

FIG. 1. Magnetic effects in Cr-Mn alloy single crystals containing 0.05 and 0.1 at. % Mn

P. Smit and H. L. Alberts
Department of Physics, Rand Afrikaans University, P.O. Box 524, Auckland Park, Johannesburg 2006, South Africa

Measurements of the thermal expansion, ultrasonic wave velocity, and ultrasonic attenuation are reported for very dilute Cr-Mn alloy single crystals. The threshold Mn concentration needed to drive the first-order antiferromagnetic transition in Cr to second order is found to be smaller than 0.05 at. % Mn. This result is discussed in terms of recent theories. The critical behavior of the sound velocity and ultrasonic attenuation of Cr+0.1 at. % Mn is well described by a power law near T_N but not for the thermal expansion.

I. INTRODUCTION

Pure Cr condenses into an incommensurate I spin density wave (SDW) antiferromagnetic state below the Néel temperature T_N. The magnetic transition is weakly first order, showing a small discontinuity in the thermal expansivity[1] and neutron-diffraction intensity[2] at T_N. Both the magnetic structure and the first-order nature of the phase transition at T_N of pure Cr can be significantly altered through the addition of impurities (e.g., V or Mn), even for very small additions. Fishman and Liu[3] recently addressed theoretically the problem of the effects of impurities on the order of the phase transition at T_N for pure Cr. The first-order nature of the transition is caused by a charge density wave (CDW) induced by the Coulomb interaction between two-hole Fermi surface sheets of pure Cr. Scattering by impurities suppresses the CDW and drives the transition to second order. As the first-order transition in pure Cr is weak, Fishman and Liu[3] showed that only a very small impurity concentration is needed to accomplish this. They found that a threshold concentration c_t exists which separates the regions of first- and second-order phase transitions on the $T-c$ magnetic phase diagram.

For Cr-V alloys, which remain in the ISDW phase up to about 4 at. % V where antiferromagnetism disappears,[4] Fishman and Liu[3] calculated a value c_t=0.15 at. % V, which corresponds well with experimental results. The addition of Mn to Cr drives the ISDW state of pure Cr to a commensurate C SDW state, and from theory[3] a lower c_t value is expected for such a system than for Cr-V. An experimental study of c_t for Cr-Mn alloys has, however, not been done yet. In order to investigate this phenomenon in the Cr-Mn system, we conducted thermal-expansion ($\Delta L/L$) measurements on two Cr-Mn alloy single crystals containing 0.05 and 0.1 at. % Mn, respectively. This experimental parameter is a sensitive probe[1] in studying the order of the transition at T_N for Cr and its dilute alloys. We also report on an ultrasonic study of the Cr+0.1 at. % Mn crystal near T_N.

II. EXPERIMENT

Single crystals of pure Cr and Cr-Mn alloys containing nominal concentrations of 0.05 and 0.1 at. % Mn were grown by a floating-zone technique using rf heating in a pure Ar atmosphere. A bar of the alloy, roughly cylindrical in form, about 10 cm in length and between 7 and 10 mm in diameter, was first prepared by rf melting in a horizontal cold crucible. To ensure homogeneity of the bar, it was prepared from seven separate smaller alloy ingots with a mass of about 8 g each and each prepared by arc melting in a purified Ar atmosphere. In the arc-melting process of the ingots, each was remelted five times, turning it upside down between melts, then taken out of the arc furnace and crushed to small pieces. It was then remelted five times, again turning it upside down between melts. The crushing and remelting procedures were repeated three times for each ingot in order to get the homogeneity as good as possible for the prepared alloy bar. The bar was then grown to a single crystal of length about 5 cm and diameter about 6 mm by the floating-zone technique with the bar in a vertical position. For the concentrations considered, Mn forms solid solutions in Cr. The starting materials were 99.996% pure Cr and 99.99% pure Mn. The homogeneity of the alloys was checked through electron microprobe analyses at different points on the samples (50 measurements done in total). Due to the very low impurity content the experimental error in obtaining absolute concentrations was relatively large, resulting in an error of observation of about 20% in the Mn concentration determined at each point. We were, nevertheless, able to verify that the alloys are homogeneous to within this error of observation, but could not tell whether the homogeneity was in fact even better than this. From previous experience on Cr-Si single[5] crystals (containing up to 3 at. % Si) that we prepared in a similar manner as that above, we indeed expect the homogeneity of the two Cr-Mn crystals to be better than the above-quoted error of observation. The Si content in the Cr-Si crystals was large enough to allow for accurate concentration determination and they were found to be homogeneous to within 5%.

Thermal expansion ($\Delta L/L$) of the Cr-Mn crystals was measured relative to a Cr+5 at. % V sample using a strain gauge technique, while a standard pulse-overlap technique was used to obtain longitudinal ultrasonic wave velocities v_L and ultrasonic attenuation coefficients γ. The Cr+5 at. % V alloy remains paramagnetic at all temperatures and serves to simulate the nonmagnetic component of the thermal expansion of the Cr-Mn alloy single crystals, that is,

$$(\Delta L/L)_{\text{measured}}=(\Delta L/L)_{\text{Cr-V}}-(\Delta L/L)_{\text{sample}}.$$

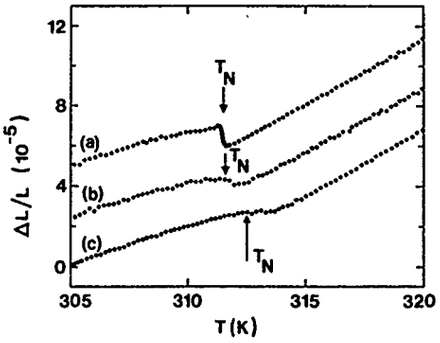

FIG. 1. The temperature dependence of the thermal expansion $(\Delta L/L)_{\text{sample}}$ near the Néel transition for (a) pure Cr, (b) Cr+0.05 at. % Mn, and (c) Cr+0.1 at. % Mn along [100]. The dots in curves (b) and (c) represent the measured points. In the case of pure Cr [curve (a)], measurements were recorded at 0.03 K temperature intervals near T_N. All the points are not plotted for the sake of clarity.

The $\Delta L/L$ measurements were conducted along [100] and v_L and γ were measured for 10 MHz ultrasonic waves propagating along [100]. The experimental error in the absolute $\Delta L/L$ values amounts to about 5% while changes in $\Delta L/L$ of 3×10^{-7} could be detected. Changes in v_L of 1 in 10^5 could be detected.

III. RESULTS AND DISCUSSION

Figure 1 shows the ISDW-P transition at T_N observed in the temperature dependence of $(\Delta L/L)_{\text{sample}}$ for the Cr, Cr +0.05 at. % Mn, and Cr+0.1 at. % Mn alloy single crystals. The T_N values, marked in Fig. 1, were taken at the minimum points in the $\alpha(T)$ curves, shown in Fig. 2. The ISDW-P transition shown in Fig. 1(a) for the pure Cr crystal occurs within a temperature range of approximately 0.3 K, which compares very favorably with that of 3 K observed by Fawcett *et al.*[1] in $\Delta L/L$ measurements. This indicates that our Cr crystal is of very good quality. The transition in pure Cr is furthermore characterized by an almost jumplike discontinuity, which is indicative of the transition's weak first-order nature. $\Delta L/L$ data around T_N were recorded for pure Cr at temperature intervals of approximately 0.03 K during both

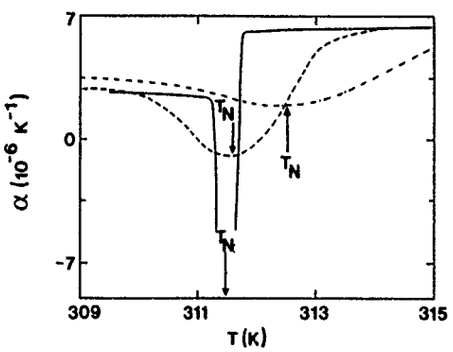

FIG. 2. Temperature dependence of the thermal-expansion coefficient α near the Néel transition for pure Cr (solid line), Cr+0.05 at. % Mn (dashed line), and Cr+0.1 at. % Mn (dashed-dotted line).

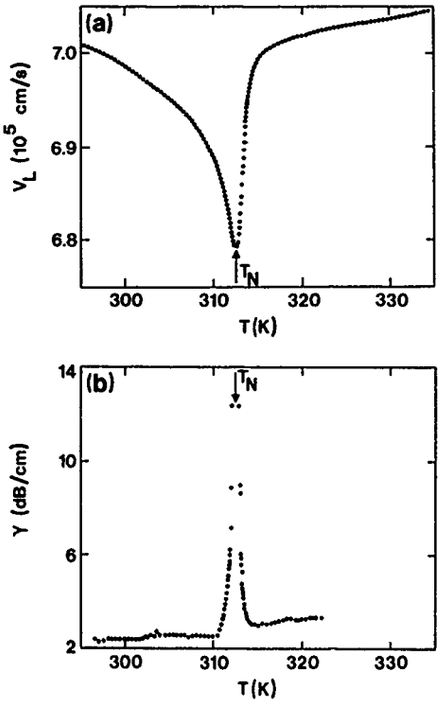

FIG. 3. Temperature dependence of (a) the longitudinal sound velocity v_L and (b) the ultrasonic attenuation coefficient γ near the Néel transition for Cr+0.1 at. % Mn. Wave propagation was along [100].

cooling and heating runs. Hysteresis effects of the order of 0.02 K in temperature, which is of the same order as the experimental error, were observed in the Néel transition for pure Cr. Curves (b) and (c) in Fig. 1 show that the transitions at T_N for the Cr+0.05 at. % Mn and Cr+0.1 at. % Mn crystals are continuous which is indicative of a second-order transition. One may reason that the continuous transitions in these crystals are the result of sample inhomogeneities. The observed width of the transitions, however, cannot be explained by sample inhomogeneities. As previously discussed, our crystals are expected to be homogeneous to better than 20%. The addition of 0.1 at. % Mn increases T_N of Cr by about 1 K (see the T_N values below). If the T_N transition in a perfectly homogeneous Cr+0.1 at. % Mn crystal was discontinuously first order, one therefore expects that variations as large as 20% in the Mn concentration throughout the volume of our Cr+0.1 at. % Mn crystal should result in broadening of the transition of about 0.2 K, which is smaller than the observed width of 2.3 K. The width of the transition was taken between the temperatures where the experimental $\Delta L/L-T$ points start to deviate from the roughly linear temperature behavior above and below the transition region. The width of 2.3 K on the $\Delta L/L-T$ curve of Fig. 1 for Cr+0.1 at. % Mn compares well with the width of about 3 K observed on the $\gamma-T$ curve of Fig. 3(b). For comparison the width of the transition for pure Cr in Fig. 1 is about 0.3 K. The effect of the addition of Mn on the first-order nature of the transition at T_N for pure Cr is clearly illustrated in the $\alpha(T)$ curves of Fig. 2 which display the Néel transitions for both Cr+0.05 at. % Mn and Cr+0.1 at. % Mn as shallow

and broad, compared to that of pure Cr. We obtain T_N=(311.5±0.1) K for pure Cr, T_N=(311.6±0.1) K for Cr +0.05 at. % Mn, and T_N=(312.5±0.2) K for Cr+0.1 at. % Mn. The value T_N=(312.5±0.2) K obtained from the $\Delta L/L$ measurements for Cr+0.1 at. % Mn is confirmed by the $v_L(T)$ and $\gamma(T)$ measurements shown in Fig. 3.

From the results in Figs. 1 and 2, we conclude that for an impurity concentration as small as 0.05 at. % Mn the first-order Néel transition at T_N for pure Cr is driven to a second-order one. The threshold impurity concentration c_t for Cr-Mn is therefore below 0.05 at. % Mn. The smaller c_t value for Mn impurities (c_t<0.05 at. % Mn), compared to that for V (c_t≈0.15 at. % V), is expected from the theoretical analyses of Fishman and Liu[3] and can be ascribed to two effects that influence the CDW. These effects are changes in commensurability of the SDW and impurity scattering as the solute concentration is varied. Doping Cr with Mn increases the commensurability (and decreases the energy mismatch z_0) of the SDW, while V doping decreases the commensurability. As $z_0 \rightarrow 0$, Fishman and Liu[3] find that the CDW vanishes at T_N and the transition is always second order. With Mn doping, the CDW is suppressed both by decreasing z_0 and by impurity scattering. For V doping, the CDW is enhanced by increasing z_0 but suppressed by impurity scattering, with the last effect being dominant. Consequently, the threshold impurity concentration is smaller for Mn doping.

The observed second-order transition in the Cr+0.1 at. % Mn crystal allows for an analysis of the critical behavior near T_N. Figure 3 shows the temperature dependence of v_L and γ for this crystal. The $v_L(T)$ curve [Fig. 3(a)] shows a minimum at T_N=312.5 K, while a sharp attenuation peak is observed in the $\gamma(T)$ curve at 312.4 K [Fig. 3(b)]. The critical behavior close to T_N for γ, $\Delta L/L$, and $\Delta v/v_0$, where Δv is the magnetic contribution and v_0 the nonmagnetic component of v, determined in the same manner as previously,[5] was assessed for Cr+0.1 at. % Mn in terms of a power law $A|1-T/T_N|^{-\eta}+B$, where A and B are constants. Plots of $\ln(\Delta v/v_0-B)$ and $\ln(\gamma-B)$ vs $\ln|1-T/T_N|$ were found to be straight lines within temperature intervals, just below and just above T_N, of about 5 K in the case of $\Delta v/v_0$ and 1 K in the case of γ. The values of η, determined from the gradients of these straight lines, are $\eta_{T<T_N} = 0.13$ and $\eta_{T>T_N} = 1.00$ for $\Delta v/v_0$ and $\eta_{T<T_N} = 1.35$ and $\eta_{T>T_N} = 3.00$ for γ. Sato and Maki[6] predicted $\eta_{T>T_N} = 0.5$ in the case of γ for ISDW antiferromagnets and no divergence at T_N for $\Delta v/v_0$. This does not compare well with the observed values for Cr+0.1 at. % Mn. In the case of $\Delta L/L$, the data close to T_N could not be fitted to the power law.

In conclusion, the threshold Mn concentration that drives the antiferromagnetic transition in pure Cr to second order is found to be less than 0.05 at. % Mn. The critical behavior near T_N of $\Delta v/v_0$ and γ for Cr+0.1 at. % Mn is successfully described in terms of a power law $A|1-T/T_N|^{-\eta}+B$. This is, however, not the case for $\Delta L/L$.

Antiferromagnetism of metastable Cr-rich Cr-Gd alloys

Jen Hwa Hsu and Y. W. Fu
Department of Physics, National Taiwan University, Taipei, Taiwan, Republic of China

Cr is an antiferromagnet with a Néel temperature of 311 K. The addition of impurities will alter the antiferromagnetic properties of materials. Studies of the effect of magnetic Gd atoms on the Cr-rich Cr_xGd_{1-x} alloys are reported. The metastable Cr_xGd_{1-x} alloy films ($1.00 \geq x \geq 0.96$) have been prepared by the rapid-quenching method. It has been found from x-ray diffraction that the alloy films with $1.00 \geq x \geq 0.97$ have body-centered-cubic structure, the same as Cr. For higher Gd concentration, the alloy film contains both body-centered cubic and amorphous phases. The variation of the Néel temperature T_N as well as the spin-flip temperature T_F of metastable Cr-Gd alloys has been investigated by resistiviity measurements between 10 and 300 K. It has been found that T_N decreases slowly from 311 K for pure Cr to about 290 K for $Cr_{0.97}Gd_{0.03}$. These results seem to indicate that magnetic Gd atoms show little effect on the antiferromagnetism of Cr. Furthermore, there is a broad resistivity minimum at low temperatures. This broad minimum occurs at higher temperature as Gd concentration is increasing. Thus, it suggests that a different mechanism accounts for this resistivity minimum. A detailed discussion is reported.

I. INTRODUCTION

Chromium is an itinerant antiferromagnet whose magnetism arises from some of the conduction electrons which condense through an exchange interaction to form a static spin-density wave (SDW) characterized by its wave vector **Q** and its spin polarization **S**. Its Néel temperature T_N is 312 K and its spin-flip temperature T_F has been determined to be 122 K. Between T_N and T_F, the SDW has transverse polarization ($\mathbf{S} \perp \mathbf{Q}$), and at T_F the spins rotate through 90° so that the SDW is longitudinally polarized.[1]

In the past the antiferromagnetic properties of Cr alloys containing small amounts of the transition metals have been investigated extensively.[2] The results show that there is a strong and systematic dependence on the number of *d* electrons of the impurity element. Elements with more *d* electrons than Cr raise T_N, while those with fewer *d* electrons depress T_N, the same conclusion as with Mn.[3] It is also interesting to know whether the magnetism of Cr is altered by the introduction of magnetic Gd impurities; however, little work has been done related to it. This is because Gd and Cr are mutually immiscible. Previously, one of the authors has demonstrated that the rapid-quenching method is very useful to prepare metastable Gd-Cr alloys.[4] In this matter, we are now able to investigate the effect of Gd atoms on the antiferromagnetism of Cr. Thus, we expect from this work to provide firmer experimental data in order to understand the theoretical aspect of antiferromagnetic coupling in the Cr system.

II. EXPERIMENT

The metastable Cr_xGd_{1-x} alloy films ($1 \geq x \geq 0.96$) were prepared by the dc magnetron sputtering method. Kaptons were used as the substrates which were cooled by liquid N_2 during sputtering. The thickness of films was estimated to be around 5 μm. The film structures were determined from powder-x-ray diffraction in the θ-2θ geometry.

The resistivity of alloy films has been determined from 10 to 320 K. The four-probe method was used. The Néel temperature T_N and spin-flip temperature T_F were determined from resistivity measurements. It has been shown that there are anomalies in the electrical resistivity of Cr around T_N and T_F.[5-7] The selection of T_N and T_F are taken from either the points of minimum or the points of inflection.

III. RESULTS AND DISCUSSION

In Fig. 1 it is indicated that the the structure of the alloys with $1.00 \geq x \geq 0.97$ is a single body-centered phase, the same as with pure Cr. For the alloys with higher Gd concentration, an amorphous phase appears mixed with bcc phase. Thus, the concentration range chosen to investigate the effect on antiferromagnetism is between 1.00 and 0.96.

