Abstract

The M–Machine is an experimental multicomputer being developed to test architectural concepts motivated by the constraints of modern semiconductor technology and the demands of programming systems. The M–Machine computing nodes are connected with a 3–D mesh network; each node is a multithreaded processor incorporating 12 function units, on-chip cache, and local memory. The multiple function units are used to exploit both instruction-level and thread-level parallelism. A user accessible message passing system yields fast communication and synchronization between nodes. Rapid access to remote memory is provided transparently to the user with a combination of hardware and software mechanisms. This paper presents the architecture of the M–Machine and describes how its mechanisms maximize both single thread performance and overall system throughput.

This report describes research done at the Artificial Intelligence Laboratory of the Massachusetts Institute of Technology. The research described in this paper was supported by the Advanced Research Projects Agency and monitored by the Air Force Electronic Systems Division under contract F19628-92-C-0045 and in part by the Air Force Office of Scientific Research under contract F49620-94-1-0462.

1 Introduction

Because of the increasing density of VLSI integrated circuits, most of the chip area of modern computers is now occupied by memory and not by processing resources. The M-Machine is an experimental multicomputer being developed to test architecture concepts which are motivated by these constraints of modern semiconductor technology and the demands of programming systems, such as faster execution of fixed sized problems and easier programmability of parallel computers.

Advances in VLSI technology have resulted in computers with chip area dominated by memory and not by processing resources. The normalized area (in λ^2) of a VLSI chip[1] is increasing by 50% per year, while gate speed and communication bandwidth are increasing by 20% per year [10]. As a result, a 64-bit processor with a pipelined FPU ($400M\lambda^2$) is only 11% of a $3.6G\lambda^2$ 1993 0.5μm chip and only 4% of a $10G\lambda^2$ 1996 0.35μm chip. In a system with 64 MBytes (256 MBytes in 1996) of DRAM, the processor accounts for 0.52% (0.13% in 1996) of the silicon area in the system. The memory system, cache, TLB, controllers, and DRAM account for most of the remaining area. Technology scaling has made the memory, rather than the processor, the most area-consuming resource in a computer system.

To address this imbalance, the M-Machine increases the fraction of chip area devoted to processor, to make better use of the critical memory resources. An M-Machine multi-ALU processor (MAP) chip contains four 64-bit three-issue *clusters* that comprise 32% of the $5G\lambda^2$ chip and 11% of an 8 MByte (six-chip) node. The multiple execution clusters provide better performance than using a single cluster and a large on-chip cache in the same chip area. The high ratio of arithmetic bandwidth to memory bandwidth (12 operations/word) allows the MAP to saturate the costly DRAM bandwidth even on code with high cache-hit ratios. A 32-node M-Machine system with 256 MBytes of memory has 128 times the peak performance of a 1996 uniprocessor with the same memory capacity at 1.5 times the area, a 85:1 improvement in peak performance/area. Even at a small fraction of this peak performance, such a machine allows the costly, fixed-sized memory to handle more problems per unit time resulting in more cost-effective computing.

The M-Machine is designed to extract more parallelism from problems of a fixed size, rather than requiring enormous problems to achieve peak performance. To do this, nodes are designed to manage parallelism from the instruction level to the process level. The 12 function units in a single M-Machine node are controlled using a form of Processor Coupling [13] to exploit instruction level parallelism by executing 12 operations from the same thread, or to exploit thread-level parallelism by executing operations from up to six different threads. The fast internode communication allows collaborating threads to reside on different nodes.

The M-Machine also addresses the demand for easier programmability by providing a incremental path for increasing parallelism and performance. An unmodified sequential program can run on a single M-Machine node, accessing both local and remote memory. This code can be incrementally parallelized by identifying tasks, such as loop iterations, that can be distributed both across nodes and within each node to run in parallel. A flat, shared address space simplifies naming and communication. The local caching of remote data in local DRAM automatically migrates a task's data to exploit locality.

The remainder of this paper describes the M-Machine in more detail. Section 2 gives an overview of the machine architecture. Mechanisms for intra-node parallelism are described in Section 3. Section 4 discusses inter-node communication including the user-level communication primitives and how they are used to provide global coherent memory access.

2 M-Machine Architecture

The M-Machine consists of a collection of computing nodes interconnected by a bidirectional 3-D mesh network, as shown in Figure 1. Each six-chip node consists of a multi-ALU (MAP) chip and 1 MW (8 MBytes) of synchronous DRAM (SDRAM). The MAP chip includes the network interface and router, and it provides an equal bandwidth of 800 MBytes/s to the local SDRAM and to each network channel. I/O devices may be connected either to an I/O bus available on each node, or to I/O nodes (IONs) attached to the face channels.

As shown in Figure 2, a MAP contains: four execution clusters, a memory subsystem comprised of four cache banks and an external memory interface, and a communication subsystem consisting of the network interfaces and the router. Two crossbar switches interconnect these components. Clusters make memory requests to the appropriate bank of the interleaved cache over the 150-bit wide (address+data) 4×4 M-Switch. The 90-bit wide 10×4 C-Switch is used for inter-cluster communication and to return data from the memory system. Both switches support up to four transfers per cycle.

MAP Execution Clusters: Each of the four MAP clusters is a 64-bit, three-issue, pipelined processor consisting of two integer ALUs, a floating-point ALU, associated register files, and a 1KW (8KB) instruction cache, as shown in Figure 3. One of the integer ALUs in each cluster, termed the memory unit, serves as interface to the memory system. Each MAP instruction

[1] The parameter λ is a normalized, process independent unit of distance equivalent to one half of the gate length [18]. For a $0.5\mu m$ process, λ is $0.25\mu m$.