The normalized resistivity of metastable Cr_xGd_{1-x} is plotted in Fig. 2. It shows that the resistivity initially decreases as the temperature falls. At the temperature denoted as T_N, either a minimum or a drastic change of slope is found. With further decreasing temperature, a broad minimum denoted as T_{m_2} is found. For pure Cr, the value of T_N from our experimental results is 311 K, which is identical to the Néel temperature of Cr. Therefore, T_N of all alloys in this work can be ascribed to the appearance of antiferromagnetism. As shown in Fig. 3, the Néel temperature of Cr alloys decreases slowly from 311 K for pure Cr to 286 K for 3 at. % Gd. This shift rate is much smaller than those of Cr alloys with other transition elements.[2] This suggests that the introduction of $4f$ electrons has little effect on the antiferromagnetism of Cr. This is consistent with the prediction of a two-band model.[8]

Regarding the occurrence of T_{m_2}, the value of T_{m_2} for pure Cr is around 78 K which is far below the spin-flip temperature of Cr. According to Meaden and Sze,[5] a step-type change should be found around T_F. This is not true in our case. Therefore, the occurrence of T_{m_2} is not related to the phenomenon of spin-flip transition. Again as shown in Fig. 3, T_{m_2} rises rapidly from 78 K for pure Cr to 182 K for $Cr_{0.97}Gd_{0.03}$. Due to the small variation of resistivity in the low-temperature range, it is difficult to locate T_{m_2} for $Cr_{0.96}Gd_{0.04}$, but a higher T_{m_2} is still easily observed. We might first ascribe T_{m_2} to the unexpected impurities in the sample; but, the systematic dependence of T_{m_2} on Gd concentration excludes this possibility. It is evident that the existence of Gd is crucial to the occurrence of T_{m_2} As is known, the resistivity of Cr is very sensitive to the strain induced in the sample.[9] Our samples were prepared using the quick-quenching method so that a large strain is expected to be induced during sample preparation. Furthermore, due to the larger size of the Gd atom, the substitution by the Gd atom will cause lattice mismatch; this will also create strain.

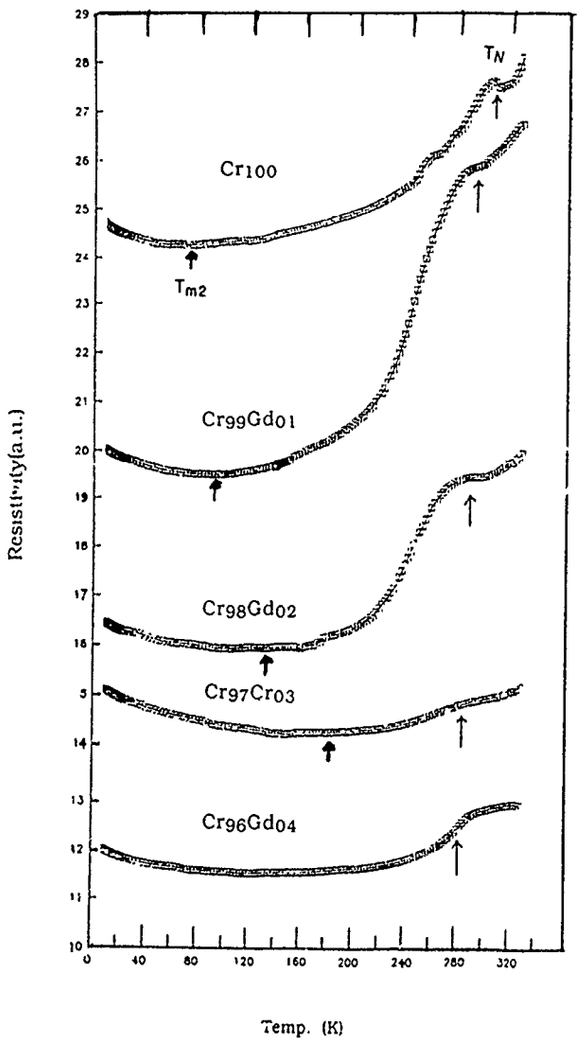

FIG. 2. Normalized resistivity of metastable Cr_xGd_{1-x} alloys ($1 \geq x \geq 0.96$) between 10 and 320 K.

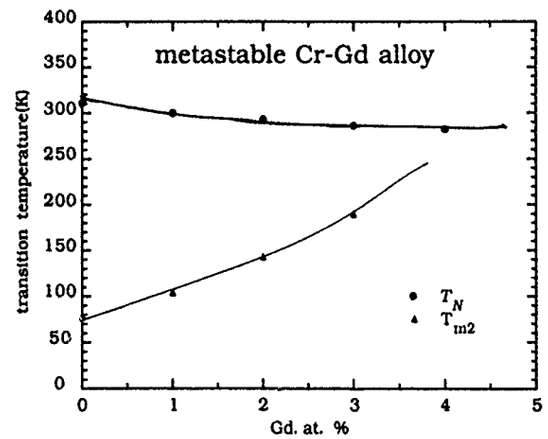

FIG. 3. The Néel temperature T_N and T_{m_2} as a function of Gd concentration.

The process to clarify this possibility by using strain-free sample is underway.

The formation of two new materials, $Sm_2Ni_3Si_5$ and $Gd_2Ni_3Si_5$, of the rare-earth series $R_2M_3Si_5$ (R denotes rare earth and Y) and their magnetic and transport properties are reported here. These materials crystallize in the orthorhombic $U_2Co_3Si_5$-type structure (space group Ibam). The magnetic susceptibility of $Gd_2Ni_3Si_5$ follows a Curie–Weiss behavior with an effective magnetic moment $8.1\mu_B$/Gd ion. The material orders antiferromagnetically at $\approx$15 K. The magnetic susceptibility of $Sm_2Ni_3Si_5$ exhibits a deviation from the Curie–Weiss behavior which is attributed to the low-lying excited state of Sm^{3+} ions and also to crystal-field effects. This material also orders antiferromagnetically, but at $\approx$11 K. This value of the ordering temperature does not seem to follow the de Gennes scaling with respect to that of $Gd_2Ni_3Si_5$.

I. INTRODUCTION

Rare-earth (R) intermetallic materials have been of interest both in the area of fundamental physics and in application areas. Rare-earth-based materials have interested physicists because of the localized f-electron core and the related systematics emerging in the properties of the rare-earth series of a system. The well-known example is the lanthanide contraction often observed in the lattice parameters of isotypic compounds of a rare-earth series. However, the electronic properties of compounds within a series do get modified in the presence of other elements and deviations occur in the expected gradation of the properties with respect to the number of f electrons. These deviations provide us the means to study the physical mechanisms taking place in these materials and solids in general. For example, Ce compounds tend to exhibit anomalous phenomenon due to hybridization of the $4f$ electronic level with the $3d$ electronic level. This results in the phenomenon of heavy fermion behavior, valence fluctuation (VF), Kondo effect, etc. The effects of hybridization can also modify the magnetic interactions. In view of this, we are carrying out a program of synthesis and study of the physical properties of new rare-earth intermetallic compounds. We initiated the study of the series of compounds $R_2Ni_3Si_5$. In an earlier study, we showed the VF behavior of Ce and Eu in $Ce_2Ni_3Si_5$ (Ref. 1) and $Eu_2Ni_3Si_5$,[2] respectively. The formation of $Ce_2Ni_3Si_5$, $Dy_2Ni_3Si_5$, and $Y_2Ni_3Si_5$ has been reported in the literature.[3] Here we report the synthesis of the two new compounds, $Gd_2Ni_3Si_5$ and $Sm_2Ni_3Si_5$, and the preliminary results of magnetic susceptibility and resistivity studies on them.

II. EXPERIMENT

The compounds $Gd_2Ni_3Si_5$ and $Sm_2Ni_3Si_5$ were prepared by the standard arc-melting technique using a water-cooled copper hearth in a flowing argon atmosphere. The purity of the starting materials was better than 99.9% for Sm, Gd, and Ni and better than 99.999% for Si. Each of the arc-melted buttons was wrapped in tantalum foil, vacuum sealed in a quartz capsule, and annealed at 1100 °C for 1 day and at 1000 °C for 7 days. The materials were characterized at room temperature by powder-x-ray-diffraction using Cu$K\alpha$ radiation in a commercial x-ray diffractometer (Jeol, Japan).

Magnetic susceptibility studies were carried out using a Faraday-type susceptometer (George Associates, U.S.A.). The measurements were performed over the temperature range from 4.2 to 300 K using a gas-flow-type helium cryostat. The temperature was measured by a gold-Chromel thermocouple.

Electrical resistivity studies over the temperature range 4.2–300 K were carried out using a home-built cryostat and employing the standard four-probe dc method. Thin silver wires were used as electrical leads and contacts to the samples were made using conducting silver paint. Commercial units were used in the electrical measurements (Keithley model 220 for current source and Keithley model 184 nanovoltmeter). In order to eliminate the effects of thermo emf, the resistance was first measured when the current was passing in one direction, then it was measured again with the current passing in the reverse direction, and then the average of these two readings was taken. The temperature was measured using a calibrated silicon diode.

III. RESULTS AND DISCUSSION

A. Structure

The room-temperature powder-x-ray-diffraction patterns (Fig. 1) confirmed the formation of single-phase materials of $Gd_2Ni_3Si_5$ and $Sm_2Ni_3Si_5$ in the orthorhombic $U_2Co_3Si_5$-type crystal structure (space group Ibam) as is the case with other known materials of this series of Ni compounds.[1–3] The unit-cell parameters of the materials were determined by a least-squares-fit procedure of the observed set of d spacing for each material. The resulting parameters were: $a=9.616$ Å,

 0021-8979/94/75(10)/7155/3/$6.00 © 1994 American Institute of Physics

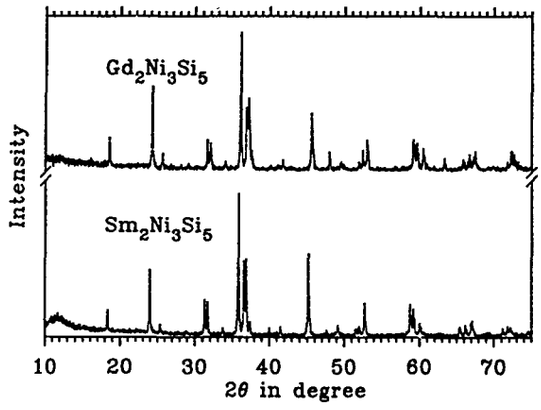

FIG. 1. Powder-x-ray-diffraction pattern for $Gd_2Ni_3Si_5$ and $Sm_2Ni_3Si_5$ at room temperature.

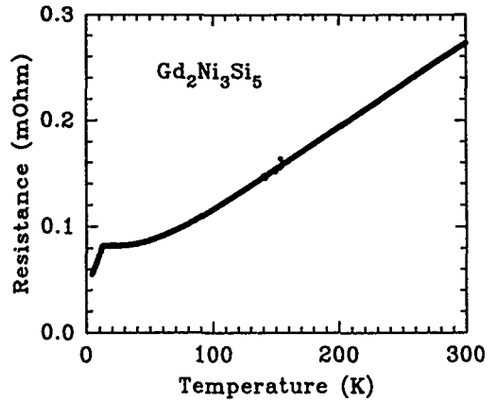

FIG. 3. The thermal variation of resistance (in mΩ) for $Gd_2Ni_3Si_5$.

$b=11.292$ Å, $c=5.705$ Å for $Sm_2Ni_3Si_5$; and $a=9.560$ Å, $b=11.197$ Å, $c=5.665$ Å for $Gd_2Ni_3Si_5$. It is pointed out that the unit-cell parameters of $Sm_2Ni_3Si_5$ are smaller than those of $Gd_2Ni_3Si_5$ as it should be on the basis of "lanthanide contraction," in which one expects the unit cell to contract as the number of f electrons increase in a rare-earth series of compounds.

B. Magnetic and resistivity measurements

1. $Gd_2Ni_3Si_5$

The dc magnetic susceptibility result of $Gd_2Ni_3Si_5$ as a function of temperature is shown in Fig. 2. The material appears to order magnetically, $T_N \approx 15$ K. From the cusplike behavior of the susceptibility peak we infer the nature of the ordering to be antiferromagnetic. The temperature dependence of the inverse susceptibility of $Gd_2Ni_3Si_5$ is linear above T_N (Fig. 2). A Curie–Weiss fit to this data yielded the magnetic moment per Gd ion to be $8.1\mu_B$. Generally, it is believed that in materials of this structure, the transition-metal ion does not carry the magnetic moment. In such a case, the entire observed moment would be attributed to the Gd ion. The moment per Gd ion in this case is slightly higher than the free-ion value of Gd^{3+}. At present we are not sure if this slightly higher value is due to any small impurity phase or due to intrinsic effects such as contribution from conduction electrons. We would like to point out that we synthesized and measured the magnetic susceptibility of $Y_2Ni_3Si_5$ also. It was found to behave in a Curie–Weiss manner with a magnetic moment of $0.27\mu_B$/formula unit.[1] Since the Y ion is not expected to carry any magnetic moment, if we assume that all the moment belongs to Ni and not to any impurity phase, then the observed moment indicates a value of $0.16\mu_B$/Ni ion in $Y_2Ni_3Si_5$.

The temperature dependence of the electrical resistance of $Gd_2Ni_3Si_5$ is shown in Fig. 3. It shows a typical metallic behavior. The reduction in the magnetic scattering of electrons below the magnetically ordered state is clearly seen. The transition temperature seen here is consistent with that observed through magnetic susceptibility.

2. $Sm_2Ni_3Si_5$

The magnetic susceptibility of $Sm_2Ni_3Si_5$ is shown in Fig. 4 as a function of temperature. An antiferromagnetic transition is clearly seen at ≈11 K. It is interesting to note that the well-known de Gennes scaling seems to be breaking down here. The de Gennes factor for Sm with respect to Gd is 0.28. From this one would have expected an ordering tem-

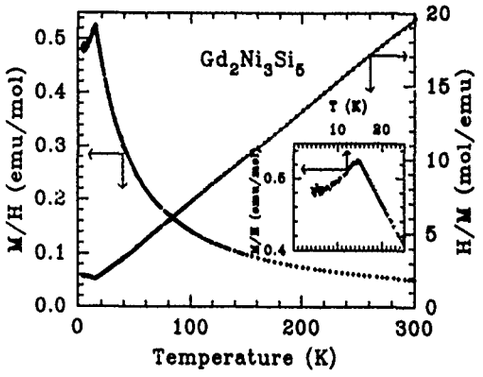

FIG. 2. dc magnetic susceptibility and its reciprocal for the compound $Gd_2Ni_3Si_5$. The solid line is a fit to the Curie–Weiss formula. The expanded region near T_N is shown in the inset.

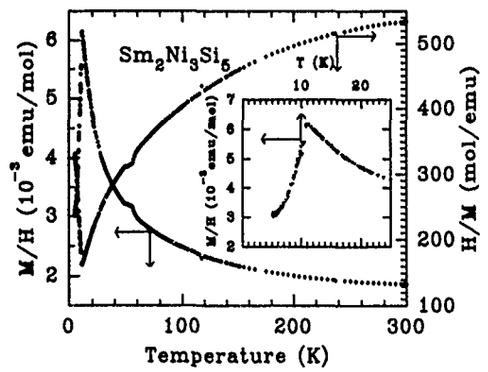

FIG. 4. dc magnetic susceptibility and its reciprocal for the compound $Sm_2Ni_3Si_5$. The expanded region near T_N is shown in the inset.

perature of ≈5 K. The observed value of T_N (≈11 K) is much higher than this. We believe that the small anomaly observed in the susceptibility near 55 K is due to a small impurity phase which is below the limit of detection in the x-ray-diffraction pattern. The temperature dependence of inverse susceptibility is not linear. This is not unexpected in a Sm-based material. This is primarily due to the fact that the ionic excited states are at a rather low level and, hence, they are also populated at moderate temperatures resulting in a effective value of magnetic moment which is different from that of the free Sm^{3+} ion in ground state. It is quite likely that at low temperatures, crystal-field effects also contribute to the deviation from the Curie–Weiss behavior.

IV. CONCLUSION

We have synthesized two new materials, $Gd_2Ni_3Si_5$ and $Sm_2Ni_3Si_5$, and shown that they form in orthorhombic $U_2Co_3Si_5$-type structure similar to other members of this rare-earth series. Both the materials seems to order antiferromagnetically (T_N≈15 and ≈11 K for $Gd_2Ni_3Si_5$ and $Sm_2Ni_3Si_5$, respectively). The ordering temperature of $Sm_2Ni_3Si_5$ does not follow the de Gennes scaling with respect to that of $Gd_2Ni_3Si_5$.

Low-field ac magnetic susceptibility under pressure in $GdMn_2$ and $TbMn_2$ intermetallics

M. R. Ibarra,[a] Z. Arnold,[b] C. Marquina, L. García-Orza, and A. del Moral
Departamento de Física de la Materia Condensada e Instituto de Ciencia de Materiales de Aragón, Universidad de Zaragoza-CSIC, 50009-Zaragoza, Spain

Low-field ac magnetic susceptibility experiments under pressure up to 10 kbar have been performed on the $GdMn_2$ and $TbMn_2$ compounds in the temperature range of 4–300 K. The results reveal the possible coexistence of two phases below T_N, one in which the magnetic moment of Mn is stable and other in which the Mn does not present any magnetic moment.

The RMn_2 compounds crystallize in the Laves phase structures. The hexagonal $C14$ phase is stabilized in the case of R=Pr, Nd, Sm, Ho, Er, Tm, or Lu and the cubic $C15$ for R=Y, Gd, Tb, Dy, and Ho. The magnetic properties of these compounds are strongly related to the intraatomic Mn-Mn distance.[1] The existence of a critical distance for these compounds is assumed (at room temperature $d_{Mn\text{-}Mn}$=2.67 Å). Below this value the magnetic moment on Mn (μ_{Mn}) is not stable. On the other hand, the appearance of a local magnetic moment takes place at a specific temperature through a first-order structural and antiferromagnetic transition, (T_N mostly around 100 K), when $d_{Mn\text{-}Mn}$ is greater than the critical value. At this transition very large spontaneous magnetovolume effects occur. The transition temperature is very sensitive to external parameters, such as the applied pressure[2] or the magnetic field.[3] However, from nuclear magnetic resonance (NMR)[4] on YMn_2 and neutron-diffraction experiments on YMn_2 and $TbMn_2$[5] under pressure, a constant value for the μ_{Mn} was observed. Magnetostriction experiments using high pulsed magnetic fields up to 15 T demonstrated the stability of μ_{Mn} in YMn_2, $GdMn_2$, and $NdMn_2$,[6,7] and the collapse of μ_{Mn} in the case of $TbMn_2$.[8]

Up to now, pressure studies were related to the pressure sensitivity of the antiferromagnetic transition and little attention has been paid to the more tiny effects connected with the magnetic ordering observed at different temperatures on compounds with several rare earths. For our high-pressure studies of $GdMn_2$ and $TbMn_2$ compounds we used the low-field ac susceptibility $\chi(T)$ technique.

The polycrystalline RMn_2 compounds were prepared by arc melting the high-purity constituents. The sample annealing was carried out under a stabilized argon atmosphere at a pressure of 0.2 bar for 5 days at 800 °C. The nonexistence of secondary phases was checked by x-ray powder diffraction. Also, the low value of the $\chi(T)$ at room temperature was a more positive test of the absence of the ferromagnetic R_6Mn_{23} phase.

The $\chi(T)$ was measured using a low-frequency (15 Hz) mutual inductance bridge, with a peak value of the magnetic field of ≈30 mOe. The high-pressure measurements were done using a CuBe cell under fixed hydrostatic pressures up to 10 kbar. The pressure was measured *in situ*, using a manganin pressure sensor.

$GdMn_2$:

In this compound T_N=104 K and below this temperature an antiferromagnetic behavior was observed. From magnetization measurements a magnetic ordering of the Gd sublattice below T_c≈40 K was observed;[9–11] however from specific heat[12] and Mössbauer[13] measurements, it was evident that the Gd sublattice is ordered up to T_N. There exists a large controversy about the magnetic structure due to the difficulty of performing neutron-diffraction experiments. Our recent results of magnetostriction[7] clarified this magnetic behavior. We proposed a model[14] considering a diffusionless (first-order) transformation at T_N with the existence of two phases below T_N; one transformed phase (TP), which is the responsible for the huge thermal-expansion anomaly, and other nontransformed phase (NTP), in which μ_{Mn}≈0 in the entire range of temperature. Evidence that the transition is not complete was found in $Y_{1-x}Sc_xMn_2$ (Ref. 4) and $TbMn_2$ (Ref. 5) under pressure. The TP phase appears below T_N and both Gd and Mn magnetic sublattices become antiferromagnetically ordered. The Mn sublattice is ordered through the $3d$-$3d$ exchange interaction and the Gd sublattice through the $3d$-$4f$ exchange interaction. The NTP magnetically order at T_c≈35 K. This magnetic transition occurs because of the $4f$-$4f$ exchange interaction between Gd ions (in this phase μ_{Mn}≈0). The reliability of this model was tested by $\chi(T)$ under pressure and magnetostriction measurements performed on $GdMn_2$.[14] In the above-mentioned work an increase of T_c in the NTP and a decrease of T_N in the TP phase was observed for increasing pressures. The transition in both phases occurs simultaneously at $T_N=T_c=70$ K for a pressure of 6.9 kbar. At higher pressures it was observed that the first-order transition at T_N could take place in the ordered regime ($T_c>T_N$). Because the maximum pressure available in this range of temperature was 7.8 kbar, we performed $\chi(T)$ measurements in the series $Gd(Mn_{1-x}Ni_x)_2$ creating a chemical pressure[11] by substitution of smaller Ni atoms. We have selected Ni because the RNi_2 crystallizes in the same crystallographic structure and Ni does not carry a magnetic moment in this structure and, consequently, we cannot expect a perturbation of the $3d$ magnetism observed in pure $GdMn_2$. In Fig. 1 we report the results obtained for selected concentrations. The x=0 compound shows a small anomaly at T_c=35 K which is associated with the establishment of magnetic order in the NTP phase and no anomaly is observed

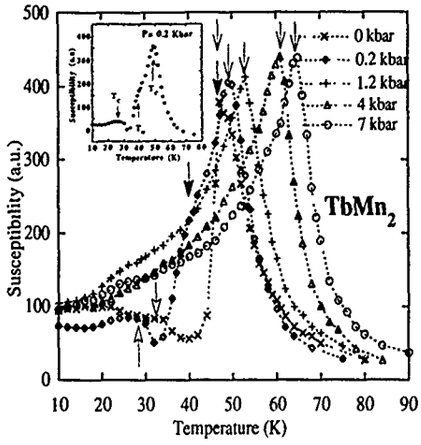

FIG. 2. $\chi(T)$ at different pressures in $TbMn_2$. Inset $\chi(T)$ at $p=0.2$ kbar; T_c (↑), T_c' (⇑), T_N (↑).

at T_N. For $x=0.025$, a large anomaly in $\chi(T)$ is observed at 45 K which is associated with an increase of T_c and an anomaly in thermal-expansion measurements[7] gave a value of $T_N=95$ K. For higher Ni concentrations, we start to observe an anomaly in $\chi(T)$ at T_N in good agreement with thermal-expansion results.[7] The dependence of T_c and T_N on concentration can be clearly followed in Fig. 1 for the rest of the compounds. For $x=0.1$, we observe $T_c>T_N$, in close agreement with magnetization under pressure measurements in $GdMn_2$.[11] These results constitute a good test of the model that we proposed[14] and also clearly establish the stability of the TP, besides the existence of magnetic order in the R sublattice. Consequently, the appearance of local magnetic moment on Mn can take place below T_c. This conclusion is also in support of the stability of the μ_{Mn} and TP found in $GdMn_2$ up to applied magnetic field of 15 T.[14]

$TbMn_2$:

In RMn_2 compounds, $TbMn_2$ has the intraatomic Mn-Mn distance which is the closest to the critical distance below which $\mu_{Mn}=0$. It is assumed that this is one of the reasons why $T_N\approx45$ K is significantly lower than in the rest of compounds (i.e., R=Sm, Pr, Nd, and Gd). Neutron-diffraction studies[3,5] indicated the existence of two magnetic phases below T_N, which were called S_1 and S_2. We can assume the S_1 phase is associated with the so-called TP. In this phase $\mu_{Mn}\neq0$. Similarly the NTP presents a S_2-type magnetic structure, reminiscent of that observed in $DyMn_2$.[15] Either under applied[5] or chemical pressure a new ferrimagnetic phase appears as was observed in $Tb(Mn_{1-x}Fe_x)_2$ (Ref. 16) and $Tb_{1-x}Sc_xMn_2$.[17,18] In the present work we report $\chi(T)$ measurements under hydrostatic pressure. The thermal dependence of the $\chi(T)$ is presented in Fig. 2 for different applied pressures. In the range of pressure $p>2$ kbar only one anomaly is observed, which is associated with T_c (paraferrimagnetic transition) and increases with increasing pressures at the rate $dT_c/dp=2$ K/kbar. The structural transformation is absent in this range of pressure and consequently a local magnetic moment on Mn atoms does not exist, in good agreement with neutron-diffraction and magnetization results.[5,3] The low-pressure behavior is rather complex and can be understood from the results obtained at $p=0.2$ kbar. We analyze these results considering that both TP and NTP coexist. Three anomalies on the thermal dependence of susceptibility can be distinguished at 30, 40, and 50 K. We can assume $T_c=50$ K for the magnetic transitions in the NTP. The shoulder observed at $T_c'\approx30$ K can be associated with the magnetic ordering temperature within the NTP, from the ferrimagnetic ordering at higher temperature toward the S_2 magnetic structure ($DyMn_2$ type). The other anomaly at $T_N\approx40$ K—a sharp decrease of susceptibility—corresponds to the temperature at which the TP appears. The T_N is extremely pressure dependent ($dT_N/dp\approx-30$ K/kbar); in fact, TP disappears at a pressure above 2 kbar, in good agreement with former magnetization and neutron measurements.[2,5] At normal pressure both T_c and T_N merge at $T_N\approx T_c\approx45$ K, as can be observed in Fig. 2. At lower temperatures a shoulder appears at $T_c'=35$ K, which can be associated with the transition to the S_2 magnetic structure within the NTP. Evidence of this NTP was found using neutron-diffraction experiments; at normal pressure this NTP only represents a few percent of the total sample volume.[19] The volume of this phase rapidly increases with pressure. This result is in good agreement with the thermal-expansion results obtained on the same sample.[8] Based on these arguments, we suggest the magnetic phase diagrams (T,p) of Figs. 3(a) and 3(b) for the TP and NTP, respectively. These results clarify some of the uncertainties implicit in the interpretation of the neutron-diffraction results in the region of temperature 35–50 K in $Tb(Mn_{1-x}Fe_x)_2$ (Refs. 3 and 16) and in $Tb_{1-x}Sc_xMn_2$.[18] The instability of the TP under pressure in this compound can be supported from other points of view. The existence of a ferrimagnetic phase at $T_c>T_N$ is not a stable situation for the existence of the TP in the case of $TbMn_2$. Consequently, the increase of the molecular field induced by pressure in the NTP will have the same role as the increase of the applied magnetic field and will suppress the TP.

As a general conclusion from this systematic study of $TbMn_2$ and $GdMn_2$ compounds under pressure we propose an explanation for the complex magnetic behavior of these

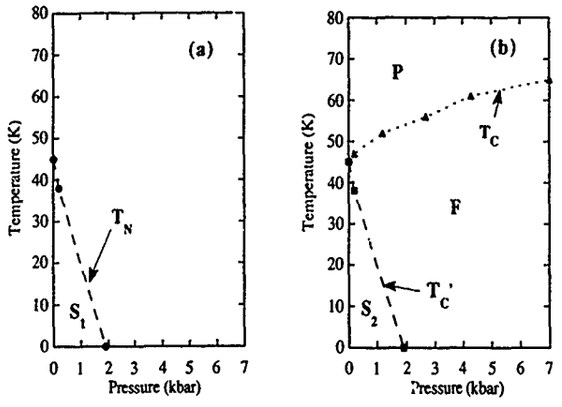

FIG. 3. Magnetic-phase diagram for the (a) TP and the (b) NTP in $TbMn_2$.

compounds based on the coexistence of two phases TP and NTP originated by a diffusionless first-order phase transformation at T_N. The observed thermal dependence of the magnetic behavior under pressure is satisfactorily explained following the thermal pressure dependence of the different magnetic behaviors within each phase.

Time evolution of magnetization in the FeRh system near antiferromagnetic-ferromagnetic transition temperature (abstract)

Shinji Yuasa, Yoshichika Otani, and Hideki Miyajima
Department of Physics, Faculty of Science and Technology, Keio University, Hiyoshi 3-14-1, Kohoku, Yokohama 223, Japan

The body-centered cubic FeRh is known to exhibit a first-order phase transition from antiferromagnetic to ferromagnetic at about 400 K, accompanied by a volume expansion of about 1%. The time evolution of the magnetization M of ordered $Fe_{0.5}Rh_{0.5}$ and $FeRh_{0.958}Pt_{0.042}$ just below and above the transition temperature (T_0) was measured as functions of temperature and magnetic field. Around T_0, the magnetization increased logarithmically with time up to M^*(=41 emu/g), the value of which indicates that the ferromagnetic grains occupy one third of the antiferromagnetic matrix. When $M=M^*$, there appeared a jump in M. After that, M varies as $M(t)=M_\infty[1-\exp(-t/\tau)]$, where τ is a relaxation time. It should be noted that the value of M^* is independent of both temperatures and external magnetic fields. Microscopic observation and x-ray diffraction measurement showed that the ferromagnetic grains nucleated in the antiferromagnetic matrix began to grow with time just below T_0. In this work, the time evolution of the phase transition was analyzed by considering the magnetic free energy, the elastic energy, and the strain energy at the surface of the grains. The above mentioned magnetic relaxation process is deeply related to the time evolution of the grain size.

Unusual magnetic properties and time dependent magnetization in $ErCo_3Ga_2$ (abstract)

Naushad Ali and Xianfeng Zhang
Department of Physics and Molecular Science Program, Southern Illinois University, Carbondale, Illinois 62901

In this abstract we will present the measurements of magnetization, ac susceptibility, and the time dependent effects on the magnetization of polycrystalline samples of $ErCo_3Ga_2$ and YCo_3Ga_2. The field cooled (FC) and zero field cooled (ZFC) magnetization data suggest a spin glass transition in YCo_3Ga_2 below 160 K. The FC magnetization $ErCo_3Ga_2$ exhibits a negative minimum at 25 K and a compensation temperature at 150 K. It is suggested that $ErCo_3Ga_2$ has two magnetic phase transitions: one at 150 K (most likely a spin glass transition due to Co sublattice) and the other below 25 K (due to Er sublattice ordering). We have found an unusual time dependence of magnetization of $ErCo_3Ga_2$ at a constant temperature (below 150 K) and constant applied magnetic field. The magnetization M increases with time t and dose not attain a constant value over a period of 64 h. The time dependence of magnetization follows the relation $M_{T,H}(t)=M_{T,H}(t_0)+a_{T,H}\ln t$. The slope $a_{T,H}$ is always positive and depends on temperature and the applied magnetic field. The field dependence of the slope shows a peak at a field H_a. The value of H_a decreases with increasing temperature. At a constant temperature the slope $a_{T,H}$ increases exponentially with the applied magnetic field and then decays towards zero values at high applied magnetic field. This suggests an activation energy process. Detailed experimental results on time effects will be presented.

H. Tsuda
Clinical Laboratory, Kyushu University Hospital, Kyushu University, Fukuoka 812, Japan

In this study, we investigated the possible effects of magnetic fields on the fibrinolytic process. Fibrin dissolution was observed and the fibrinolytic activities were evaluated. First, fibrinolytic processes in magnetic fields were investigated by the fibrin plate method. We gathered solutions from the dissolved fibrin, and measured mean levels of fibrin degradation products (FDPs) in solutions. Mean levels of FDPs exposed to 8 T magnetic fields were higher than those not exposed to fields. Second, we carried out an experiment to understand how fibrin oriented in a magnetic field dissolves. FDPs in solutions of dissolved fibrins in fibrin plates were assayed. The result was that fibrin gels formed in a magnetic field at 8 T were more soluble than those not formed in a magnetic field. A model based on the diamagnetic properties of macromolecules was explained, and changes of protein concentrations in a solution in gradient magnetic fields were predicted.

I. INTRODUCTION

Fibrinogen, which is the prime factor in blood coagulation, changes to fibrin monomer by the action of protease thrombin, and fibrin monomers are polymerized. Fibrin polymers are diamagnetic materials that are oriented in a magnetic field. In the course of the polymerization process, when a magnetic field of intensity 10–20 T is applied, the fibrin fibers orient parallel to the magnetic fields.[1] When no magnetic field is applied, fibrin fibers become entangled in mesh, and no orientation is observed. This is an effect of strong static magnetic fields on the blood coagulation system.

On the other hand, the fibrinolytic process also occurs in vessels in a mutually compensating and balanced state with coagulation. Fibrin gels are dissolved when polymerized fibrins are degraded to fragments by plasmin. There have been some studies on the positive effect of weak magnetic fields (~0.3 T) on fibrinogen degradation products level in rabbits *in vivo*.[2] We have been studying the fibrinolysis in intense magnetic fields up to 8 T, to clarify the mechanism of enzyme reactions in magnetic fields, and reported about some *in vitro* studies of fibrinolysis.[3,4] We have investigated how fibrin oriented in a magnetic field dissolves. Fibrin plates were prepared and the fibrinolytic process was observed. It was observed that the shapes of holes in dissolved fibrin changed to ellipsoidal patterns when fibrin plates were formed with a magnetic field at 8 T. The transversal axis of the ellipse was parallel to the magnetic fields.[4]

In the present study, we focus on the possibility that one of the enzyme reactions engaged in those coagulation and fibrinolysis cascades, could be influenced by magnetic fields. Fibrinolytic processes in magnetic fields are investigated by a fibrin plate method, and mean levels of fibrin degradation products (FDPs) in solutions are measured.

II. MATERIALS AND METHODS

A. Magnetic fields exposure system

We used a horizontal type of superconducting magnet with a bore 100 mm in diameter and 700 mm long. The magnet produced 8 T at its center, where the z axis was directed along the bore axis.

The distributions of magnetic fields at the center of a bore are shown in Fig. 1. In a sectional plane of a bore, the maximum field strength is in bore's wall, and the minimum field strength is in the center of the plane.

Figure 2 shows the distributions of magnetic fields on the z axis. This exposure system has a field distribution in which magnetic field strength changes from 7.84 to 4.30 T at $z=0\sim\pm100$ mm in the center of a sectional plane of a bore. When the magnet produced 8 T at its center, the maximum product of the magnetic field and the gradient was 400 T^2/m at $z=\pm75$ mm, where the z axis was along the bore axis.

B. Assay of FDPs released under magnetic fields

Fibrinolytic activity was evaluated by the fibrin plate method.[5] Fibrin plates were prepared and the fibrinolytic process was observed. Thrombin (80 μl 3.1 NIH units/ml) was

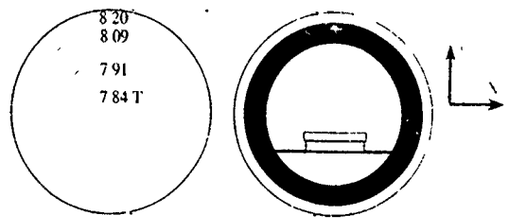

FIG. 1. Distribution of magnetic fields at the center of the bore.

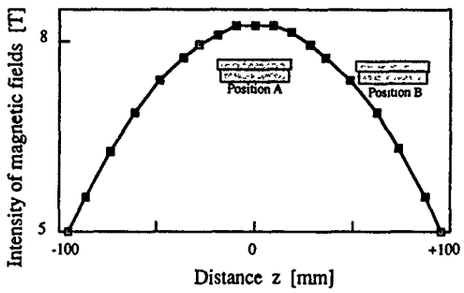

FIG. 2. Distribution of magnetic fields on the bore axis.

added to 3 ml of fibrinogen (4.8 mg/ml in 0.05 M Tris-HCl buffer, *p*H 7.4, containing 0.10 M NaCl). This solution was divided into two dishes and incubated at 25 °C for 60 min without magnetic fields. A hole was made in the centers of the fibrin plates by a gel puncher, and 20 μl of plasmin (4 casein units/ml) was added to each hole.

Fibrin plates were incubated at 37 °C for 15 h, either with a magnetic field at 8 T or without magnetic fields, and dissolution of both types of fibrin was observed. The position of fibrin plates exposed to 8 T magnetic fields (position A) is shown in Fig. 2. We gathered solutions from the dissolved fibrin, and measured absorbencies at 280 nm with a spectrophotometer. Mean levels of FDPs in solutions were obtained using absorbance coefficiencies ($A_{1\%-1\ cm}$ at 280 nm) of 1.51.[6]

The same experiment was carried out in gradient magnetic fields (position B: 350–400 T^2/m).

C. Assay of fibrinolysis of fibrin colts formed in magnetic fields

We carried out an experiment to understand how the fibrin oriented in a magnetic field dissolves. Thrombin was added to a solution of fibrinogen. This solution was divided into two dishes; one was for magnetic field exposures and the other for the control. After incubation at 25 °C for 60 min, a hole was made in fibrin plates in which a protease plasmin was added. The dissolution of both fibrins was observed after incubation at 37 °C for 15 h. We gathered solutions from the dissolved fibrin, and measured mean levels of FDPs in solutions.

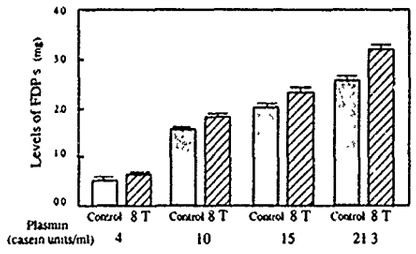

FIG. 3. Fibrinolytic processes in an 8 T magnetic field. Vertical axis shows the levels of FDPs. Various concentrations of plasmin (20 μl) were added into a hole made in the center of fibrin plates. Data were expressed as means +SD for independent experiments.

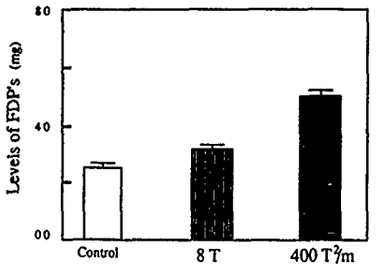

FIG. 4. Effects of gradient magnetic field on fibrinolytic process. Vertical axis shows the levels of FDPs. Plasmin (20 μl, 21.3 casein units/ml) were added into the holes made in the center of fibrin plates. Data were expressed as means +SD for independent experiments.

III. RESULTS

A. Fibrinolysis under magnetic fields

Figure 3 shows the mean levels of FDPs in samples exposed to an 8 T magnetic field and in those not exposed. Fibrin plates exposed to fields were placed in the center of a magnet's bore axis, 20 mm below the center of the bore's sectional plane.

The maximum release of FDPs was observed when plasmin activity was 21.3 casein units/ml. Mean levels of FDPs in samples exposed to an 8 T magnetic field were higher than those not exposed by 18% on the average.