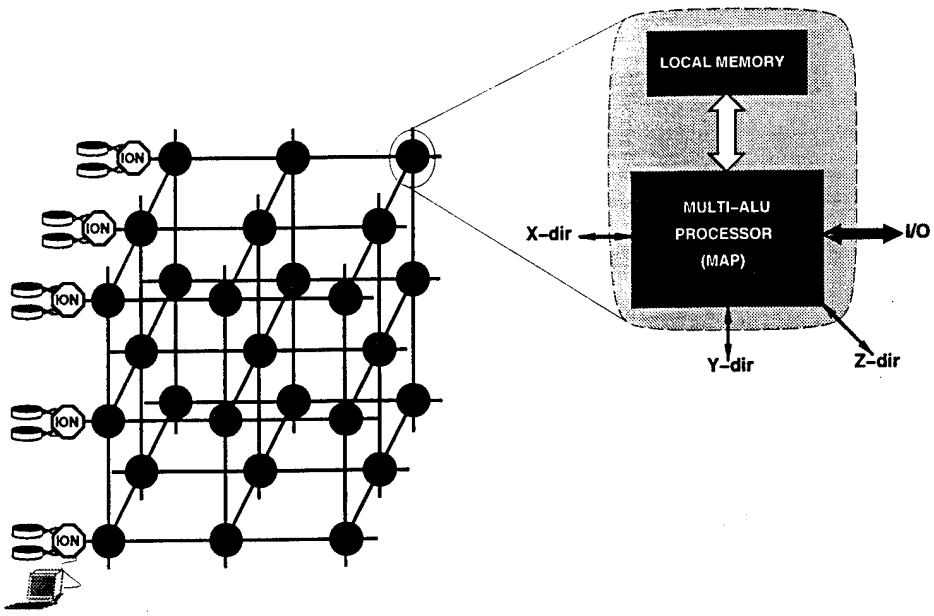

Figure 1: The M–Machine architecture.

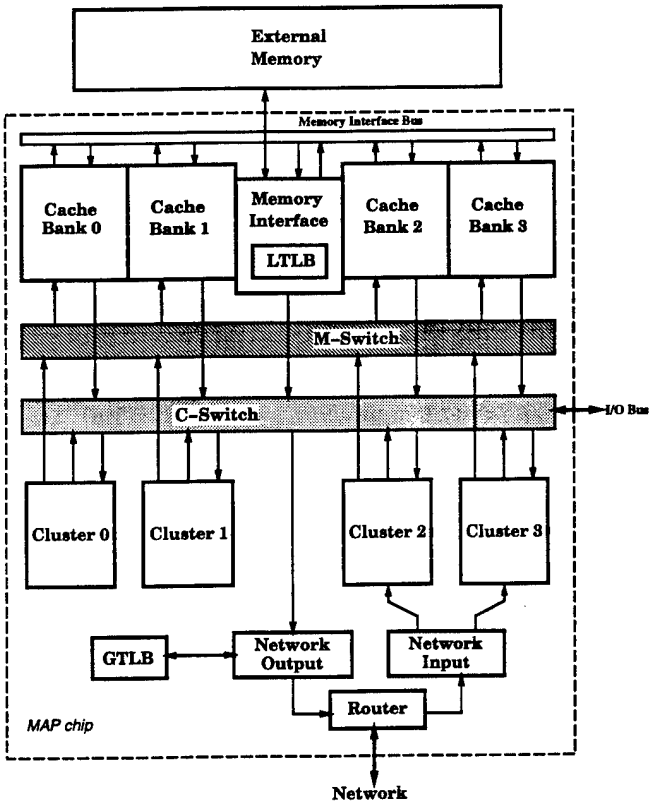

Figure 2: The MAP architecture.

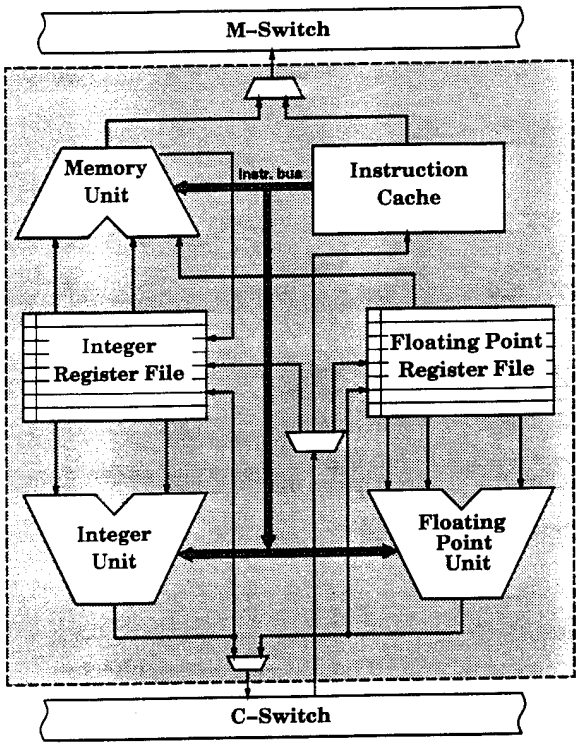

Figure 3: A MAP cluster consists of 3 execution units, 2 register files, an instruction cache and ports onto the memory and cluster switches.

contains 1, 2, or 3 operations, one for each ALU. All operations in a single instruction issue together but may complete out of order.

Memory System: As illustrated in Figure 2, the on–chip cache is organized as four word-interleaved 4KW (32KB) banks to permit four consecutive word accesses to proceed in parallel. The cache is virtually addressed and tagged. The cache banks are pipelined with a three-cycle read latency, including switch traversal.

The external memory interface consists of the SDRAM controller and a local translation lookaside buffer (LTLB) used to cache local page table (LPT) entries. Pages are 512 words (64 8-word cache blocks). The SDRAM controller exploits the pipeline and page mode of the external memory and performs SECDED[2] error control.

A synchronization bit is associated with each word of memory. Special load and store operations may specify a precondition and a postcondition on the synchronization bit. These are the only atomic read-modify-write memory operations.

The M–Machine supports a single global virtual address space. A light-weight capability system implements protection through guarded pointers [3], while paging is used to manage the relocation of data in physical memory within the virtual address space. The segmentation and paging mechanisms are independent so that protection may be preserved on variable-size segments of memory. The memory subsystem is integrated with the communication system and can be used to access memory on remote nodes, as described in Section 4.2.