Figure 4 shows the effects of gradient magnetic fields on the fibrinolytic process. The mean level of FDPs released in a gradient magnetic field of 400 T^2/m was more than 190% of the control samples, and 160% of the samples exposed to an 8 T magnetic field.

B. Fibrinolysis of fibrin colts formed in magnetic fields

FDPs in the dissolved holes in the fibrin prepared in either the presence or the absence of an 8 T magnetic field were assayed. The result is shown in Fig. 5. Plasmin concentrations were varied from 10 to 21.3 casein units/ml. Fibrin gels formed with a magnetic field were more soluble than those formed without a magnetic field.

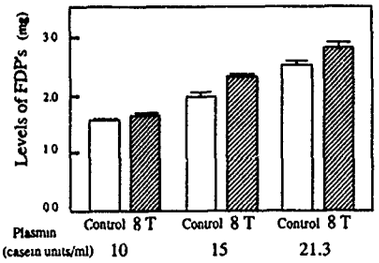

FIG. 5. Fibrinolysis in the fibrin that formed in a 8 T magnetic fields. Vertical axis shows the levels of FDPs. Various concentrations of plasmin (20 μl) were added to the holes made in the center of fibrin plates. Data were expressed as means +SD for independent experiments.

IV. DISCUSSION

The results of the present study indicate that a reaction of the last cascade of fibrinolytic system, degradation of fibrin clots by protease plasmin, is influenced by magnetic fields up to 8 T.

In the first experiments, mean levels of FDPs in the center of a magnet's bore axis (position A; $z=0$ mm, $y=-19$ to -15 mm), were higher than those not exposed to magnetic fields by 18% on the average.

We have carried out the same experiment in the gradient magnetic fields area, where products of B and dB/dz are 350–400 T^2/m at $z=\pm 60$–95 mm (position B). Result shows that the effect of gradient magnetic fields is significant in this position.

We propose a model to explain these results. The model is the effect of magnetic fields on the kinetics of macromolecules, observed at macroscopic levels, that is caused by the diamagnetic properties.

Almost all materials in living systems are diamagnetic materials. Fibrin polymers have a distinguishable property, which is the large diamagnetic anisotropy resulting in magnetic torque energy $(1/2)\Delta\chi H^2$ which exceeds thermal energy kT. There is another kinetic property of diamagnetic materials. If there is a magnetic gradient, diamagnetic materials in this area can drift to less magnetic fields.

In the experiment of fibrinolysis under magnetic fields, at position A, where the bottom of a fibrin plate is exposed to 7.90 T ($y=-19$ mm) and the top is exposed to 7.86 T ($y=-15$ mm), fibrin gel is in the gradient field of 7.5 T/m. Products of fields and gradient in this space are ~ 59 T^2/m.

Let us introduce a situation in which there is a gradient magnetic field whose intensity decreases with the altitude increase. When there is a diamagnetic material, such as water, in gradient magnetic fields. A gravity force of $\rho_w g V_w$ acts downward on this material, where ρ_w is a mass of water per unit volume, g is the gravitational constant, and V_w is a volume of water cluster. On the other hand, a magnetic force $-\chi_w V_w \mu_0 \Delta(H^2)/2$ acts upward, where χ_w is a susceptibility of water.

Fibrin clots are gels that contain water clusters and ions, etc. When these clots are digested by the action of protease plasmin, many FDPs are released in the solution. If there are polymerized fibrins which have been isolated from clots, these fibrin polymers are adrift in the solution because of buoyancy. If we do not consider random movements caused by thermal energy, and viscosity is neglected, a force that acts on a diamagnetic material in the water is described as

$$F=\rho g V-\rho_w g V+(\chi_v-\chi_w)V\mu_0\Delta(H^2)/2, \quad (1)$$

where ρ, χ_v, and V are constants of fibrin, FDPs, or plasmin.

If $(\rho-\rho_w)gV$ was small compared to $(\chi_v-\chi_w)V\mu_0 \times\Delta(H^2)/2$, and when magnetic energy $-(\chi_v-\chi_w)V\mu_0 H^2/2$ was larger than thermal energy kT, it is possible for the diamagnetic proteins in the solution to drift in a specific direction.

Drifting of fibrin polymers and FDPs in a specific direction results in the change of concentration of these proteins. When there is an increase of the concentrations of substrates and enzymes in a local space of a solution, an enzyme reaction such as fibrinolysis can be effected.

The effect of a gradient magnetic field of 400 T^2/m was more distinguished as shown in Fig. 4. In this case, there are large gradients along the horizontal line. Solutions containing water, plasmin, and fibrin could diffuse to horizontal directions to promote the reactions of fibrinolysis.

An enhancement of fibrinolysis of clots formed with magnetic fields also seems to be due to magnetically induced changes in concentration of fibrins.

V. CONCLUSION

To investigate the effect of magnetic fields on the fibrinolytic process in thrombus, we carried out the above described experiments.

In the experimental results of the fibrin plate method, fibrinolysis under magnetic field gradient and fibrinolysis of clots formed with magnetic fields were enhanced.

Early embryonic development of frogs under intense magnetic fields up to 8 T

S. Ueno and M. Iwasaka
Biomagnetics and Biosystems Laboratory, Department of Computer Science and Communication Engineering, Faculty of Engineering, Kyushu University, Fukuoka 812, Japan

K. Shiokawa
Zoological Institute, Faculty of Science, University of Tokyo, Tokyo 113, Japan

A possible influence of intense magnetic fields on the embryonic development of frogs was studied in reference to a potential hazard in magnetic resonance imaging technology. Some of the most serious hazardous effects that could be induced by intense magnetic fields are teratogenic effects on developing embryos. In the present experiment, the possible influence of intense magnetic fields up to 8 T on the early embryonic development of *Xenopus laevis* was studied. Embryos were exposed to magnetic fields up to 8 T for the period from the precleavage stage to neurula in a small glass vial. Embryos were then cultured in Brown–Caston's medium until the feeding-tadpole stage. No apparent teratogenic effects were observed when embryos were cultured for 20 h from the stage of uncleaved fertilized egg to the neurula stage under magnetic fields of 8 T. We conclude that static magnetic fields up to 8 T do not appreciably affect the rapid cleavage and the following cell multiplication and differentiation in *Xenopus laevis*. We have also studied the early embryonic development of *Xenopus laevis* in a 40 nT magnetic field, or 1/1000 of the earth's magnetic field, and obtained negative results. Thus, again under this very low magnetic field, fertilized eggs developed normally and formed tadpoles with no appreciable abnormality.

INTRODUCTION

The question of biological effects of magnetic fields has become serious recently in association with the appearance of superconducting magnets and magnetic resonance imaging (MRI) for medical applications.

One of the most serious hazardous effects that could be induced by intense magnetic fields is a teratogenic effect on developing embryos. Generally, fertilized eggs of animals divide quite actively. For example, a fertilized egg of the African clawed toad *Xenopus laevis* cleaves approximately every 25 min for the first 12 cycles of cell division,[1] and after such rapid and synchronous division, the embryo reaches the blastula and then gastrula stages to undergo formative movements to become a feeding tadpole, which is provided with all the necessary "organ anlage" to become a frog.

Thus embryos of *Xenopus laevis* provide a unique test system to examine both cytostatic and teratogenic effects of magnetic fields, because they first divide extremely rapidly during the cleavage stage, and then later differentiate various organs, the essential mechanisms of which are comparable to those of humans.

A preliminary study on embryogenesis in *Xenopus laevis* cultured in magnetic fields up to 1 T, 1000 T/m, and 6.34 T has been reported previously.[2,3]

In these previous studies,[2,3] embryos were exposed to the strong magnetic field after they reached 2–8 cell stages. In the initial phase of embryogenesis, *Xenopus* eggs undergo remarkable rearrangement of cytoplasmic substances and cortical rotation, which is induced by sperm entrance and determines the future dersoventral polarity.[4] Therefore, it is important to see if the developing embryos are affected by the strong magnetic field during such extensive cytoplasmic relocalization.

To test the susceptibility of the egg rotation and accompanying changes to the strong magnetic field, it is necessary to expose the egg to the magnetic field shortly after insemination.

In the present experiment, the possible influence of intense magnetic fields up to 8 T on the early embryonic development of *Xenopus laevis* was studied by exposing eggs shortly after fertilization (before egg rotation).

MATERIALS AND METHOD

A female of *Xenopus laevis* which had not ovulated for at least six months was injected with 150 units of a gonadotropic hormone gonatropin,[5] and unfertilized eggs squeezed out from the female were artificially inseminated following the methods of Wolf and Hedrick.[6] About 20 min after fertilization, eggs were cultured at 21–22 °C in a Brown–Caston Ringer solution[7] and eggs were exposed to magnetic fields up to 8 T in a small glass vial. Eggs that were arrested in development were counted as unfertilized and were eliminated from the culture within 2 h. Embryos were then cultured in Brown–Caston's medium until the feeding-tadpole stage, following the methods of Nieuwkoop and Faber.[8] Tadpoles were fed a dried powder of alfalfa leaves.

We also studied embryonic development of *Xenopus laevis* in a magnetically shielded room where field strength is 40 nT.

The experimental design to expose eggs or embryos to magnetic fields is illustrated in Fig. 1. We used a horizontal type of superconducting magnet with a bore 100 mm in diameter and 700 mm long. The magnet produced 8 T at its center.

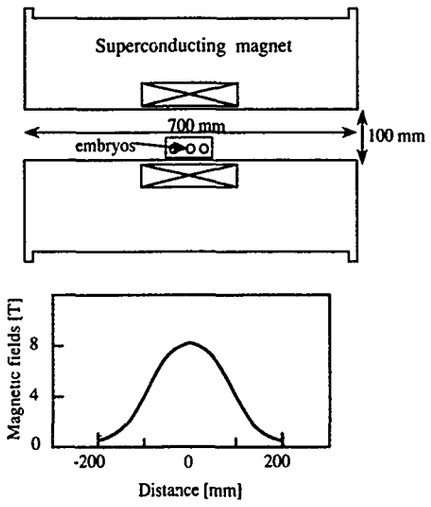

FIG. 1. Experimental setup to observe the embryonic development of frog embryos in a superconducting magnet.

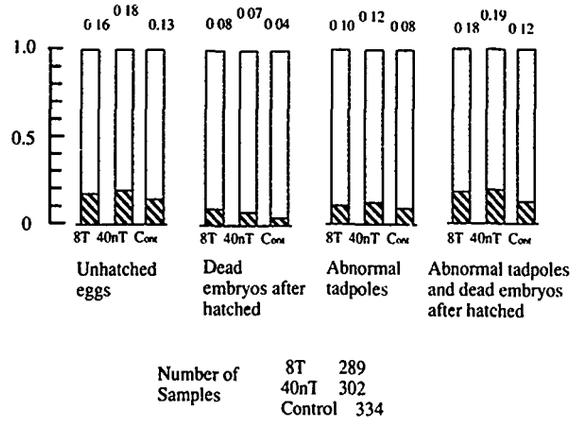

FIG. 3. The embryonic development under static magnetic fields. 8 T: embryos cultured in an 8 T magnetic field. 40 nT: embryos cultured in a 40 nT magnetic field. Cont: Control group. Samples 8 T 289, 40 nT 302, Cont 334.

RESULTS AND DISCUSSION

Figure 2 shows the outer appearance of exposed embryos at various stages. It is shown that embryos at the stages of blastla, neurula, and hatched tadpole treated with an 8 T or 40 nT magnetic field are quite similar in their outer appearance to the untreated control embryos.

The results are summarized in Fig. 3. The percentage of embryos that reached late neurula stage was the same between the control and the embryos cultured in 8 T and 40 nT. The 14% of the embryos that died relatively early during the experiment is assumed to have been overripe eggs. Those designated as abnormal are tadpoles with faint coloring or albino formation, or axial bending including curled tail, edema formation, or a small head (microcephaly).

Neurath[9] has done experiments on the embryonic development of frogs under gradient magnetic fields and obtained a significant difference in the hatching rate of the embryo. Neurath tried to explain the results through the movement of ferritin, a paramagnetic material in the cells.

Gradient magnetic fields will exert mechanical forces on heterogeneous materials of different magnetic susceptibility. Assuming that biomagnetic effects are due to forces between heterogeneous materials of different magnetic susceptibility in the body, the effect should be proportional to the product of the magnetic field and the gradient.

High gradient magnetic separation (HGMS) has made it possible to separate micron-sized paramagnetic particles from solution.[10] Melville, Paul, and Roath[11] succeeded in separating red cells from whole blood by HGMS when the hemoglobin was in the completely deoxygenated state.

We have reported a study on the magnetic field effects on the embryonic development of *Xenopus laevis* by a similar technique used in HGMS.[2] Embryos were exposed to 1.0 T magnetic fields with different gradients of a range from 10 to 10^3 T/m during a period from cleavage to neurula stage. The results obtained suggested that strong magnetic fields with gradients higher than at least 10^4 T/m would be necessary to cause more clear teratogenic effects.

We have also reported results of a preliminary study on embryogenesis in *Xenopus laevis* cultured in static magnetic fields of 6.34 and 4.5 T.[3] It is possible for diamagnetic materials in living systems to orient by static magnetic fields up to 10 T order. The magnetic orientation of cellular constituents, especially of those in cytoplasmic membranes, could occur in the rapidly dividing cells of early embryos. It is also considered that magnetic fields could induce some effects on

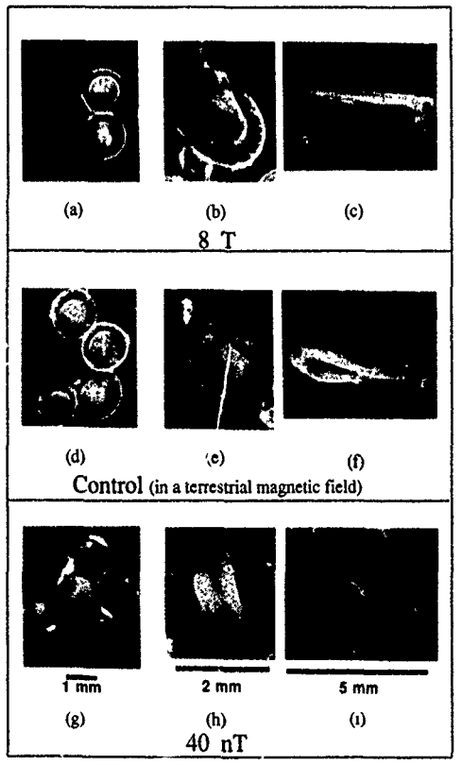

FIG. 2. Outer appearance of exposed embryos at various stages. (a),(d),(g) blastra stage; (b),(e),(h) tail bud-stage embryos; (c),(f),(i) tadpoles after hatching.

the mitochondrial energy supplying system, which in turn induces some alteration in DNA and RNA metabolism. Results obtained showed that static magnetic fields up to 6.34 T did not appreciably affect the rapid cleavage and the following cell multiplication and differentiation in *Xenopus laevis*.

In the present study, the possible influence of intense magnetic fields up to 8 T on the early embryonic development of *Xenopus laevis* was studied by exposing eggs shortly after fertilization (before egg rotation). However, we observed no appreciable defect in the development of embryos. Also it was shown here that an almost zero or 1/1000 of the earth's magnetic field, has no teratogenic effect on *Xenopus* development.

Therefore, we concluded that as far as the rotation of cortical cytoplasm of fertilized eggs and subsequent cleavage and early development of *Xenopus laevis* are concerned, 8 T and 40 nT magnetic fields exert practically no appreciable effect.

Influence of spreading neuronal electric sources on spatio-temporal neuromagnetic fields

K. Iramina, K. Ueno, and S. Ueno
Biomagnetics and Biosystems Laboratory, Department of Computer Science and Communication Engineering, Kyushu University, Fukuoka 812, Japan

This study focuses on the influences of spreading multiple dipoles in the human head upon surface magnetic fields. A source model of the magnetoencephalogram (MEG) activity is proposed. This source model is expressed by spreading multiple dipoles which have time-varying dipole moments. Using this source model, spatio-temporal patterns of MEGs are simulated. Effects of spreading dipoles on spatio-temporal magnetic fields are investigated. The computer simulations show that the wave forms and amplitude of magnetic fields are affected significantly by the spread of the source and the conduction velocity of traveling dipoles. The latency of the peak magnetic field generated by spreading multiple dipoles varies with the measurements points on the surface of the head.

INTRODUCTION

It is difficult to solve the inverse problem in magnetoencephalography (MEG) and electroencephalography (EEG) because of the complexity of electrical sources and inhomogeneities of electrical conductivities in the human head. We have investigated the influence of inhomogeneous regions in the human head on surface magnetic fields.[1–5] We have also investigated spatial patterns of magnetic fields produced by multiple dipoles.[6,7] MEG measurements have an advantage over EEG techniques in that the underlying neural source in the brain is localized. The conventional methods used to address the inverse problem have been concerned with estimation of positions and orientations of current sources which were modeled as a small number of dipoles. These inverse problems are solved using magnetic and electric signals at a fixed time. However, the neural sources in the brain are intricate in construction and electrical activities of neural sources change by the moment. There are many cases that cannot conform to the simple dipole model, such as single-current dipole or two-current dipoles.

Recently it became possible to measure magnetic fields at many points of the head simultaneously using the multichannel superconducting quantum interference device (SQUID) system. Multichannel SQUID measurements have revealed that sources of the N100 component of auditory evoked magnetic fields are represented by moving dipoles.[8,9]

It is important to consider spatially distributed multiple dipoles as the sources of magnetic fields.

This study is focused on the influence of spreading dipoles upon spatio-temporal magnetic fields. Sources of electrical activity in the human brain are assumed as multiple traveling dipoles. Using this source model, spatio-temporal patterns of magnetic fields are simulated. The computer simulation shows that the spread of the source and conduction velocity of traveling dipoles have significant effects upon the wave forms and amplitude of magnetic fields.

MODELS AND METHODS

The human head is assumed to be a homogeneous spherical volume conductor with 0.1 m radius. We assume that sources of MEG activity are diffused in the brain. The source area is represented by a square with 20 mm sides. This dipole layer exists under the vertex and orients perpendicular to the surface of the sphere. 10 000 current dipoles are arrayed in a lattice in the dipole layer. All dipoles orient perpendicular to the dipole layer. Each dipole has a time-dependent dipole moment. It is assumed that the dipole moment changes sinusoidally. The excitation of the adjacent cortical neuron propagates in the source area. The propagation of excitation is represented by the propagation of change of dipole moment. Magnetic fields are reflected by the spatio-temporal summation of these dipole activities. Figure 1 shows a schema of the propagation of the excitation of cortical neurons. The time-dependent dipole moment of the exciting dipole moves to the next dipole after a slight time lag. Figure 2 shows the head model and the dipole layer.

Magnetic field components perpendicular to the surface of the sphere are calculated by Biot–Savart low.

RESULTS AND DISCUSSION

Figure 3 shows the wave forms of magnetic fields generated by multiple dipoles that move in the dipole layer, and the wave forms generated by a fixed dipole that locates at the center of the dipole layer. The magnetic fields generated by a single dipole show the same pattern as the change of dipole moment, whereas the magnetic fields generated by multiple dipoles have various patterns which are different according to the measurement points. In particular, the peak latency varies with the measurement point. The delay of the latency is noticeable in the points away from the source area.

Figure 4 shows the distributions of the latency at the peak of the N pole of magnetic fields on the surface of the sphere. That is, the contour lines show the arrival time of the peak of magnetic fields. The depth of the dipole layer from the surface of the sphere is changed at 20, 50, and 70 mm. The contour of the latency is quantized by eight levels in the map. The patterns of distributions of peak latency vary in the positions of dipole layer. When the dipole layer is located deeper in the head, a widespread region is influenced in latency.

Figure 5 shows the change of wave forms of magnetic fields at the point C3 when the direction of traveling dipoles changes from the horizontal direction (along Y axis) to the vertical direction (along z axis). The peak of the wave forms occurs at an earlier time when the direction of traveling dipoles changes from horizontal to vertical.

Figure 6 shows the effects of conduction velocity of propagation of excitation in the source area. In this simulation, it is assumed that each dipole moment changes in 10 ms and the peak of the dipole moment is 3.0×10^{-13} A m. The length of the dipole layer is 10 mm. The dipole layer is located 50 mm under the vertex. Conduction velocity of traveling dipoles in dipole layer varies in six cases (1.25, 2.5, 5, 10, 20, and 40 mm/ms). These results show that wave forms and the amplitude of magnetic fields are remarkably different when the conduction velocity of traveling dipoles change. When the dipoles travel slowly, the amplitude of the magnetic field is small and the wave form shows a trapezoidal pattern. The amplitude of peak magnetic field is about 25 fT (2.5×10^{-14} T). The peak of wave forms becomes sharp as the conduction velocity increases. When the conduction velocity is 40 mm/ms, the amplitude of peak magnetic field is about 300 fT. These phenomena can be explained by the assumption that many dipoles in a wide area excite at the same time when the conduction velocity is fast. In contrast, when the conduction velocity is slow, the number of dipoles

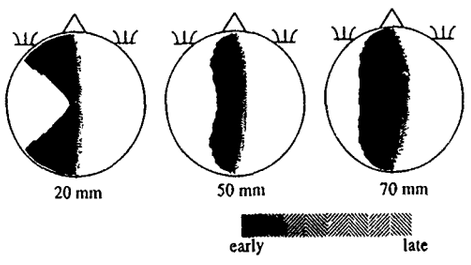

FIG. 4. Distributions of the latency of peak magnetic fields on the surface of the sphere. The depth of the dipole layer from the surface of the sphere is changed to 20, 50, and 70 mm.

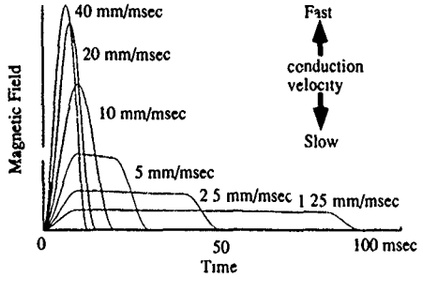

FIG. 6. The effects of conduction velocity of propagation of excitation. Conduction velocity of multiple dipoles in the source layer varies in six steps from 1.25 to 40 mm/ms.

excited at the same time is small and the excited region propagates slowly.

These simulated results suggest that it is possible to estimate the spreading area of the cortical excitation and conduction velocity of the propagation by using the spatio-temporal pattern of magnetic fields, in particular, peak latency, wave form, and amplitude. When both spatial and temporal distributions of the magnetic fields are considered in the inverse problem of MEG activities, the electrical activity in the brain can be estimated dynamically.

Magnetite coating prepared by ferrite plating on expanded polytetrafluoroethylene membrane for medical use

Q. Zhang, T. Itoh, and M. Abe
Department of Physical Electronics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152, Japan

As the first step to the study of increasing biocompatibility of expanded polytetrafluoroethylene (EPTFE) membranes, cardiovascular patches of EPTFE substrates were coated with Fe_3O_4 layer, which is expected to accelerate proliferation of endothelial cells. The ferrite layers were formed by the thin liquid film ferrite plating method at T=75–90 °C and pH (in oxidizing solution)=6.9–7.4. At a fixed pH value, a single-phase Fe_3O_4 layer is obtained when T is higher than a threshold temperature, which increases with an increasing pH value; below the threshold temperature, the layer has an impurity phase of γ-FeOOH. The obtained Fe_3O_4 layers are polycrystalline with no preferred orientation, having magnetization and coercive force which agree with those reported for bulk samples.

I. INTRODUCTION

Ferrite plating facilitates the formation of crystalline films of spinel ferrites, $M_xFe_{3-x}O_4$, containing various transition metals M=Ni, Co, Zn, Mn, Cr, etc.[1–3] Although prepared at low temperatures (<100 °C), the magnetic and electrical properties of ferrite-plated films are as good as those of the films prepared at high temperatures by conventional techniques (e.g., sputting, pyrolysis). This opens the door to fabricating ferrite film devices using as substrates nonheat-resistant materials such as plastics and biomaterials. Furthermore, ferrite films prepared by ferrite plating from aqueous solution are strongly compatible with water and organic compounds.

Thus the ferrite-plated films have found novel applications to biomedical use. Fe_3O_4 films prepared by ferrite plating have been used as glucose (or urea) sensor electrodes, in which urease (or GOD), an enzyme decomposing glucose (or urea), is fixed on the film surface mediated by dextran (a saccharose).[4] Polymer microspheres coated by ferrite plating have been used as carriers for a clinical enzyme immunoassay,[5,6] in which antibodies are fixed on the ferrite layer. This novel type of enzyme immunoassay (CA19-9, CA125, etc., Fujirebio Inc.) is already on the market and is being used clinically as cancer markers.

It has been suggested that an artificial blood vessel improves in performance if its inner wall is coated with a ferromagnetic layer. This is because the leakage flux from the magnetic layer accelerates the proliferation of endothelial cells, which enhances the biocompatibility of the artificial vessel wall, preventing thrombi (blood clots) from sticking onto the wall.[7,8] This idea was applied in an animal experiment in which magnetic flux was applied to the inner wall of an artificial blood vessel (embedded in the body of a living dog) by a ferromagnetic metal tape which surrounded the vessel. The results revealed that the endothelial reorganization on the surface of the vessel surrounded by the magnetic tape was enhanced significantly as compared to that obtained on a control (a vessel not surrounded by the magnetic tape). To realize this idea ultimately in a clinical environment, we must coat the inner wall of an artificial vessel with a ferrite layer (a metal layer is unsuitable because it is toxic to a living body) at low temperatures, because artificial blood vessels are made of a polymer which lacks heat resistance. Conventional ferrite film preparation techniques (e.g., sputtering, pyrolysis, etc.) require heating of substrate at above several 100 °C for crystallization of ferrite, and also they are inadequate to deposite ferrite film on inner wall of a tube, especially when it is long. Ferrite plating, on the other hand, can easily coat the inner wall of a long tube by flowing the aqueous solution inside the tube at low temperature.

Current artificial blood vessels are made of extended polytetrafluoroethylene (EPTFE). As the first step to the study of the ferrite-inner-wall-coated artificial vessel, a magnetite (Fe_3O_4) layer is deposited by the ferrite plating method on substrates of EPTFE patches.

In this paper we describe the conditions for which Fe_3O_4 layer is successfully deposited on the EPTFE patch, and report the structural and magnetic properties of the ferrite layer.

II. EXPERIMENT AND RESULTS

By the thin liquid film method[9] Fe_3O_4 layers were deposited at 75–90 °C on substrates (1.5×1.0×0.6 mm^3) of an EPTFE patch [a cardiovascular patch (GORE-TEX, PC06)]. Prior to plating, the substrates were exposed to a rf-excited oxygen plasma (frequency: 13.56 MHz, power: 30 W, pres-

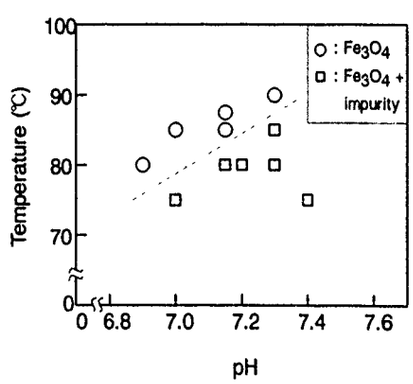

FIG. 1. Phase diagram of ferrite layers formed at various temperatures and pH values.

sure: 0.2 Torr) for 1 min to increase the wettability of the surface.[10] A reaction solution of $FeCl_2$ (3 g/l, pH=6.8) and an oxidizing solution were conducted for about 1 h through a gap (~1.0 mm) between substrate surface and glass cell wall.

The crystallographic phase, morphology, and magnetic properties of the plated layers were examined by a Cu $K\alpha$ x-ray diffractometer, a scanning electron microscope (SEM), and a vibrating sample magnetometer (VSM) at room temperature. The chemical composition of the ferrite layers was analyzed with an inductively coupled plasma (ICP) spectroscope, after dissolving the ferrite films in a 50% HCl solution. The thickness of the layer was calculated from the results of the chemical analysis assuming that the density of the layer is the same as that of a bulk sample.

Figure 1 shows a phase diagram of the layers deposited at various temperatures and pH values. Single-phase spinel (Fe_3O_4) type layers grow only when the temperature is higher than threshold temperature shown by a dashed line in the figure. The threshold temperature increases linearly with increasing pH value. Below the threshold temperature line, the impurity phase of γ-FeOOH appears in x-ray diffraction diagram, as shown in Fig. 2. This is consistent with the known fact that, in ferrite plating of Fe_3O_4, γ-FeOOH is synthesized as a precursor from which Fe_3O_4 is produced.[11] The Fe_3O_4 layers are polycrystalline having no crystallographic orientation.

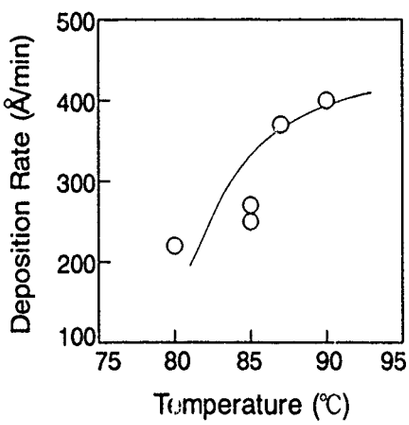

FIG. 3. Deposition rate of Fe_3O_4 layer plotted as a function of synthesizing temperature.

Figure 3 shows the deposition rate of the single-phase Fe_3O_4 layer plotted as a function of temperature. The rate increases with temperature, from ~200 Å/min at 80 °C to ~400 Å/min at 90 °C. These values agree with those obtained for Fe_3O_4 plating on substrates of continuous media [e.g., glass, polyethlanetelephthalate (PET), etc.].

Figure 4 shows SEM photographs for the EPTFE patch substrate and the layers deposited on it at various temperatures and pH values. The substrate [Fig. 4(a)] has a web structure of PTFE fibers with various thicknesses. The ferrite layer of single-phase Fe_3O_4 [Fig. 4(d)] forms a continuous layer on the porous substrate surface, while the layers with impurity phase [Figs. 4(b) and 4(c)] are discontinuous and porous with acicular or angular grains.

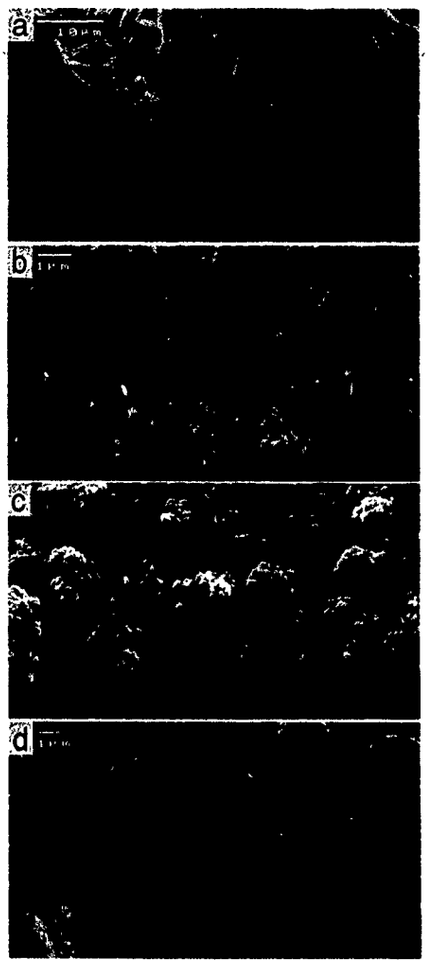

FIG. 4. SEM observations on (a) EPTFE patch substrate and ferrite layers formed on the EPTFE substrate at (b) T=75 °C, pH=7.0, (c) T=80 °C, pH=7.2, and (d) T=87 °C, pH=7.15.

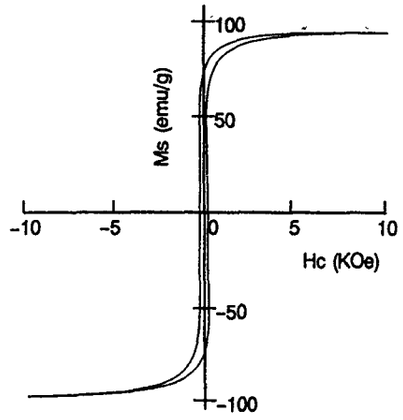

FIG. 5. Magnetization curve for a single-phase Fe_3O_4 layer (deposited at T=87 °C, pH=7.15), obtained applying external field parallel to layer plane.

A typical example of a magnetization curve for these specimens is shown in Fig. 5. Ferrite layers of single-phase Fe_3O_4 have magnetization of about 80–90 emu/g and coercive force of about 40–70 Oe, which agree with those reported for bulk samples of Fe_3O_4.

III. CONCLUSIONS

By using the thin liquid film method, iron monooxide layers were successfully deposited on EPTFE patches at various temperatures and pH values of oxidizing solution. For a fixed pH value, a threshold temperature exists, above which single-phase Fe_3O_4 layer is obtained. Below the threshold temperature, the layer has an impurity phase of γ-FeOOH, the precursor from which Fe_3O_4 is produced in ferrite plating. The Fe_3O_4 layers are polycrystalline with no crystallographic preferred orientation, and have magnetic properties which agree with those of bulk sample of Fe_3O_4. Biocompatibility of the Fe_3O_4 layers will be examined in future investigations.

Redistribution of dissolved oxygen concentration under magnetic fields up to 8 T

S. Ueno, M. Iwasaka, and T. Kitajima
Biomagnetics and Biosystems Laboratory, Department of Computer Science and Communication Engineering, Faculty of Engineering, Kyushu University, Fukuoka 812, Japan

The influence of static magnetic fields on the behavior of oxygen dissolved in an aqueous solution was studied in order to clarify the interaction mechanism of dynamic movements of dissolved oxygen with magnetic fields and to broaden the basic understanding of biological effects of magnetic fields. A horizontal type of superconducting magnet with a bore 100 mm in diameter was used. A cylindrical chamber filled with distilled water was exposed to magnetic fields up to 8 T and a gradient of 50 T/m. The spatial distribution of oxygen concentration dissolved in water was measured by a dissolved oxygen meter. A clear redistribution of oxygen concentration was observed, and the dissolved oxygen concentration increased more than 10% around the center of the magnet.

I. INTRODUCTION

It is an interesting problem for human beings whether or not magnetic fields have any influence on the life processes in living systems. Numerous investigations of magnetic field effects on biological systems have been reported.[1–4] However, the biological effects of static magnetic fields have not yet been clarified. Among several reviews and papers, the importance of the role of oxygen has been suggested by Aceto, Tobias, and Silver.[3]

Since oxygen is a paramagnetic molecule, recognition of a paramagnetic component has been emphasized in unravelling the underlying mechanisms in magnetic field effects on life processes. In spite of the importance of the topic, no experiment has been carried out to determine quantitative relationships between the intensity of dc magnetic fields and the behavior of oxygen gas dissolved in aqueous solution.

In our previously reported experiment using an electromagnet with 1.0 T and the gradient of 10 T/m, redistribution of dissolved oxygen was observed during oxygen desorption and absorption processes, but no redistribution of dissolved oxygen was observed in an equilibratory state of oxygen pressure.[5]

The effect of magnetic fields produced by a permanent magnet on oxygen dissolved in saline solution has also been studied by a Russian group.[6]

In relation to oxygen dynamics in water, we observed oxygen dynamics in air. We have observed the phenomenon that candle flames are pressed down by magnetic fields.[7] We have also observed the phenomenon that flow patterns of gases are influenced by magnetic fields.[8] A model called a magnetic curtain has been introduced to explain these phenomena.[8,9] The magnetic curtain is an invisible barrier which is produced in air by the interaction between magnetic fields and paramagnetic oxygen molecules. We have demonstrated that candle flames are extinguished by the magnetic fields.[10] The interception of oxygen by the magnetic curtain extinguishes flames. To explain the mechanism of magnetic curtain, a collision model has been simulated, introducing a technique of molecular dynamics.[11] We observed the oxygen concentration in air by a manometer, however, the oxygen concentration was not influenced.

The purpose of this paper is to investigate the influence of intense magnetic fields up to 8 T on oxygen gas dissolved in water. An experiment was carried out to determine the relationship between the applied magnetic field and spatial distributions of oxygen concentration in water. A definite redistribution of oxygen concentration was realized by magnetic fields with 8 T and the gradient of 50 T/m.

II. METHOD

The experimental setup is shown in Fig. 1. We used a horizontal type of superconducting magnet with a bore 100 mm in diameter and 700 mm long as shown in Fig. 2. It produces strong magnetic fields up to 8 T and the gradient of 50 T/m. When the magnet produces 8 T at its center, the maximum product of the magnetic field and the gradient is 400 T^2/m at $z=\pm 75$ mm, where the z axis is directed to the bore axis.

An acrylic cylindrical water chamber (30 mm in diameter, 620 mm long) was filled 100% with distilled water. The

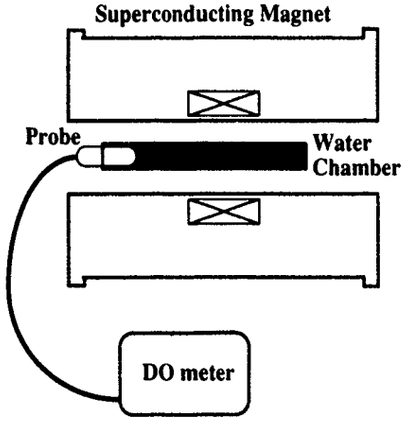

FIG. 1. Experimental setup. A horizontal type of superconducting magnet with a bore 100 mm in diameter produced magnetic fields up to 8 T. An acrylic chamber filled with distilled water was inserted into the bore of the magnet. The water chamber was exposed to magnetic fields, and the oxygen concentration was measured by a dissolved-oxygen (DO) meter.