Communication Subsystem: Messages are composed in the general registers of a cluster and launched atomically using a user-level `SEND` instruction. Protection is provided by sending a message to a virtual memory address that is automatically translated to the destination node identifier by a global translation lookaside buffer (GTLB), which caches entries of a global destination table (GDT). Arriving messages are queued in a register-mapped hardware FIFO readable by a system-level message handler. Two network priorities are provided, one for requests and one for replies.

3 Intra–node Concurrency Mechanisms

The amount and granularity of parallelism varies enormously across application programs and even during dif-

[2]Single error correcting, double error detecting

ferent phases of the same program. Some phases have an abundance of instruction level parallelism that can be extracted at compile time. Others have data dependent parallelism that can be executed using multiple threads with widely varying task sizes.

The M–Machine is designed to efficiently execute programs with any or all granularities of parallelism. On the MAP, parallel instruction sequences (*H–Threads*) are run concurrently on the four clusters to exploit ILP across all 12 of the function units. Alternatively they may be used to exploit loop level parallelism. To exploit thread-level parallelism and to mask variable pipeline, memory, and communication delays, the MAP interleaves the 12-wide instruction streams from different tasks, *V–Threads*, within each cluster on a cluster-by-cluster and cycle-by-cycle basis, thus sharing the execution resources among all active tasks.

This arrangement of V–Threads (Vertical Threads) and H–Threads (Horizontal Threads) is summarized in Figure 4. Six V–Threads are resident in the cluster register files. Each V–Thread consists of four H–Threads, one on each cluster. Each H–Thread consists of a sequence of 3-wide instructions containing integer, memory, and floating point operations. On each cluster the H–Threads from the different V–Threads are interleaved over the execution units.

3.1 H–Threads

An *H–Thread* runs on a single cluster and executes a sequence of operation triplets (one operation for each of the 3 ALUs in the cluster) that are issued simultaneously. Within an H–Thread, instructions are guaranteed to issue in order, but may complete out of order. An H–Thread may communicate and synchronize via registers with the 3 other H–Threads in the same V–Thread, each executing on a separate cluster. Each H–Thread reads operands from its own register file, but can directly write to the register file of any H–Thread in its own V–Thread.

H–Threads support multiple execution models. They can execute as independent threads with possibly different control flows to exploit loop-level or thread-level parallelism. Alternatively, the compiler can schedule the four H–Threads in a V–Thread as a unit to exploit instruction level parallelism, as in a VLIW machine. In this case the compiler must insert explicit register-based synchronization to enforce instruction ordering between H–Threads. Unlike the lock-step execution of traditional VLIW machines, H–Thread synchronization occurs infrequently, only being required by data or resource dependencies, While explicit synchronization incurs some overhead, it allows H–Threads to slip relative to each other in order to accommodate variable–latency operations such as memory accesses.

Figure 5 shows an illustrative example of the instruction sequences of a program fragment on 1 and 2 H–Threads. The program is the body of the inner loop of a "smoothing" operation using a 7-point stencil on 3-D grid. On a particular grid point, the smoothed value is given by $u_* = u_* + a \times r_* + b \times (r_u + r_d + r_n + r_s + r_e + r_w)$, where r_* is the residual value at that point, and r_u, r_d, r_n, r_s, r_s and r_w are the residuals at the neighboring grid points in the six directions UP, DOWN, NORTH, SOUTH, EAST and WEST respectively. In order to better illustrate the use of H–Threads, advanced optimization (such as software pipelining) is not performed.

Figure 5*(a)* shows the single H–Thread program, with a 12 long instruction stream which includes all of the memory and floating point operations. The weighting constants `a` and `b` are kept in registers. Figure 5*(b)* shows the instruction streams for two H–Threads working cooperatively. Each H–Thread performs four memory operations and some of the arithmetic calculations. Instruction 7 in H–Thread 0 calculates a partial sum and transmits it directly to register `t2` in H–Thread 1. The **empty** instruction on H–Thread 1 is used to prepare `t2` for H–Thread synchronization; H–Thread 1 will not issue instruction 7 until the data arrives from H–Thread 0 as explained below.

The use of multiple H–Threads reduces the static depth of the instruction sequences from 12 to 8. On a larger 27-point stencil, the depth is reduced from 36 to 17 when run on 4 H–Threads. The actual execution time of the program fragments will depend on the pipeline and memory latencies.

H–Thread Synchronization

As shown in the example of Figure 5, H–Threads synchronize through registers. A scoreboard bit associated with the destination register is cleared (empty) when a multicycle operation, such as a load, issues and set (full) when the result is available. An operation that uses the result will not be selected for issue until the corresponding scoreboard bit is set.

Inter-cluster data transfers require explicit register synchronization. To prepare for inter-cluster data transfers, the receiving H–Thread executes an EMPTY operation to mark empty a set of destination registers. As each datum arrives from the transmitting H–Thread over the C-Switch, the corresponding destination register is set full. An instruction in the receiving H–Thread that uses the arriving data will be not eligible for issue until its data is available.

Four pairs of single-bit global condition code (CC) registers are used to broadcast binary values across the clusters. Unlike centrally located global registers, the MAP global CC registers are physically replicated on each of the clusters. A cluster may broadcast using either register in only one of the four pairs, but may read and empty its local copy of any global CC register. Using these registers, all four H–Threads can execute

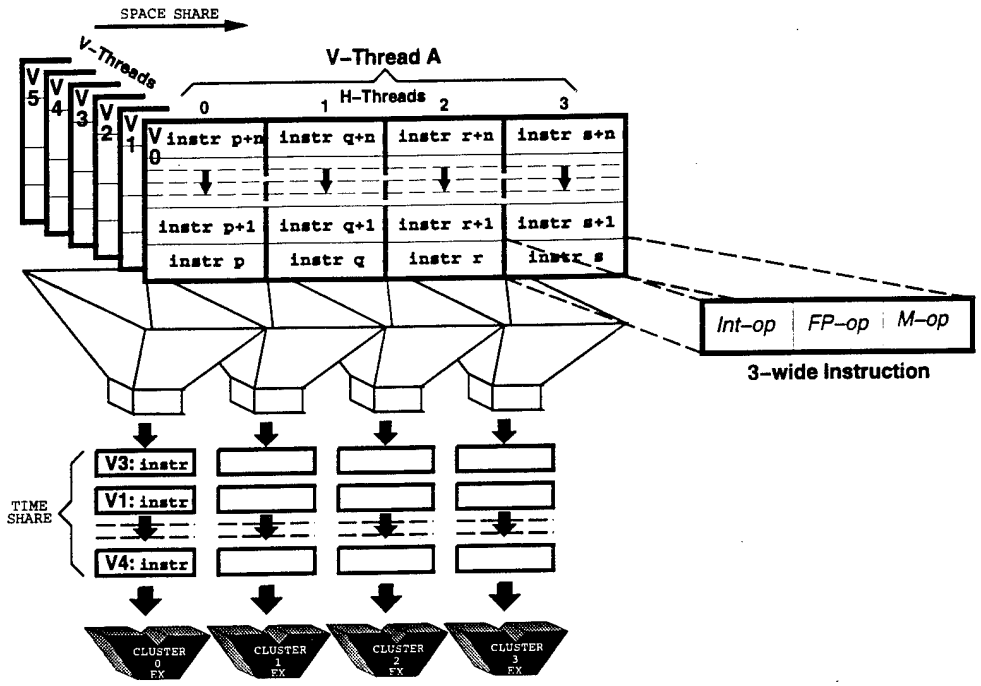

Figure 4: Multiple V-Threads are interleaved dynamically over the cluster resources. Each V–Thread consists of 4 H–Threads which execute on different clusters.

conditional branches and assignment operations based on a comparison performed in a single cluster.

The scoreboard bits associated with the global CC registers may be used to rapidly synchronize the H–Threads within a V–Thread. Figure 6 shows an example of two H–Threads synchronizing at loop boundaries. Two registers are involved in the synchronization, in order to provide an interlocking mechanism ensuring that neither H–Thread rolls over into the next loop iteration.

H–Thread 0 computes `bar`, compares it (using `eq`) to `end`, and broadcasts the result by targetting `gcc1`. H–Thread 1 uses `gcc1` to determine whether to branch, marks `gcc1` empty again, and writes to `gcc3` to notify H–Thread 0 that the current value of `gcc1` has been consumed. H–Thread 0 blocks until `gcc3` is full, and then empties it for the next iteration. Neither thread can proceed with the next iteration until both have completed the current one. Due to the multicopy structure of MAP global CC registers, this protocol can easily be extended to perform a fast barrier among 4 H–Threads executing on different clusters, without combining or distribution trees.

3.2 V–Threads

A V–Thread (vertical thread) consists of 4 H–Threads, each running concurrently on a different cluster. As discussed above, H–Threads within the same V–Thread may communicate via registers. However, H–Threads in different V–Threads may only communicate and synchronize through messages or memory. The MAP has enough resources to hold the state of six V–Threads, each one occupying a *thread slot*. Four of these slots are *user* slots, one is the *event* slot, and one is the *exception* slot. User threads run in the user slots, handlers for asynchronous events and messages run in the event slot, and handlers for synchronous exceptions detected within a cluster, such as protection violations, run in the exception slot.

On each cluster, six H–Threads (one from each V–Thread) are interleaved dynamically over the cluster resources on a cycle-by-cycle basis. A synchronization pipeline stage holds the next instruction to be issued from each of the six V–Threads until all of its operands are present and all of the required resources are available [13]. At every cycle this stage decides which instruction to issue from those which are ready to run. An H–Thread that is stalled waiting for data or resource availability consumes no resources other than the thread slot that holds its state. As long as its data and resource

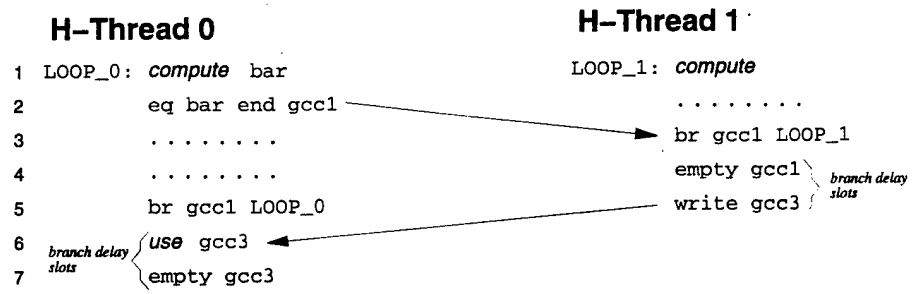

Figure 6: Loop synchronization between two H–Threads using MAP global CC registers.

dependencies are satisfied, a single thread may issue an instruction every cycle. Multiple V–Threads may be interleaved with zero delay, which allows task switching to be used to mask even very short pipeline latencies as well as longer communication and synchronization latencies.

3.3 Asynchronous Exception Handling

Exceptions that occur outside the MAP cluster are handled asynchronously by generating an *event record* and placing it in a hardware event queue. LTLB misses, block status faults, and memory synchronizing faults, for example, are handled asynchronously. These exceptions are precise in the sense that the faulting operation and its operands are specifically identified in the event record, but they are handled asynchronously, without stopping the thread.

A dedicated handler in an H–Thread of the event V–Thread processes event records to complete the faulting operations. The event handler loops, reading event records from the register-mapped queue and processing them in turn. A read from the queue will not issue if the queue is empty. For example, on a local TLB miss, the hardware formats and enqueues an event record containing the faulting address as well as the write data or read destination. A TLB miss handler reads the record, places the requested page table entry in the TLB, and restarts the memory reference. The thread that issued the reference does not block until it needs the data from the reference that caused the miss. Inter-node message arrival is treated as an event in which the contents of the message are written into the appropriate event queue (which serves as the message queue).