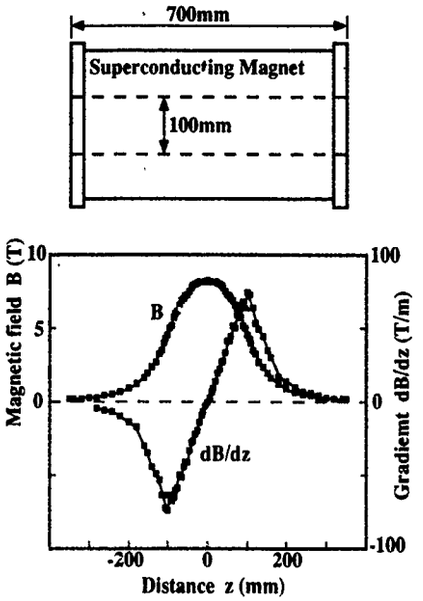

FIG. 2. The shape of the superconducting magnet and magnetic field B, and the gradient of magnetic field with respect to the bore axis, or z axis dB/dz.

dissolved oxygen concentration was controlled by introducing oxygen gases into the distilled water.

The cylindrical chamber was inserted into the bore, and the dissolved oxygen concentration was measured by a dissolved-oxygen meter (DO meter). The probe of the DO meter was fixed at the edge of the chamber. The chamber was moved together with the probe in the direction of bore of the magnet.

III. RESULTS AND DISCUSSION

The effect of an 8 T magnetic field on dissolved oxygen concentration is shown in Fig. 3. The probe fixed at the cylindrical chamber was inserted into the center of the magnet from the edge of the bore, the probe always looked toward the center of the magnet. Before the cylindrical chamber was inserted into the bore, the dissolved oxygen concentration in an equilibratory state was 7.8 mg/l at 25 °C. The chamber

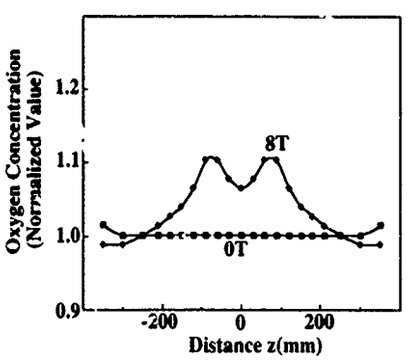

FIG. 3. Spatial distribution of oxygen concentration in water. The chamber was inserted into the center of the magnet from the edge. The probe of the DO meter always looked toward the center of the magnet.

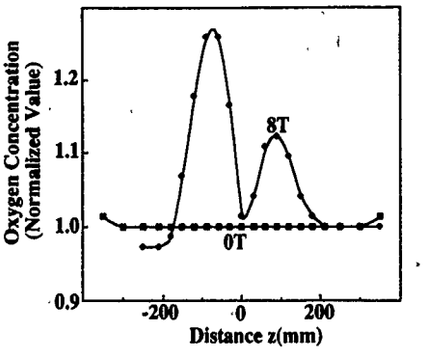

FIG. 4. Spatial distribution of oxygen concentration in water. The chamber was passed through the bore. The probe of the DO meter looked toward the edge of the bore after the probe passed through the magnet's center.

was exposed to 8 T magnetic fields. At the edge of the superconducting magnet, the dissolved oxygen concentration slightly decreased to 7.7 mg/l. The dissolved oxygen concentration gradually increased to 8.6 mg/l at $z=\pm 60$ mm, and 8.3 mg/l in the center of the magnet. The data in Fig. 3 were normalized by the value in an equilibratory state, i.e., 7.8 mg/l.

We also measured the oxygen concentration in a different procedure. The results are shown in Fig. 4. The probe was passed through the bore from one edge to the other. Before the probe passed through the center of the magnet, it detected increased oxygen concentration. When the probe passed through the center of the magnet, it detected an even higher oxygen concentration.

Because oxygen molecules were attracted toward the center of the magnet, the probe of the DO meter sensed more oxygen molecules when the head of the probe looked toward the edge of magnet's bore.

To observe more clearly the redistributions of oxygen concentration by gradient magnetic field, we introduced oxygen gases into the distilled water so that the oxygen concentration was saturated. The results are shown in Fig. 5. Compared to the distilled water, the oxygen concentration of the oxygen-bubbled water (oxygen introduced into the distilled water) in the center of the magnet increased about 20%. The

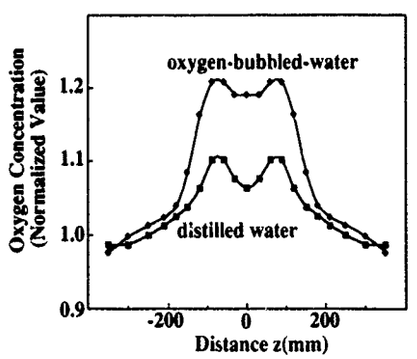

FIG 5. Spatial distribution of oxygen concentration in water (comparing distilled water to oxygen-bubbled water).

results obtained show that the magnetic force affects dissolved oxygen in water.

In the present study we used a superconducting magnet which produced strong magnetic fields up to 8 T and a gradient of 50 T/m, and the magnetic force of 400 T^2/m was strong enough to act on the movement of oxygen molecules dissolved in water.

Properties of diamagnetic fluid in high gradient magnetic fields

S. Ueno and M. Iwasaka
Biomagnetics and Biosystems Laboratory, Department of Computer Science and Communication Engineering, Kyushu University, Fukuoka 812, Japan

This study focuses on the properties of diamagnetic fluid in static magnetic fields up to 8 T with the gradient of 50 T/m. We used a horizontal type of superconducting magnet with a bore 100 mm in diameter and 700 mm long. We observed the phenomenon that the surface of the water was pushed back by magnetic fields of higher gradients. Two "frozen" cascades were formed at $z=\pm 50-80$ mm; the surface of the water near the center of the magnet was parted, and the bottom of the water chamber appeared. The water level at both ends of the chamber was lifted up. In order to investigate the hydrodynamics of diamagnetic fluid in magnetic fields, we made a fluidic circuit with plastic tubing which passed through the superconducting magnet's bore. When magnetic fields in the center of the bore were changed from 0 to 8 T, the flow velocity of distilled water decreased, and the flow was stopped at 8 T. A stress analysis of diamagnetic fluid in magnetic fields was carried out to explain the mechanism of these phenomena. The hydrodynamics of diamagnetic fluid in $\sim 400\ T^2/m$ is able to compare with that of ferromagnetic fluid in weak magnetic fields. Studying the role of diamagnetic fluid in gradient magnetic fields is important in understanding the mechanism of biological effects of magnetic fields.

I. INTRODUCTION

Water, which is a diamagnetic material, is one of the most general and abundant diamagnetic fluids. It is an interesting problem for the human being whether or not magnetic fields have any influence on water. Diamagnetic water is often used for calibration and correction in determining magnetic susceptibilities of materials by the magnetic balance systems.

However, little has been observed about the hydrodynamic behavior of water, or diamagnetic fluid, in horizontal magnetic fields of 100–1000 T^2/m order.

In this paper, we investigate the dynamic behavior of water in high gradient magnetic fields, using a horizontal type of superconducting magnet, which produces magnetic fields up to 8 T. We carry out a stress analysis of a diamagnetic fluid in high gradient magnetic fields. Furthermore, we show a model experiment for effects of magnetic fields on water flow.

II. METHODS

A. Magnetic fields exposure system

We used a horizontal type of superconducting magnet with a bore 100 mm in diameter and 700 mm long. When the magnet produced 8 T at its center, the maximum product of the magnetic field and the gradient was 400 T^2/m at $z=\pm 75$ mm, where the z axis was directed to the bore axis. A distribution of magnetic fields is shown in Fig. 1.

B. Water chamber

A water chamber, 50 mm wide, 23 mm high, and 700 mm long was filled 50% with distilled water, which is a diamagnetic material. The water chamber was inserted into the bore of the magnet.

C. Hydrodynamic experiments

In order to investigate the hydrodynamics of diamagnetic fluid in magnetic fields, we formed a fluidic circuit with plastic tubing which passed through the superconducting magnet's bore as shown in Fig. 2. We used a plastic tubing made of vinyl chloride with 8 mm in inner diameter. Distilled water ran in the tube along the z axis of the magnet's bore. Changes of flow velocities were measured by a flow meter. The tubing was hard enough to eliminate contributions of any stress induced changes in the plastic tubing.

To investigate the effects of dissolved oxygen on the flow of diamagnetic fluid, oxygen gas was bubbled into distilled water, and the flow velocities were measured.

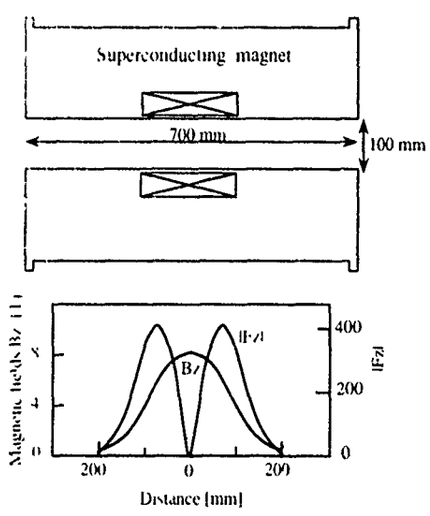

FIG. 1. Horizontal superconducting magnet and the distributions of magnetic fields. F_z is the product of magnetic fields and gradient.

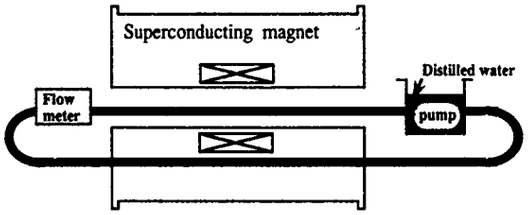

FIG. 2. Experimental setup for water flow experiment with a fluidic circuit with plastic tubing which is passed through the superconducting magnet's bore.

III. RESULTS AND DISCUSSION

A. Behavior of water in magnetic fields

When the water chamber was inserted into the bore of the magnet, we observed the phenomenon that the surface of the water was pushed back by magnetic fields of higher gradients. Two "frozen" cascades were formed at $z=\pm 50-80$ mm as shown in Fig. 3; the surface of the water near the center of the magnet was parted, and the bottom of the water chamber appeared. The water level at both ends of the chamber was lifted up.

We also realized the "frozen" cascades with agarose gel. The agarose solution was coagulated into a gel state in the superconducting magnet. Figure 4 shows that the surface of the agarose gel was formed in the same manner as in the water experiment.

A stress analysis was carried out to explain the mechanism of the formation of the "frozen" cascades.

The stress tensor of a diamagnetic fluid (in indicial notation) is given by

$$\mathbf{T}^m_{ij}n_j=(p^m+\mu_0H^2/2+\mu_0MH/2)n_i, \tag{1}$$

$$p^m=-\mu_0MH/2+\mu_0\int_0^H M\ dH-\rho gz+\text{const}, \tag{2}$$

where $\mathbf{n}=(n_i,n_j,n_k)$ is a unit vector that is perpendicular to the water surface, p^m is the static fluid pressure, μ_0 is the magnetic permeability, ρ is mass per unit volume, g is gravitational constant, M is the magnetization of diamagnetic fluid, and H is a magnetic field.[1]

On the other hand, the stress tensor that is outside of the diamagnetic fluid is given by

$$\mathbf{T}^0_{ij}n_j=-(p^0+\mu_0H^2/2)n_i, \tag{3}$$

where p^0 is the environmental pressure.

On the surface of the "frozen" cascades, $\mathbf{T}^m_{ij}n_j$ equal to $\mathbf{T}^0_{ij}n_j$.

Equations (1), (2), and (3) can be combined to give

$$z=h=(\mu_0/\rho g)\int_0^H M\ dH=\chi_m\mu_0H^2/2\rho g. \tag{4}$$

The distribution of h given by Eq. (4) is shown in Fig. 5. It seems that the curve in Fig. 5 corresponds to the surface lines of the "frozen" cascades. The behavior of water in

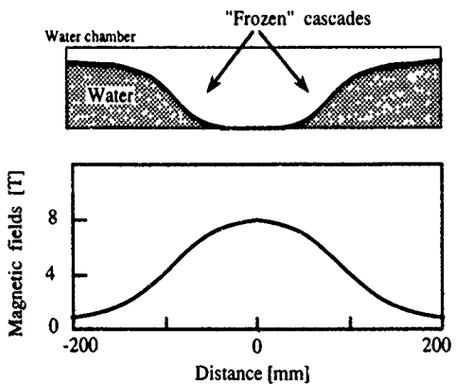

FIG. 3. An illustration of "frozen cascades" of water in gradient magnetic fields up to 8 T.

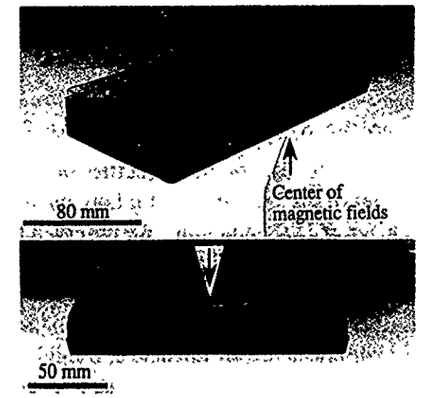

FIG. 4. A photograph of "frozen cascades" of agarose gel that formed in magnetic fields up to 8 T.

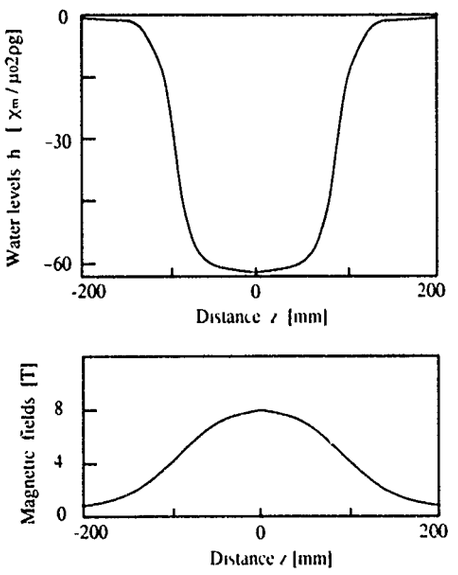

FIG. 5. Formation of "frozen cascades" of diamagnetic fluids. The curve is obtained by stress analysis.

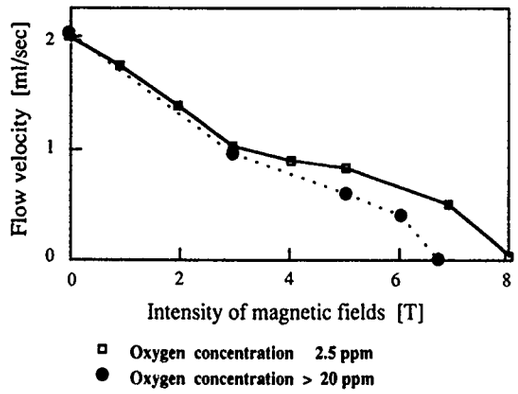

FIG. 6. Effects of magnetic fields up to 8 T on water flow.

horizontal high gradient magnetic fields and the formation of "frozen" cascades are understood by this stress analysis.

In reference to the properties of diamagnetic materials in vertical magnetic fields, there is a report about a numerical analysis of the necessary conditions for magnetic levitation of diamagnetic particles.[2]

B. Hydrodynamic experiments

Figure 6 shows the results of an experiment of water flow in magnetic fields. When magnetic fields in the center of the bore were changed from 0 to 8 T, the flow velocity of distilled water (2.0 ml/s, 18 mm/s) decreased and the flow was stopped at 8 T.

To investigate the effects of paramagnetic molecules, or dissolved oxygen, on the flow of diamagnetic fluid, oxygen gas was bubbled into distilled water. Changes of flow velocity resulting from the interaction of paramagnetic and diamagnetic materials with magnetic fields were observed. As shown in Fig. 6, the result was that flow velocity decreased compared to that of fluid without dissolved oxygen.

The flow of distilled water containing dissolved oxygen (2.0 ml/s, 18 mm/s) was stopped when the magnetic field in the center of the bore was 6 T. These results show that flow of diamagnetic fluid is controlled by 8 T magnetic fields.

IV. CONCLUSION

We have observed the phenomenon that diamagnetic fluid, such as water, behaves dynamically in high gradient magnetic fields of up to 8 T and 50 T/m. The hydrodynamics of diamagnetic fluid in ~400 T^2/m is able to compare with that of ferromagnetic fluid in weak magnetic fields.

Using a horizontal type of superconducting magnet with high gradient fields allowed us to observe a phenomenon; the surface of the water near the center of the magnet was parted, and the bottom of the water chamber appeared.

We also have shown experimental results that indicate a possibility in flow control of diamagnetic fluid by magnetic fields of up to 8 T and 50 T/m.

These results indicate that when a living body is exposed to magnetic fields of 100–500 T^2/m order, diamagnetic liquids such as water in tissues are affected by magnetic forces. Remarkable effects of high gradient magnetic fields are expected in blood circulation, cerebral spinal fluid system, and other intracellular and extracellular solutions.

Studying the role of diamagnetic fluid in gradient magnetic fields is important in understanding the mechanism of biological effects of magnetic fields. The phenomena observed in the present experiments will provide a new aspect to applied physics and biomagnetics.

Influence of ultraworking frequency alternating weaking magnetic field on the microvasculture of mice (abstract)

Ningjiang Yang[a)]
Department of Pathology, 465th Air Force Hospital, Jilin City 132011, China

Changmin Zhang[b)]
Department of Physiotherapy, 465th Air Force Hospital, Jilin City 132011, China

The physical effect produced by the ultraworking frequency alternating weaking magnetic field (UWFAWM) is demagnetization. We used two methods to study the influence of UWFAWM on the microvasculture of Kunmin mice. Method 1 (in vivo) included 21 mice (the experimental group 11 and the control group 10). Method 2 (in vitro) included 25 mice (the experimental group 13, the control group 12). Each group was put in the coil of the JDM-1 Type Demagnetometer which produced UWFAWM. The coil was electrified for the experimental groups, but not for the control groups, for 20 min, once a day. (1) Method 1. On the 10th day of demagnetization, the surface microvascultural diameters of liver and mesenterium were measured in two groups.[1] The results showed that those in the experimental group (25.05 ± 3.92 μm and 24.44 ± 4.7 μm, respectively) were markedly greater than those in the control group (10.70 ± 1.72 μm and 18.37 ± 1.93 μm, respectively. (2) Method 2. On the 40th day of demagnetizing, we killed all mice and immediately preserved the brain, heart, lung, liver, kidney, stomach, intestine, and submandibular gland in 10% formalin, then used continuous paraffin sections of 5 μm and HE stain, and measured the microvascular diameter of each group.[2] The results showed that mean diameters of the organs in the experimental group were also significantly greater than those in the control group ($p<0.01$). This study confirms that UWFAWM can dilate the microvascultures of various organs, resulting in local aterial hyperemia of the organ, advance local tissue metabolism, and an increase in organic function, thus providing a basis for treating some diseases and for health care.