Each H–Thread in the event V–Thread handles one class of events. Memory synchronization and status faults are run on cluster 0, local TLB misses are run on cluster 1, and arriving messages are run on clusters 2 and 3, depending on the priority of the message.

Handling exceptions asynchronously obviates the need to cancel all of the issued operations following the faulting operation, a significant penalty in a 12-wide machine with deep pipelines. Dedicating H–Threads to this purpose accelerates event handling by eliminating the need to save and restore state, and allows concurrent (interleaved) execution of user threads and event handlers. Asynchronous event handling does require sufficient queue space to handle the case where every outstanding instruction generates an exception. To reduce queue size requirements, exceptions that are detected in the first execution cycle, such as protection violations and some arithmetic exceptions, stall all user H–Threads in the affected cluster, and are handled synchronously by the local H–Thread of the exception V–Thread.

3.4 Discussion

There are two major methods of exploiting instruction level parallelism. Superscalar processors execute multiple instructions simultaneously by relying upon runtime scheduling mechanisms to determine data dependencies [23, 12]. However, they do not scale well with increasing number of function units because a greater number of register file ports and connections to the function units are required. In addition, superscalars attempt to schedule instructions at runtime (much of which could be done at compile time), but they can only examine a small subsequence of the instruction stream.

Very Long Instruction Word (VLIW) processors such as the Multiflow Trace series [4] use only compile time scheduling to manage instruction-level parallelism, resource usage, and communication among a partitioned register file. However, the strict lock-step execution is unable to tolerate the dynamic latencies found in multiprocessors.

Processor Coupling was originally introduced in [13] and used implicit synchronization between the clusters on every wide instruction. Relaxing the synchronization, as described in this section, has several advantages. First, it is easier to implement because control is localized completely within the clusters. Second, it allows more slip to occur between the instruction streams running on different clusters (H–Threads), which eliminates the automatic blocking of one thread on long latency operations of another, providing more opportunity for latency tolerance. Finally, the H–Threads can be used flexibly to exploit both instruction and loop level parallelism. When H–Threads must synchronize, they do so explicitly though registers, at a higher cost than implicit synchronization. However, fewer synchronization operations are required, and many of them can be included in data transfer between clusters.

Using multiple threads to hide memory latencies and pipeline delays has been explored in several different studies and machines. Gupta and Weber explore the use of multiple hardware contexts in multiprocessors [8], but the context switch overhead prevents the masking of pipeline latencies. MASA [9] as well as HEP [22] use fine grain multithreading to issue an instruction from a different context on every cycle in order to mask pipeline latencies. However, with the required round-robin scheduling, single thread performance is degraded by the number of pipeline stages. The zero cost switching among V–Threads and the pipeline design of the MAP provide fast single thread execution as well as latency tolerance for better local memory bandwidth utilization.

4 Inter–node Concurrency Mechanisms

The M–Machine provides a fast, protected, user-level message passing substrate. A user program may com-

municate and synchronize by directly sending messages or by reading and writing remote memory using a coherent shared memory system layered on the message-passing substrate. Direct messaging provides maximum performance data transfer and synchronization while shared memory access simplifies programming. Remote memory access is implemented using fast trap handlers that intercept load and store operations that reference remote data. These handlers send messages to other nodes to complete remote memory references transparently to user programs. Additional hardware and software mechanisms allow remote data to be cached locally in both the cache and external memory.

4.1 Message Passing Support

The M-Machine provides hardware support for injecting a message into the network, determining the message destination, and dispatching a handler on message arrival. For example, Figure 7 shows the M-Machine instruction sequences for both the sending and receiving components of a remote memory store. The message sending sequence (Figure 7*(a)*) loads the data to be stored into general register `MC1`. The `SEND` instruction takes three arguments, the target address (`Raddr`), the dispatch instruction pointer (`Rdip`), and the message body length (`#1`). When the `SEND` issues, the Global Translation Lookaside Buffer (GTLB) translates virtual address `Raddr` into a physical node identifier and sends that node a 3 word message containing `Rdip`, `Raddr`, and `MC1`. When the message arrives at the destination (Figure 7*(b)*) hardware enqueues it in the priority 0 message queue. An H-Thread dedicated to message handling jumps to the handler via `Rdip`, executes a store operation and branches back to the dispatch portion of the code.

Message Injection: A message is composed in a cluster's general registers and transmitted atomically with a single `SEND` instruction that takes as arguments a *destination* virtual address, a *dispatch instruction pointer (DIP)*, and the message body length. Hardware composes the message by prepending the destination and DIP to the message body and injects in into the network. Two message priorities are provided: user messages are sent at priority zero, while priority 1 is used for system level message reply, thus avoiding deadlock.

Message Address Translation: As described in [19], the explicit management of processor identifiers by application programs is cumbersome and slow. To eliminate this overhead, the MAP implements a Global Translation Lookaside Buffer (GTLB), backed by a software Global Destination Table (GDT), to hold mappings of virtual address regions to node numbers. These mappings may be changed by system software. The user specifies the destination of a message with a virtual address, which the network output interface hardware uses to access the GTLB and calculate the physical destination node.

With a single GTLB entry, a range of virtual addresses (called a page-group) is mapped across a region of processors. In order to simplify encoding, the page-group must be a power of 2 pages in size, where each page is 1024 words. The mapped processors must be in a contiguous 3-D rectangular region with a power of 2 number of nodes on a side. This information is encoded in a single GTLB entry as shown in Figure 8. The *virtual page* field is used as the tag during the fully associative GTLB lookup. The *starting node* specifies the coordinates of the origin of the region of mapped processors, while the *extent* specifies the base 2 logarithm of the X, Y, and Z dimensions of the region. The *page-group length* field specifies the number of local pages that are mapped into the page group. The *pages-per-node* field indicates the number of pages placed on each consecutive processor, and is used to implement a spectrum of block and cyclic interleavings.

Message Reception: At the destination node, an arriving message is automatically placed in a hardware message queue. The head of the message queue is mapped to a register accessible by an H-Thread (in either cluster 2 or 3, depending on message priority) in the *event* V-Thread. The message dispatch handler code running in that H-Thread stalls until the message arrives, and then dequeues the dispatch instruction pointer (DIP) and jumps to it. This starts execution of the specific handler code to perform the action requested in the message. Some of the actions include remote read, remote write, and remote procedure call. The message need not be copied to or from memory, as it is accessible via a general register. In order to avoid overflow of the fixed size message queue and back up of the network, only short, well-bounded tasks are executed by message handlers. Longer tasks are enqueued to be run as a user process on a user V-Thread.

Protection: The M-Machine communication substrate provides fully protected user-level access to the network. The `SEND` instruction atomically launches a message into the network, preventing a user from occupying the network output indefinitely. The automatic translation provided by the GLTB ensures that a program may only send messages to virtual addresses within its own address space. Finally, restricting the set of user accessible DIPs prevents a user handler from monopolizing the network input. If an illegal DIP is used, a fault will occur on the sending thread before the message is sent.

Throttling: In order to prevent a processor from injecting messages at a rate higher than they can be consumed, the M-Machine implements a *return-to-sender* throttling protocol. A portion of a local node's memory

(a) Message Send

```
LOAD    A[0], MC1          ;  load A[0] into message composition register 1
SEND    Raddr, Rdip, #1    ;  send a remote store message to the processor
                           ;  containing VA Raddr, with a 1 word body
```

(b) Message Receive

```
loop:  JMP     Rnet              ;  jump to DIP (remote write) when message arrives

       ;  start of remote write code
       MOVE    Rnet, R1          ;  move virtual address into R1
       STORE   Rnet, R1          ;  store the body word of the message into memory
       BRANCH  loop              ;  branch back to message dispatch code
```

Figure 7: Example of M–Machine code implementing a remote store: *(a)* Sending a 3 word remote store message. *(b)* Receiving and performing the store.

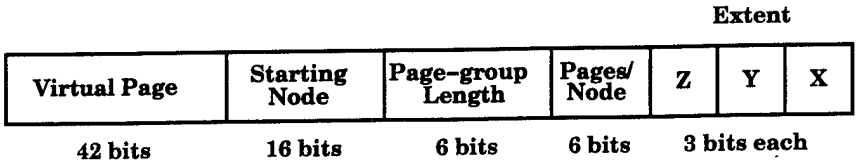

Figure 8: Format of a Global Destination Table (and GTLB) entry, used to determine a physical node identifier from a virtual address.

is used for returned message buffering. When a message is sent, a counter is automatically decremented, which reserves buffer space for that message, should it be returned. If the counter is zero, no buffer space is available and no additional messages may be sent; threads attempting to execute a **SEND** instruction will stall. When the message reaches the destination a reply is sent indicating whether the destination was able to handle the message. If the message was consumed, the reply instructs the source processor to increment its counter, deallocating the buffer space. Otherwise, the reply contains the contents of the original message which are copied into the buffer and resent at a later time.

Discussion: The M–Machine provides direct register-to-register communication, avoiding the overhead of memory copying at both the sender and the receiver, and eliminating the dedicated memory for message arrival, as is found on the J–Machine [6]. Register-mapped network interfaces have been used previously in the J-Machine and iWarp [2], and have been described by *T [20] as well as Henry and Joerg [11]. However, none of these systems provide protection for user-level messages.

Systems, like the J-Machine, that provide user access to the network interface without atomicity must temporarily disable interrupts to allow the sending process to complete the message. The M–Machine's atomic **SEND** instruction eliminates this requirement at the cost of limiting message length to the number of cluster registers. Most messages fit easily in this size and larger messages can be packetized and reassembled with very low overhead.

Automatic translation of virtual processor numbers to physical processor identifiers is used in the Cray T3D [5]. The use of virtual addresses as message destinations in the M–Machine has two advantages. When combined with translation hardware, it provides protection for user initiated messages, without incurring the overhead of operating system invocation, as messages may not be sent to processors mapped outside of the user's virtual address space. It also facilitates the implementation of global shared memory. The interleaving performed by the GTLB, although not as versatile as the CRAY T3D address centrifuge or the interleaving of the RP3 [21], provides a means of distributing ranges of the address space across a region of nodes.

In contrast to both *T and FLASH [14] which use a separate communication coprocessor for receiving messages, the M–Machine incorporates that function on its already existing execution resources, an H–Thread in

the event V-Thread. This avoids idling resources associated with a dedicated processor. During periods of few messages, user threads may make full use of the cluster's arithmetic and memory bandwidth.

4.2 Non-Cached Shared Memory

Fast access to remote memory is provided transparently to the user with a combination of hardware and software mechanisms. When a load or store operation causes a Local Translation Lookaside Buffer (LTLB) miss, a software trap is signalled. Like the hardware dedicated to message arrival, one H-Thread in the *event* V-Thread is reserved for handling LTLB misses. The LTLB miss handler code probes the GTLB to determine where the requested data is located, and if necessary, sends a message to the destination node. If the data is in fact local, the LTLB miss handler fetches the required page table entry and places it in the LTLB. Using a small portion of the execution resources for fast trap handling reduces the latency of both local LTLB misses and remote data access.

The sequence of operations required to satisfy a remote memory load is shown below. The labels *HW* and *SW* indicate whether the action is performed by hardware or software.

1. *HW*: Memory operation accesses the cache and misses (2 cycles).
2. *HW*: LTLB miss occurs, enqueueing an event (2 cycles).
3. *SW*: Software accesses the local page table (LPT), probes the GTLB, and composes and sends a message containing the referenced and return addresses (48 cycles).
4. *HW*: Message delivered to remote node (5 cycles).
5. *SW*: Message handler fetches requested data from memory, formats a reply message, and sends it (29 cycles).
6. *HW*: Return message delivered (5 cycles).
7. *SW*: Message handler decodes the original load destination register and writes the data directly there (41 cycles).