Enzymatic oxidation-reduction processes under magnetic fields up to 8 T (abstract)

M. Iwasaka and S. Ueno
Department of Computer Science and Communication Engineering, Biomagnetics and Biosystems Laboratory, Faculty of Engineering, Kyushu University, Fukuoka 812, Japan

The question of whether magnetic fields affect enzymatic activities or not is of considerable interest in biochemistry and in biomagnetics. Xanthine oxidase, contained in liver, lungs, intestine, and other organs, catalyzes the degradation of hypoxanthine to xanthine, and xanthine to uric acid, which is the terminal waste of purine nucleotides in mammals. During the oxidation of xanthine, the enzyme releases superoxide anion radicals as intermediates which reduce ferricytochrome *c* (Fe^{3+}). Superoxide anion, as well as any type of free radical, is also paramagnetic. The study is focused on whether these magnetically related enzymatic activities can be affected by magnetic fields. There is a possibility that free radicals, as intermediates, can be modified by magnetic fields of specific intensities. In our previously reported study, we examined a possible effect of magnetic fields up to 1.0 T on biochemical reaction catalyzed by xanthine oxidase, and obtained negative results.[1] In the present abstract, we examine the effect of magnetic fields up to 8 T on this oxidation-reduction process. Reduced cytochrome *c* (Fe^{2+}) has an absorption maximum at 550 nm which can be detected by a spectrophotometer. Xanthine oxidase was assayed by superoxide dismutase—inhibitable reduction of cytochrome *c*. We measured optical absorbance of reduced cytochrome *c* by superoxide anion which was produced by the reaction catalyzed by xanthine oxidase. The absorbances of the mixture exposed to an 8 T magnetic field at 25 °C were higher than control samples in the re-oxidation proces of cytochrome *c*. The results show that the 8 T magnetic fields altered the rate of reduction of cytochrome *c* by superoxide anion which was produced by the reaction catalyzed by xanthine oxidase. It may conclude that the electron transfer from xanthine to molecular oxygen or the transfer from superoxide anion to cytochrome *c*, can be affected by the magnetic fields up to 8 T.

Induction of mutations by magnetic field for the improvement of sunflower (abstract)

V. Kiranmai
Cytogenetics and Tissue Culture Lab., Dept. of Botany, Osmania University, Hyderabad 500 007, A.P., India

Mutagenic effect of magnetic field was studied in two varieties of *Helianthus annus* L. var. S.S.56 and CO-2. Dry seeds of both the varieties were exposed to 1000, 2000, and 3000 G of magnetic field for over 90 min. The parameters screened were germination percentage, plant height, days to flowering, days to maturity, and yield of the plant. The mutants obtained were tall mutant, dwarf mutant, early flowering mutant, branched mutant, bold seeded mutant, and stripped seed mutant. The mutants were screened for biochemical analysis. Oil content and fatty acid analysis of the seeds were done by NMR and GLC techniques, respectively. Quantitative and qualitative analysis of the proteins in leaf and seeds were done for all the mutants obtained, along with the electrophoretic studies among the three doses studied, 2000 G was found to produce positive mutations in both varieties of sunflower.

The magnetic transformation of iron hydroxides under the action of micro-organism (Azotobacter vinelandii) (abstract)

Nadezda V. Verkhovtseva
State University, Yaroslavl, Russia

Irina V. Shpilkina
Polytechnical Institute, Yaroslavl, Russia

Vyacheslav F. Babanin
Polytechnical Institute, Yaroslavl, Russia

To analyze the action of Azotobacter vinellandii intact cells on synthetic high-dispersed iron hydroxides, Mössbauer spectroscopy and magnetic measurements were used for different conditions: for the nitrogen-free medium and for the NH-containing medium. The preparations of Azotobacter vinelandii obtained on the nitrogren-free medium with decreased acidity is characterized by relatively high contents of paramagnetic combinations ($\chi_{par}=(6.6...31.4)\times10^{-6}$ sm^3/g, $I_{sat}=(0.12...0.73)\times10^{-3}$ at 12 day cultivations, $\chi_{par}=(8.1...23.2)\times10^{-6}$ sm^3/g, $I_{sat}=(0.07-0.93)\times10^{-3}$ at 35 day cultivation). The quantity of magnetic ordered combinations in these samples is greater than 1.5–7 times that in bacteria at pH=7. The paramagnetic attributes of samples in the medium with NH is decreased more in 12 day culture (up to 50% compare to nitrogen-free variation) then in 35 day culture (up to 20%). The presence of doublets in Mössbauer spectra at different conditions (room temperature in damp, air-dry states, and frozen at the 100 K state) and strong differences in probability of sorption of Mössbauer radiation of damp preparations allow us to conclude that magnetic ordered combinations in the type of crystallines with particle size <10 nm are present in the composition of preparations. It is found from magnetic measurements that at pH<7 the paramagnetic component of susceptibility and magnetic saturation is high. At pH=7 the most intensive decrease of susceptibility and magnetic saturation is medium with nitrogen and at large aeration.

Magnetic properties of heterotrophic bacteria (abstract)

Nadezda V. Verkhovceva and Irina N. Glebova
University of Yaroslavl, Yaroslavl, Russia

Anatoly V. Romanuk
Polytechnical Institute of Yaroslavl, Yaroslavl, Russia

The magnetic properties (magnetic susceptibility and saturation magnetization) of six species of heterotrophic bacteria were studied: alcaligenes faecalis 81, arthrobacter globiformis BKM 685, bacillus cereus 8, leptothrix pseudo-ochracea D-405, proteus vulgaris 14, and seliberia stellata. It has been shown that the magnetic properties of bacteria depend on (1) the peculiarity of the micro-organism (species-specific and connected with cultivation conditions); (2) the source of the iron in the media. Most of the bacteria are diamagnetic in media with a minimum of iron ($\chi_\infty=-7.2...3\times10^{-6}$ sm^3/g). The spore forming species (bacillus cereus) has increased diamagnetism. Usually the bacteria are paramagnetic in iron-containing media because they concentrate into Fe compounds. The paramagnetism of the iron-concentrating species (anthrobacter globiformis $-\chi_{par}=2.4\times10^{-6}$, leptothrix pseudo-ochtracea $\chi_{par}=11.0\times10^{-6}$ and seliberia stellata $\chi_{par}=3.2\times10^{-6}$ sm^3/g) depends, in general, on magnetically ordered compounds. Iron compounds not accumulated by proteus vulgaris and these species are always diamagnetic .

Spin-glass structures in biological systems (abstract)

Alexandre I. Tsapin and L. A. Blumenfeld
Institute of Chemical Physics, Kosygina Strasse 4, 117977, Moscow, Russia

We have discovered spin-glass structures in different biological systems like animal and plant tissues, cells, chloroplasts, mitochondria, etc. These structures were detected by the ESR method. This work has been done using a synchronous culture of yeasts, saccharomyces cer. To detect spin-glass structures in a biological system, the sample must be cooled in the presence of a strong magnetic field, from 77 to 10 K. After such cooling, we recorded the ESR signal at g factor about 3.0 caused by spin-glass structures. The rotation of the sample at 10 K relative to the permanent magnetic field (always present in ESR experiments) leads to the significant change in the intensity of the ESR signal as well as in its shape. The curve of the dependence of the ESR signal intensity on the magnetic field in which the sample was cooled is S-shaped. The cooling of the same sample in zero magnetic field resulted in the absence of the ESR signal at g=3,0. It had been shown that the maximum ESR signal at g factor about 3,0 was reached 15 min before the beginning of mitosis. The study of the properties of the ESR signal at g=3,0 allowed us to make the conclusion that the paramagnetic centers responsible for this signal have been formed by Fe(II) ions localized at the chromosomes. Formed during mitosis, spin-glass structures which play a significant role in cell biology, can be detected only by the ESR method in field cooling experiments.

The testing of action of chemical extracts on soils by magnetic methods (abstract)

Vyacheslav F. Babanin, Irina V. Shpilkina, and Alexandr V. Ivanov
Yaroslavl Polytechnical Institute, Yaroslavl, Russia

The participation of soil iron in the formation of physics-chemical features in feed of plants and microorganisms is well known. Because of the active role of Fe in soil landscapes the Fe state is taken into account in investigations of the genesis of soils. In spite of a relatively high content of iron in soils up to 40%–45% (relative to Fe) its numerical forms are diagnosed in a complex way by Ronthgen diffractometry, differential thermal analysis, and microscopy. Thus, chemical extracts are widely used in soil science. Extracted Fe is considered to be of amorphous, strong or weak crystallized forms. These gradations are of wide use but they are not correct. This is established by some authors by means of magnetic measurements and Mössbauer spectroscopy [Jeanory *et al.*, Sci. Solids 135 (1986)] before and after magnetic separation and chemical extracts [Fine and Singer, Soil Sci. Soc. Am. J. **53**, 191 (1989)]. We used the measurements of magnetic susceptibility and saturation and nuclear gamma resonance for the usual soils and electron paramagnetic resonance for weak magnetic Fe containing minerals (before the extract). Our results are comparable with the above research and lead to the next conclusions: (1) ordered alternations of magnetic parameters and results of action of extracts are absent; (2) the Mehra–Jackson extract (sometimes the Tamm's extract) often extracts the crystallized magneticordered and paramagnetic silicate and superparamagnetic forms of Fe; (3) magnetic susceptibility and magnetic saturation increase in some types of soils (brown earth, ferralsol, alluvial soil) at dissolution of the alumosilicate part of soils because of enrichment by chemically strong particles of magnetite; (4) the conclusions on extracts (as far as crystallized silicate amorphous forms) do not have generalized characteristics.

The magnetic diagnostics of cosmic and industrial silt in humus horizons of soils (abstract)

Vyacheslav F. Babanin and Irina V. Shplkina
Polytechnical Institute, Yaroslavl, Russia

Sergei A. Shoba
Lomonosov University, Moscow

Alexander V. Ivanov
Polytechnical Institute, Yaroslavl, Russia

In the early 50s the increase of magnetic susceptibility in head horizons of soils has been observed. The reason was accepted to be forest and steppe fire. Later we discovered that the increasing of susceptibility and magnetic saturation was observed more clearly in the soils developed on weak magnetic native rock (loam, carbonate) and the magnetic fraction was separated from these soils in a more simple fashion. An abnormal increase in magnetic parameters is observed in primitive soils and the debris layer of dry forest (particularly of pine forest). The investigations have shown that magnetic particles (MP) are contained in ash of electrostations, in buried and modern soils, in humocoll and coal sheets, and in air of industrial cities and of the country. A high magnetic separated fraction (MV) contains particles (P) that differ by morphology and color. MF of soils is separated in a difficult manner from the rest mass (it also contains α-Fe, magnetite, hematite) and is contaminated by magnetic particles from native rock. We obtained that only spherical particles contribute to the soil magnetism from $(10...50)\times10^{-6}$ sm^3/g to $(100...150)\times10^{-6}$ sm^3/g. MP come into modern soils from all sources. Magnetic particles are well conserved in automorphic and nonlogging buried soils, and in humocoll layers. Among humocoll layers investigated by us there were layers dating over 50 thousand years ago.

Dislocation etching of flux grown strontium hexaferrite single crystals (abstract)

Urvashi Raina, Sushma Bhat, and P. N. Kotru
Department of Physics, University of Jammu, India

F. Licci
Istituto MASPEC-ONR, via Chiavari, Param 18/A, Italy

Hexagonal hard ferrites like $SrFe_{12}O_{19}$ are technically interesting materials not only because they are the traditional permanent magnets but also as emerging magnetic recording media and as potential magneto-optic devices. For these reasons the study of dislocations in these samples is quite significant. Flux grown single crystals of $SrFe_{12}O_{19}$ are etched in 37% HNO_3 at 100 °C and 85% H_3P_4 at 120 °C. These two etchants produce hexagonal pits on (001) planes that are established as dislocation etchants by performing the following experiments: (1) successive etching for prolonged periods resulting in persistent point bottomed etch pits at all the stages; (2) etching of matched (0001) cleavages in similar, as well as dissimilar, etchants which produce 1:1 corresponding point bottomed etch pits on a pair of the matched cleavages; (3) etching of low angle grain boundaries which consist of a grid of equally spaced edge dislocations. An equally spaced row of etch pits is obtained along the grain boundaries. Hexagonal etch pits with smooth sloping planes are normally produced. Among such pits, unusual etch pattern features including pits with rythmically and irrythmically spaced terracings, eccentric pits, small point bottomed pits within a large flat bottomed pit with differing geometrical centers, and flat bottomed pits with beaked centers, are obtained. Unusual deviations from the perfect match of etch patterns on certain matched (0001) cleavages are examined critically. It is thought that these unusual etch patterns are due to bending, branching, and stepping of dislocations. The terracing of pits is attributed to the segregation of impurities along dislocation lines.

Dipole-dipole interactions in $KEr(MoO_4)_2$ (abstract)

A. G. Anders, S. V. Volotskii, and O. E. Zubkov
B. I. Verkin Institute for Low Temperature Physics and Engineering, Ukrainian Academy of Science, Kharkov, Ukraine

The model of a dipole-dipole magnet previously developed[1,2] has applied to a $KEr(MoO_4)_2$ crystal with two paramagnetic ions in an orthorhombic unit cell. The erbium ion in the compound has a large anisotropy of an effective g tensor which, in turn, leads to Ising-like behavior in the magnetic subsystem. As had been done earlier,[2] we had calculated the dipole configuration with the lowest energy, thus obtaining the ground-state structure that would appear at the magnetic phase transition. This dipole structure consists of ferromagnetic chains aligned along the c axis and antiferromagnetically coupled along a and b axes. The results were compared with recently done measurements of magnetic moment and low-temperature magnetic susceptibility.[3] Calculated dipole ground energy E min$=-1.325$ K is in reasonable agreement with the experimental value of $T_n \simeq 0.9$ K. The obtained easy-axis direction along the c axis also agreed with experiment. The phase transition observed in crystal at $H \| c$ in our model results in a transition to a ferromagnetic structure with $H_{cr}=700$ Oe. The last agreed with measured $H_{cr}=800$ Oe so one should conclude that a pure dipole model could well describe the main features of $KEr(MoO_4)_2$. At the same time our model could not explain the other phase transition that took place at $H=1.5$ kOe$(H \| a)$. To understand this transition one probably should also consider a small anisotropic exchange interaction.

Database of magnetochemistry in solutions (abstract)

O. Ju. Tarasov and A. G. Vinogradov
Chemical Faculty, Kazan University, Kazan 420008, Russia

The database (DB) of magnetochemistry in solutions was created to systematize and to critically review data of the magnetic susceptibility of liquids, solutions, and substances in solutions. The database "MagChemSol 1.0" was made on a MFOXPLUS base and may be supported by DBASEIII PLUS or higher. Search fields include substances, solvent, condition and method of investigation, critical magnetochemistry characteristics, and references to literature. All material is printable and the database can change and expand itself. System requirements include IBM PC or compatible with 640 Kb of RAM, 5 in. and 3 in. diskette drive or hard-disk, and DOS 3.30 or higher; printers are Epson or compatible. The DB "MagChemSol 1.0" version includes about 1000 data entries according to the magnetochemical properties, the majority solvents in general use some diamagnetic and paramagnetic salts, and also the complex compounds of d and f elements in the solutions.

The Fund of Youth Grants of Kazan University is acknowledged for financial support of this work.

The magnetodynamic filters in monitoring the contaminants from polluted water systems (abstract)

R. Swarur ¬nd Bharat Singh[a)]
Department ‹ .?hysics, D. S. College, Aligarh 202001 U. P., India

The magnetic interaction seems to influence the "structural memory" of water systems which is quenched in ideally pure water. The sedentary lifetime of each water molecule is extremely short (10^{-10} s) and its molecular structures may be influenced by some physical effect like magnetic field treatment, it's space time gradients, water velocity, pressure drop, etc. in the interpolar space, so as to yield a noticeable temporal magnetopotential development characterizing the properties of homogeneous and heterogeneous water systems. This principle is also extended to prevailing water systems which always contain various impurities, gas, molecules, ions, microscopic particles in random order. Still the existence of structural memory may be verified by reliable experimental data. The magnetopotential curves of different water systems depict the design and develop–software package for constructing the magnetodynamic-filters superior to the existing techniques on pollution studies like remote sensing, muon spin resonance, laser spectroscopy, nuclear techniques, the gamma ray peak efficiency method, trace elemental characterization due to NBS, neutron activation analysis, and graphite furnance atomic absorption spectrometer. The physiochemical characteristics of water calibrated in terms of magnetopotential curves change with the removal of dissolved gasses, impurities, thermal activation, etc. and the algae, bacteria, phosphates, etc. have been removed at a rapid rate. The magnetodynamic study of ganga water proves it to be an extremely pure and highly resourced fluid.

"Will become a classic text in climate research"

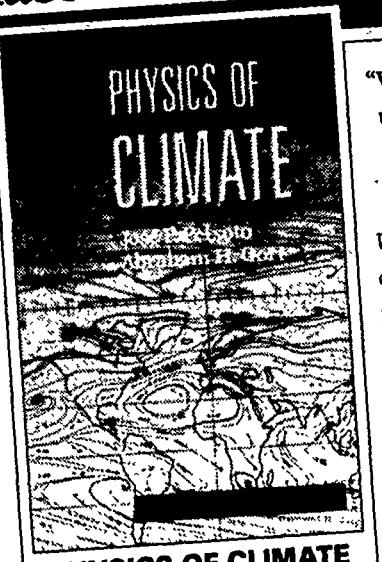
Physics World

"A superb reference. . . . Belongs on the shelf of anyone seriously interested in meteorology and climatology."—Curt Covey and Karl Taylor, *Physics Today*

"This unique book offers a broad perspective on the Earth's climate system and will become a classic text in climate research."
—*Physics World*

"Informative and authoritative on a remarkably wide range of topics. . . . a unique and useful addition to the literature on climate dynamics."—*Nature*

"A modern treatment of the nature and theory of climate. . . . Having so many relevant statistical properties of the climate system under one cover is just one of the benefits that this volume bestows."
—Edward N. Lorenz, *Massachusetts Institute of Technology*



PHYSICS OF CLIMATE
José P. Peixoto, *University of Lisbon and Geophysical Institute de Luis*
Abraham H. Oort, *NOAA and Princeton University*
Foreword by Edward N. Lorenz

1992, 512 pages, 220 illustrations
0-88318-711-6, cloth
$95.00 **Your price $76.00**

0-88318-712-4, paper
$45.00 **Your price $36.00**

"Valuable to anyone who studies, models, or uses the climate of the earth."
—Walter Robinson, *Bulletin of the American Meteorological Society*

Using such contemporary tools as satellite data, acoustic tomography, infrared radiometers, and nonlinear mathematical models, *Physics of Climate* shows how environmental phenomena worldwide interact in a single, unified system. This integrated, global perspective unites all the key features of the climate system—oceans, atmosphere, and cryosphere—describing the structure and behavior of climate over time.

With more than 220 drawings, charts, and graphs, *Physics of Climate* is an absolutely indispensable text/reference for students and researchers in aeronomy, meteorology, oceanography, physics, and geophysics.

ALSO FROM THE AMERICAN INSTITUTE OF PHYSICS

CONTINENTS IN MOTION
Second Edition
Walter Sullivan, former science editor for *The New York Times*

"As entertaining as a good detective story—and considerably more informative."—*Time*

"*Continents in Motion* is a staggering assemblage of facts; it is also a history of discovery as revealing as. . .Watson's account of unraveling the genetic code."
—*The New York Times*

"Beautifully illustrated, superbly written, and thoroughly documented."
—*San Francisco Examiner & Chronicle*

Sullivan's absorbing history of the idea of continental drift includes findings by the Consortium for Continental Reflection Profiling; data from worldwide earthquake detectors analyzed by seismic tomography; analysis of ancient magnetism, fossils, and regional rock composition; and discoveries about the sea floor made by such unmanned devices as Alvin.