Timelines for both remote read and write accesses are shown in Figure 9. These measurements are estimates based on prototype message and event handlers running on the M-Machine simulator. A user level program running on node 0 makes read and write requests to memory on neighboring node 1. Except for the message handler that runs on demand, node 1 is idle. All references to memory system data structures in the software handlers are assumed to cache hit.

Table 1 shows a comparison of preliminary results of local and remote access latencies (in cycles). A read is completed when the requested data has been written into the destination register. A write is completed when the line containing the data has been fully loaded into the cache. The remote read and write accesses are larger than their local counterparts due to the software intervention required to send the message to the remote node. However, the time to perform a remote read that hits in the cache is only a twice as large as a local read that requires software intervention (LTLB miss). For the remote write, which does not require return data, the difference is only 10%.

	Access Times (cycles)	
Access Type	READ	WRITE
Local Cache Hit	3	2
Local Cache Miss	13	19
Local LTLB Miss	61	67
Remote Cache Hit	138	74
Remote Cache Miss	154	90
Remote LTLB Miss	202	138

Table 1: Comparison of local and remote access times, assuming no resource contention.

4.3 Caching and Coherence

Even though remote accesses are fast, their latency is still large compared to local memory references. This overhead reduces the ability of the MAP to use the network and remote memory bandwidth effectively. To reduce overall latency and improve bandwidth utilization, each M-Machine node may use its local memory to cache data from remote nodes.

In addition to the virtual to physical mapping, each LTLB (and LPT) entry contains 2 status bits for each cache block in the page. These ***block status*** bits are used to provide fine grained control over 8 word blocks, allowing different blocks within the same mapped page to be in different states. This fine grained control over data is similar to that provided in hardware based cache coherent multiprocessors, and alleviates the false sharing that exists in other software data coherence systems [16]. The two block status bits are used to encode the following four states:

- `INVALID`: The block may not be read, written, or placed in the hardware cache.
- `READ-ONLY`: The block may be read, but not written.
- `READ/WRITE`: The block may be read or written.
- `DIRTY`: The block may be read or written, and it has been written since being copied to the local node.

One software policy that uses the block status bits fetches remote cache blocks on demand. When a memory reference occurs, the block status bits corresponding

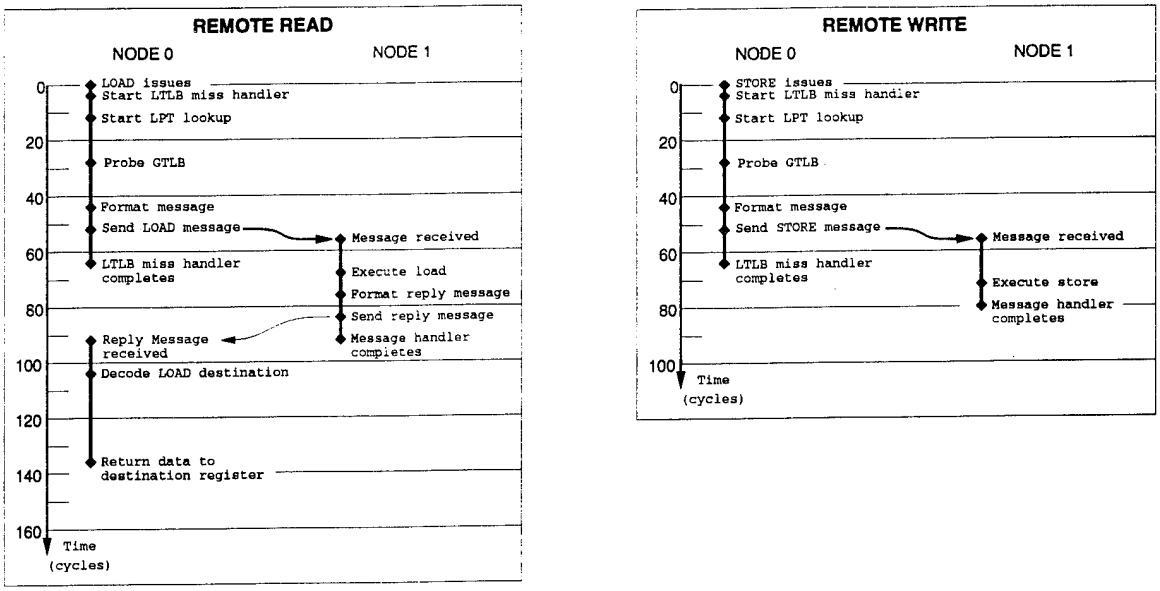

Figure 9: Timeline for remote read and write accesses.

to the global virtual address are checked in hardware. If the attempted operation is not allowed by the state of the block, a software trap called a *block status* fault occurs. The trap code runs in the event V–Thread, in the H–Thread that is reserved for handling block status and synchronization events. The block status handler sends a message to the home node, which can be determined using the GTLB, requesting the cache block containing the data. The home node logs the requesting node in a software managed directory and sends the block back. When the block is received, the data is written to memory and the block status bits are marked valid. If the virtual page containing the block is not mapped to a local physical page, a new page table entry is created and only the newly arrived block is marked valid. The remote data may be loaded into the on-chip cache, and modifications to the data will automatically mark the block state dirty. More complex coherence schemes can map blocks from different virtual pages into the same physical page, reducing the amount of unmapped physical memory.

The software handlers used to transmit data from node to node may implement a variety of coherence policies and protocols. This code is easily incorporated within the remote read and write handlers described in Section 4.2. Using local memory as a repository will allow remote data to be cached locally beyond the capacity of the local on-chip cache alone.