1991, 456 pages, illustrated
0-88318-703-5, cloth
$50 00 **Your price $40.00**

0-88318-704-3, paper
$25.00 **Your price $20.00**

CLIMATE CHANGE AND ENERGY POLICY
Edited by L. Rosen and R. Glasser, *Los Alamos National Laboratories*

Integrating key voices in the climate change community and the energy policy-making and research communities, this book looks at climate change on many levels, including its economic impact on energy technologies.

1992, 564 pages
ISBN 1-56396-017-6, paper
$55.00 **Your price $44.00**

GLOBAL WARMING
Edited by D. Hafemeister, *California Polytechnic University*, B. Levi, *Physics Today*, and R. Scribner, *Georgetown University*

"An excellent place to start for any physicist wishing to understand what global warming is all about."
—*Contemporary Physics*

AIP Conference Proceedings 247
1992, 350 pages
ISBN 0-88318-932-1, hardcover
$95.00 **Your price $76.00**

PINET

THE PHYSICS INFORMATION NETWORK

The online information service serving your varied communication, research and information needs in physics with one affordable resource.

PINET is a full-service interactive network of searchable databases, communications services, news, announcements, and job listings. PINET is your network—created specifically for physicists and astronomers. It will plug you into the Internet, give you access to abstracts from over 70 AIP and AIP Member Society journals (including abstracts of articles not yet published), let you scan news releases and research results from national laboratories such as Brookhaven and Argonne, and much more.

You'll be able to research more effectively, get a jump on research before it's published, keep up to date with news and breakthroughs, and stay in touch with colleagues—all easily and inexpensively. With PINET and your PC, you'll be able to tap into:

SEARCHABLE DATABASES

- ❑ Advance Abstracts, with abstracts of papers up to three months prior to publication
- ❑ SPIN, containing nine years of abstracts from more than 70 journals and conference proceedings
- ❑ NASA, MIT, and dozens of other databases worldwide via the Internet–the world's largest network
- ❑ The Jobs Database, featuring nearly 200 job listings in academia, government, and industry

COMMUNICATIONS SERVICES

- ❑ Inexpensive international e-mail, online fax, and telex services
- ❑ Access to users of Internet, Bitnet, Compuserve. MCIMail, and other services

LATE-BREAKING NEWS/RESEARCH RESULTS

- ❑ AIP's *Physics News Update* and *FYI*
- ❑ The American Physical Society's *What's New*
- ❑ The American Geophysical Union's KOSMOS
- ❑ USENET bulletin boards, and more

PINET includes previews of articles to appear in *Physics Today*, *Computers in Physics*, and other publications; directories of physicists in the former Soviet Union and members of AIP and AIP Member Societies; a calendar of upcoming AIP Member Society meetings and conferences. PINET also gives you the ability to download research papers and software!

To order, or for more information, please contact:

AMERICAN INSTITUTE OF PHYSICS
Electronic Products Division
Telephone: (516) 576-2262. Fax: (516) 349-9704
E-Mail: elecpub@aip.org

PLEASE REGISTER ME FOR:

❑ **THE FLAT FEE PROGRAM—UNLIMITED USAGE**

Access PINET via the Internet
- ❑ $120 for a yearly subscription!
- ❑ $32 for a 3-month subscription!

❑ **THE HOURLY PROGRAM (RATES SHOWN BELOW)**

Prime Time	$19/hr	Weekdays 8am-5pm
Off-Peak	$14/hr	Weekdays 5pm-11pm Sundays 5pm-11pm
Night	$10/hr	Every night 11pm-8am Saturdays All Day Sundays Until 5pm

- ❑ Enclosed is my check for $_____ (*Flat fee*)
- ❑ Charge my subscription or monthly usage to my:
- ❑ VISA ❑ MasterCard ❑ American Express

Card No. _____ Exp.Date _____

Signature _____
CREDIT CARD ORDERS MUST BE SIGNED

- ❑ Bill my organization: _____

Contact person: _____

Use the following for my User ID (*8 alphanumeric characters or less*):

1st choice [ ] 2nd choice [ ]

- ❑ Send me more information about PINET service and payment options.

Under U.S. copyright law, the transfer of copyright from the author(s) should be explicitly stated to enable the publisher to disseminate the work to the fullest extent. The following transfer must be signed and returned to the Editor's office before the manuscript can be accepted for publication. Please note that if the manuscript has been prepared as a Work Made For Hire, the transfer should be signed by both employer and employee. Address requests for further information or exceptions to the Office of Rights and Permissions, American Institute of Physics (AIP), 500 Sunnyside Blvd., Woodbury, New York 11797-2999 · (516) 576-2262.

TRANSFER OF COPYRIGHT AGREEMENT

Copyright to the unpublished and original article, including copyright to the abstract forming part thereof, entitled

_____

submitted by the following author(s) (names of all authors) _____

_____

is hereby transferred to American Institute of Physics (AIP) for the full term thereof throughout the world, BUT SUBJECT to the following rights reserved to the author(s) and to acceptance of the article for publication in

_____
Name of Journal

AIP shall have the right to publish the article in any medium or form, or by any means, now known or later developed.

AIP shall have the right to register copyright in the article and the accompanying abstract in its name as claimant, whether separately or as part of the journal issue or other medium in which such work is included.

The author(s) reserve the following rights:

(1) All proprietary rights other than copyright, such as patent rights.

(2) The right, after publication by AIP, to grant or refuse permission to third parties to republish all or part of the article or translations thereof. In the case of whole articles, such third parties must obtain AIP's written permission as well. However, such permission will not be refused by AIP except at the direction of the author. AIP may grant rights with respect to journal issues as a whole.

(3) The right, after publication by AIP, to use all or part of the article and abstract in compilations or other publications of the author's own works, and to make copies of all or part of such material for the author's use for lecture or classroom purposes.

(4) If the article has been prepared by an employee within the scope of his or her employment, the employer reserves the right to make copies of the work for its own internal use. If the article was prepared under a U.S. Government contract, the government shall have the rights under the copyright to the extent required by the contract.

The author(s) agree that all copies of the article or abstract made under any of the above reserved rights shall include a copyright notice in the AIP's name. The author(s) represent and warrant that the article is original with them, that it does not infringe any copyright or other rights in any other work, or violate any other rights, and that the author(s) own the copyright in it or are authorized to transfer it. If each author's signature does not appear below, the signing author(s) represent that they sign this agreement as authorized agents for and on behalf of all the authors, and that this agreement and authorization is made on behalf of all the authors.

If the manuscript has been prepared as a Work Made For Hire, the transfer should be signed by the employee (above) and by the employer (below):

_____
Name of Employer (print)

_____ _____ _____ _____
Signature Name (print) Title Date

A work prepared by a U.S. Government officer or employee as part of his or her official duties is not eligible for U.S. copyright; however, foreign copyright laws may differ. Thus, **this form should be signed even by U.S. Government** officers or employees. Signing of this form will not affect U.S. copyright law provisions in the case of works of the U.S. Government. If all the authors are in this category, check the box here and return the signed form. ☐

AMERICAN INSTITUTE of PHYSICS

500 Sunnyside Boulevard, Woodbury, NY 11797

The American Institute of Physics is a not-for-profit membership corporation chartered in New York State in 1931 for the purpose of promoting the advancement and diffusion of the knowledge of physics and its application to human welfare. Leading societies in the fields of physics, astronomy, and related sciences are its members.

The Institute publishes its own scientific journals as well as those of its member societies; publishes both technical and general interest books; provides abstracting and indexing services; provides on-line database and e-mail services; disseminates reliable information on physics to the public; collects and analyzes statistics on the profession and on physics education; encourages and assists in the documentation and study of the history and philosophy of physics; cooperates with other organizations on educational projects at all levels; and collects and analyzes information on Federal programs and budgets.

AIP Conference Proceedings

Acoustical Physics	JETP Letters	Physics of Atomic Nuclei	Semiconductors
Astronomy Reports	Low Temperature Physics	Physics of the Solid State	Journal of Optical Technology
Astronomy Letters	Optics and Spectroscopy	Plasma Physics Reports	Technical Physics
Crystallography Reports	Physics-Doklady	Physics of Particles and Nuclei	Technical Physics Letters
JETP			

Current Physics Index (CPI), quarterly and annual subject index with abstracts to all the above journals.
General Physics Advance Abstracts (GPAA), semimonthly advance abstracts of AIP-published physics literature.
Searchable Physics Information Notices (SPIN), monthly computer-readable tape of abstracts
Current Physics Microform (CPM), monthly microfilm edition of all the above journals
Current Physics Reprints (CPR), on-demand copies of any article in any of the above journals.
Physics Briefs (PB), semimonthly comprehensive index with abstracts to the world literature of physics
PINET, an online physics information network

Governing Board 1994–1995

Roland W. Schmitt, *Chair**
Reuben E. Alley
Benjamin Bederson
Roger A. Bell
Marc H. Brodsky (*ex officio*)*
Robert L. Byer*
Patricia E. Cladis
Charles Counselman, III
G. Brent Dalrymple*
Robert L. Dixon
William L. Duax
Judy R. Franz
Roderick M. Grant (*ex officio*)*
Joseph E. Greene
David Hennage
David W. Hoffman*
Karen L. Johnston
Frank J. Kerr
Bernard V. Khoury*
Carl Kisslinger
Patricia K. Kuhl
Donald N. Langenberg
Tingye Li
Harry Lustig*
Christopher H. Marshall
Gregory B. McKenna
Duncan T. Moore
Norman F. Ness
C. Robert O'Dell
C. Kumar N. Patel
Burton Richter
Barrett H. Ripin
J. William Rogers, Jr.
Charles E. Schmid*
Benjamin Snavely
A. F. Spilhaus, Jr.
Hugo Steinfink
Richard Stern
Howard G. Voss*
Martin Walt
* executive committee

AIP Officers

Marc H. Brodsky, *Executive Director and CEO*
Roderick M. Grant, *Secretary*
Arthur T. Bent, *Treasurer and CFO*
Theresa C. Braun, *Director of Human Resources*
Darlene Carlin, *Director of Publishing*
John S. Rigden, *Director of Physics Programs*

Publishing Services

James J. Donohue, *Director Publishing Services*
Edward P. Greeley, *Director Advertising and Exhibits*
Douglas LaFrenier, *Director of Marketing*
Peggy Judd, *Director of Information Technology*
Maria Taylor, *Publisher AIP Press*
Carol Fleming, *Manager Publishing II Branch*
Doreene A. Berger, *Manager Journal Production I Division*
Maya Flikop, *Manager Translation Program Division*
John T. Scott, *Manager Editorial Operations Division*
Cheryl Taub, *Manager Composition I Division*
Denise Weiss, *Manager Books/Special Projects*
Janice Wilmot, *Manager Production II Division*

APPLIED PHYSICS LETTERS: Current Table of Contents

Applied Physics Letters, a companion publication to the *Journal of Applied Physics*, is published weekly by the American Institute of Physics. Its letters are timely, short reports devoted to important new findings in applied physics. The contents list below is from a recent issue.

APPLIED PHYSICS LETTERS

Vol 64, No. 18, 2 May 1994

CODEN APPLAB ISSN 0003-6951

OPTICS

2329 Cr^{4+}:$Gd_2Sc_2Ge_2O_{12}$ passive Q-switch for the Cr^{3+}:LiCaAlF$_6$ laser — Yen-Kuang Kuo, Yang Yang, Milton Birnbaum

2332 Noise suppression for photorefractive image amplification in the $LiNbO_3$:Fe crystal sheet — Jingjun Xu, Guangyin Zhang, Simin Liu, Junmin Liu, Liqiu Men

2335 Polarization-independent wavelength filter using a grating-assisted vertical directional coupler in InP — F Heismann, L. L. Buhl, B. I. Miller, M. Newkirk, U. Koren, M. G. Young, R. C. Alferness

2338 Optical near-field imaging with a semiconductor probe tip — J. Mertz, M. Hipp, J. Mlynek, O. Marti

2341 Phase conjugation of $BaTiO_3$:Ce by backward stimulated photorefractive scattering — Yong Zhu, Changxi Yang, Mengjun Hui, Xiaojuan Niu, Jinfeng Zhang, Tang Zhou, Xing Wu

CONDENSED MATTER STRUCTURE, MECHANICAL AND THERMAL PROPERTIES

2344 Transmission electron microscopy characterization of $In_xGa_{1-x}As$ substrates grown by heteroepitaxial lateral overgrowth — J. P. McCaffrey, B. Bryskiewicz, T. Bryskiewicz, E. Jiran

2347 Anomalous laser-induced voltages in $YBa_2Cu_3O_x$ and "off-diagonal" thermoelectricity — Louis R. Testardi

2350 Raman scattering and x-ray diffraction investigations of highly textured $(Pb_{1-x}La_x)TiO_3$ thin films — Z. C. Feng, B. S. Kwak, A. Erbil, L. A. Boatner

2353 Thermal expansion of polycrystalline diamond produced by chemical vapor deposition — D. J. Pickrell, K. A. Kline, R. E. Taylor

2356 Kinetic suppression of islanding in impurity-mediated heteroepitaxial growth of germanium on silicon — H. J. Osten

2359 Absence of solute drag in solidification — J. A. Kittl, M. J. Aziz, D. P. Brunco, M. O. Thompson

SEMICONDUCTORS

2362 Threshold voltage shift of amorphous silicon thin film transistors with atmospheric pressure chemical vapor deposition silicon dioxide — Jeong Hyun Kim, Eui Yeol Oh, Jung Kee Yoon, Yong Suk Park, Chan Hee Hong

2364 Blue electroluminescent devices with high quantum efficiency from alkoxy-substituted poly(para-phenylene vinylene)-trimers in a polystyrene matrix — W. Tachelet, S. Jacobs, H. Ndayikengurukiye, H. J. Geise, J. Grüner

2367 Optical properties of porous silicon superlattices — G. Vincent

2370 Long-wavelength stacked SiGe/Si heterojunction internal photoemission infrared detectors using multiple SiGe/Si layers — J. S. Park, T. L. Lin, E. W. Jones, H. M. Del Castillo, S. D. Gunapala

2373 Photoluminescence of Si/SiGe/Si quantum wells on separation by oxygen implantation substrate — D. K. Nayak, N. Usami, S. Fukatsu, Y. Shiraki

2376 Photoluminescence of chemically vapor deposited Si on silica aerogels — Wanqing Cao, Arlon J. Hunt

2379 Single electron transport and current quantization in a novel quantum dot structure — Y. Nagamune, H. Sakaki, L. P. Kouwenhoven, L. C. Mur, C. J. P. M. Harmans, J. Motohisa, H. Noge

2382 Temperature dependence of cathodoluminescence from thin GaAs-AlGaAs multiple quantum wells — U. Jahn, J. Menniger, R. Hey, H. T. Grahn

2385 Ultrafast carrier trapping and slow recombination in ion-bombarded silicon on sapphire measured via THz spectroscopy — Stuart D. Brorson, Jucheng Zhang, Søren R. Keiding

2388 Ultraviolet photosulfidation of III-V compound semiconductors: A new approach to surface passivation — Carol I. H. Ashby, Kevin R. Zavadil, Arnold J. Howard, B. E. (Gene) Hammons

2391 Laser-induced sputtered neutral mass spectrometry study of arsenic concentration profiles in a polycrystalline silicon/single-crystal silicon system — Yasuhiro Higashi, Tetsuya Maruo, Yoshikazu Homma, Jun'ichi Kodate, Masayasu Miyake

2394 Electroluminescence from porous silicon with conducting polymer film contacts — Kun-hai Li, Dennis C. Diaz, Yueseng He, Joe C. Campbell, Chaochieh Tsai

2397 Low-temperature growth of high resistivity GaAs by photoassisted metalorganic chemical vapor deposition — J. C. Roberts, K. S. Boutros, S. M. Bedair, D. C. Look

2400 Evidence for population inversion in excited electron states of a double barrier resonant tunneling structure — J. W. Cockburn, M. S. Skolnick, D. M. Whittaker, P. D. Buckle, A. R. K. Willcox, G. W. Smith

2403 Observation of resonant tunneling through localized continuum states in electron wave interference diodes — R. E. Carnahan, M. A. Maldonado, K. P. Martin, R. J. Higgins, J. P. A. van der Wagt, J. S. Harris, Jr.

2406 Back side Raman measurements on Ge/Pd/*n*-GaAs ohmic contact structures — K. Wuyts, J. Watte, R. E. Silverans, M. Van Hove, G. Borghs, C. J. Palmström, L. T. Florez, H. Münder

2409 New interface structure for *A*-type $CoSi_2$/Si(111) — M. F. Chisholm, S. J. Pennycook, R. Jebasinski, S. Mantl

2412 Threshold dose for ion-induced intermixing in InGaAs/GaAs quantum wells — L. B. Allard, G. C. Aers, P. G. Piva, P. J. Poole, M. Buchanan, I. M. Templeton, T. E. Jackman, S. Charbonneau, U. Akano, I. V. Mitchell

2415 High efficiency indium gallium arsenide photovoltaic devices for thermophotovoltaic power systems — David M. Wilt, Navid S. Fatemi, Richard W. Hoffman, Jr., Phillip P. Jenkins, David J. Brinker, David Scheiman, Roland Lowe, Maria Fauer, Raj K. Jain

2418 Dimerization induced incorporation nonlinearities in GaAsP — J. E. Cunningham, M. B. Santos, K. W. Goossen, M. D. Williams, W. Jan

2421 Full band structure calculation of the linear electro-optic susceptibility — Ed Ghahramani, J. E. Sipe

2424 Observation of voids induced by mechanical stress and electromigration in passivated Al lines deposited at different purity levels — T. Marieb, J. C. Bravman, P. Flinn, D. S. Gardner, M. Madden

2427 Dry etching and implantation characteristics of $Al_{0.5}Ga_{0.5}P$ — S. J. Pearton, C. R. Abernathy, F. Ren

2430 Photoluminescence lifetime of GaP/AlP superlattices grown by gas-source molecular-beam epitaxy — Kumiko Asami, Hajime Asahi, Song Gang Kim, Joon Hong Kim, Akito Ishida, Setsuo Takamuku, Shun-ichi Gonda

2433 Uncooled InSb/$In_{1-x}Al_xSb$ mid-infrared emitter — T. Ashley, C. T. Elliott, N. T. Gordon, R. S. Hall, A. D. Johnson, G. J. Pryce

2436 Asymmetric dark current in quantum well infrared photodetectors — K. L. Tsai, C. P. Lee, K. H. Chang, D. C. Liu, H. R. Chen, J. S. Tsang

2439 Excitonic properties of ZnSe/ZnSeS superlattices — R. Cingolani, M. Lomascolo, N. Lovergine, M. Dabbicco, M. Ferrara, I. Suemune

SUPERCONDUCTORS

2442 Superconducting readout of semiconductor memory at liquid nitrogen temperature — Claude Hilbert, Uttam Ghoshal, Harry Kroger, Jon S. Martens, V. M. Hietala, T. A. Plut

2445 Influence of inductance induced noise in an $YBa_2Cu_3O_7$ dc-SQUID at high operation temperatures — P. Å. Nilsson, T. Claeson, J. B. Hansen, A. Kühle