Discussion: Directory-based, cache coherent multiprocessors such as Alewife [1] and DASH [15] implement coherence policies in hardware. This improves performance at the cost of flexibility. Like the M–Machine, FLASH [14] implements remote memory access and cache coherence in software, but uses a coprocessor. However, this system does not provide block status bits in the TLB to support caching remote data in DRAM. The subpage status bits of the KSR-1 [7] perform a function similar to that of the block status bits of the M–Machine.

Implementing a remote memory access and coherence completely in software on a conventional processor would involve delays much greater than those shown in Table 1 as evidenced by experience with the Ivy system [16]. The M–Machine's fast exception handling in a dedicated H–Thread avoids the delay associated with context switching and allows the user thread to execute in parallel with the exception handler. The GTLB avoids the overhead of manual translation and the cost of a system call to access the network. Finally, the M–Machine provides memory-mapped addressing of thread registers to allow the operation to be completed in software.

The major contributors to remote access latency in the M–Machine are the search for the faulting address in the local page table and decoding the reply message (about 40 cycles each). The page-table overhead is only incurred when accessing the first block of a page. Access to subsequent blocks cause block-status faults (rather than page faults) which skip the page-table access. The reply decode could be accelerated by prohibiting the faulting V–Thread from swapping out during the memory operation. However, this would complicate scheduling and remote handling of potentially long latency syn-

chronizing memory operations.

5 Conclusion

In this paper we have described the architecture of the M–Machine with an emphasis on its novel features. The M–Machine is a 3–D mesh, each node of which contains a multi-ALU processor (MAP) and 8 MBytes of synchronous DRAM. Each MAP chip consists of four 64-bit 3-issue clusters connected by a cluster switch, a 4-way interleaved on-chip cache, an external memory interface, and on-chip network interfaces and routers.

Instruction level parallelism is exploited both within a cluster and across clusters using H–Threads. An H–Thread may communicate and synchronize through registers with H–Threads on different clusters but within the same V–Thread. A 27 point stencil computation on 4 H–Threads (12-wide issue) has a static instruction length half that of 1 H–Thread (3-wide issue).

To increase use of the local memory and execution bandwidth, multiple tasks, called V–Threads, are interleaved on a cycle-by-cycle basis independently on each of the clusters. Each cycle, a different thread may be selected for execution, or if only one V–Thread is resident, it may issue an instruction every cycle on each cluster.

The M–Machine has a user–level, protected, fast message passing substrate to reduce communication and remote memory latencies. Messages are composed in general registers and sent via a user level **SEND** instruction. Arriving messages are extracted by a system-level software message dispatch handler, which is always resident in the *event* V–Thread. The message contents are accessed via a register mapped queue. The message need not be copied to or from memory on either the sending or receiving side. Two level translation is used to independently relocate objects in the physical address space on a node, and in the processor namespace.

The fast message system is used to provide the user with transparent access to remote memory. When a user's load or store instruction traps to software on a LTLB miss, a message is sent to a remote node to perform the access. While slower than local accesses, a remote load can be satisfied in 138 cycles, while a remote store can be satisfied in 74 cycles. In order to facilitate local caching of remote data, 2 status bits for each block (8 words) in a page are added to the LTLB and page table entries. When an invalid block is accessed, a trap to software occurs which can retrieve the missing block from a remote node, copy it into local memory, and mark the status bits valid.

A cycle-accurate simulator of the M–Machine has been completed and is being used for software development. M–Machine software is being designed and implemented jointly with the Scalable Concurrent Programming group at Caltech. The Multiflow compiler [17] is being ported to the M–Machine to generate long instructions spanning multiple clusters. It is currently able to generate code for a single cluster. A prototype runtime system consisting of primitive message and event handlers has also been implemented. The hardware design of the MAP is currently underway; 80% of the modules have been designed at the RTL level and some layout has begun. The MAP will be implemented on a single integrated circuit with a projected area of $17mm \times 18mm$ in $0.5\mu m$ CMOS with 5 metal layers. Tapeout is expected in 1996.

The M–Machine addresses the issues of non-uniform technology scaling and of programmability. By changing the ratio of processor to memory area, the M–Machine better balances cost and improves the utilization of the increasingly critical memory bandwidth. The M–Machine increases the ratio of processor to memory silicon area to 11% from 0.13% for a typical 1996 system. A 32–node (128 clusters) M–Machine with a total of 256 MBytes of memory requires 50% more area than a uniprocessor with the same amount of memory but provides 128 times as much peak performance, a 85:1 improvement in peak-performance/area. This increase in processing resources allows the M–Machine to saturate the costly DRAM bandwidth even for problems with good locality and thus runs programs faster allowing a fixed-size memory system to run more programs per unit time. The 85:1 improvement in peak-performance/area makes the increased parallelism of the M–Machine cost effective even in cases where only a small fraction of its peak performance is realized.

The M–Machine addresses the problem of parallel software by supporting an incremental approach to parallelization. Unlike conventional parallel machines, the M–Machine can efficiently run a sequential program that uses all the machine's memory, including that on remote nodes. A shared address space, high-performance messaging, and caching remote data in local DRAM provide fast access to remote data. The sequential program can then be divided into tasks, such as loop iterations or subroutines, that can be executed in parallel. The ability to support fine-grain parallelism increases the number of suitable tasks and allows extraction of more parallelism from small problems. Support for synchronizing memory operations and global addressing simplifies user-level communication and synchronization between tasks and reduces overhead. Caching in DRAM automates much of the data placement and migration problem. For the cases where a programmer wants to extract the maximum performance, fast, protected, user-level messages may be employed.

We expect that the architecture concepts demonstrated in the M–Machine will be useful in machines ranging from single-node personal computers, through workstations with tens of nodes, to servers with hun-

dreds to thousands of nodes. Memory bandwidth and capacity are becoming the dominant factor in the cost and performance of systems of all scales. By changing the processor/memory ratio, providing methods for extracting parallelism at all levels, and supporting an incremental approach to parallelism, the M-Machine's mechanisms will lead to more cost effective and programmable machines across the price-performance spectrum.
