ABSTRACT

The Infrared Astronomy Satellite (IRAS) was launched and operated during a 10-month period in 1983. The orbit was close to the MSX orbit design, but the science data were collected in a mode where the focal plane was pointing directly away from the Earth. Using the raw data tapes, the Space Research Institute at Groningen, Netherlands, collected approximately 139,000 tracks of data that had focal plane motion different than astronomical sources, and the IRAS Processing and Analysis Center (IPAC) determined the boresite pointing of IRAS to within 20 arcsec. This report will focus on the nonastronomical detections from IRAS, many of which are Resident Space Objects (RSOs). In particular, the focus of the study is on how many are correlated to the known RSO catalogue for 1983 and the calibration and characterization of the metric accuracy for the correlated data. This study was undertaken to prepare for analysis of RSO detections from the MSX satellite and, in particular, so that automatic analysis tools designed for analysis of surveillance experiment data could be tested. The supporting analysis tools, required corollary data, and metric calibration procedure will be described, and the results of the accuracy of the IRAS ephemeris and metric RSO detections will be presented.

1. INTRODUCTION

The Infrared Astronomy Satellite (IRAS) was launched in early 1983 and operated for a 10-month period to collect repeated observations of the star background in four infrared wavelengths: 12, 25, 60, and 100 μ . The orbit was selected to be near-circular with a 103-min period close to a sun-synchronous inclination of 99 deg. IRAS always pointed its focal plane away from the Earth and used a scan rate of 3.85 arcmin/s, which is slightly faster than the orbital motion. This way a stellar point source will go through several detectors during a typical scan.

Processing of the IRAS raw data (aimed at extracting all inertially fixed point source detections) was carried out at the IRAS Processing and Analysis Center (IPAC) at the Jet Propulsion Laboratory (JPL) and involved three aspects of a metric screening process: a "Seconds Confirmation" test, an "Hours Confirmation" test, and a "Weeks Confirmation" test. The Seconds Confirmation test verified that a point source traveled across the IRAS focal plane during a scan at the predicted rate (3.85 arcmin/s) and in the predicted (in-scan or "image") direction. The success of this test indicated that the point source was a large distance away from the IRAS platform and was probably astronomical in nature. The Hours Confirmation test verified that the point source was observed again after a full orbit of IRAS was completed and the focal plane was looking in the same part of the sky as before. This test indicated that the point source is moving very slowly with respect to the IRAS focal plane and is probably a very large distance away. The Weeks Confirmation test was used when (after several weeks) IRAS was again directed to look in the same part of the sky as the first detections. IRAS was designed to repeat coverage of the sky three times during the 10-month mission. About 96% of the sky was visited at least twice, and about 76% of the sky was visited a third time. If the Seconds, Hours, and Weeks Confirmation tests were all passed, then the point source was considered to be inertially fixed upon the sky. Those that fail the Weeks Confirmation test can be asteroids or some other astronomical point source at a large distance from the IRAS focal plane, and those that fail the Hours test can be faster-moving asteroids, pieces from comets, or other space debris particles. Those that fail the Seconds Confirmation test (that is, they have a focal plane rate different than 3.85 arcmin/s and in possibly a different direction than the in-scan direction) are possibly artificial Earth satellites, known as Resident Space Objects (RSOs), and can be close to the IRAS focal plane. An onboard procedure attempted to preclude data on particles or infrared sources very close to the IRAS focal plane, and therefore, if an RSO was observed by IRAS, it would typically be seen at a range of 1000 km or greater.

The potential RSO observations from this last category of point sources become the focus of this study, and several questions are to be addressed. First, how many of these potential RSOs were observed by IRAS, and how many are correlated to the known RSO catalogue from 1983? Second, what is the metric accuracy of the correlated RSO detections and metric error budget for the reduced data, and how can the metric data be calibrated? Third, how reliable are the uncorrelated detections to provide an observed sample of the 1983 debris population?

This study was undertaken to prepare for analysis of surveillance experiment data from the Midcourse Space Experiment (MSX) satellite program [1]. The MSX is scheduled for launch in 1995 and is a space flight program designed, in part, to demonstrate surveillance of space and the RSO background from space. The technical challenges include cryogenic technology for cooling an infrared sensor: low-

noise, high-performance focal planes; high, off-axis, stray-light rejection optics; on-orbit signal processing and data compression; and contamination control. The orbit is specified to be 900-km altitude, circular, at nearly a sun-synchronous inclination of 99.23 deg. The lifetime of the infrared sensor is expected to be 20 months, and the visible and ultraviolet sensors have a planned operation period of 60 months. The infrared sensor has a five-band scanning radiometer (from 4.3 to 26 μ) with a 14-in telescope. The pixel size is 90 μ rad, and there will be an onboard signal and data processor for compression and data processing. The IRAS nonastronomical data become a real space-based data source for testing the automatic analysis tools designed for MSX RSO detections, and all facets of the analysis are involved. The suite of test data from IRAS includes potential RSO detections from the IRAS sensor, a precise ephemeris for the IRAS platform, and supporting corollary data such as a catalogue of RSO element sets updated for each observation day of 1983 and independent metric observations on each RSO that IRAS observed. Each of these aspects of the analysis will be described, and the calibration of the IRAS detections and results from an automatic analysis of the data will be presented.

2. CALIBRATED IRAS METRIC OBSERVATIONS

2.1 REDUCTION OF FOCAL PLANE DETECTIONS TO INERTIAL COORDINATES

Detected point sources that could be potential observations of RSOs are those that have different (and often faster) focal plane motion from the scan rate of 3.85 arcmin/s. Often these sources will also have a focal plane direction different from the in-scan direction, although this is not a necessary condition. The Seconds, Hours, and Weeks Confirmation tests were designed to glean from the "hundreds of thousands of detections per day" the inertially fixed sources [2], and in this way a series of metric tests can be used. In this current study, however, where the sources are not inertially fixed upon the sky, there is no metric test that can indicate whether the detections are noise, radiation hits or infrared sources near (or from) the spacecraft (such as material emitted by IRAS itself), or actual RSOs. The Space Research Institute at Groningen, Netherlands, collected approximately 139,000 tracks of IRAS data (involving nearly 520,000 individual detections) that satisfied the following properties: (a) the focal plane motion was different than the 3.85 arcmin/s scan rate, (b) the timing of three or more detector hits was consistent with a single in-scan velocity, and (c) each detector had an observed flux value of 0.1 Jy or more [3]. This data base, referred to as the "debris data base," was designed to capture all possible RSO detections (and in particular debris measurements). The debris data base used the raw IRAS data (at IPAC), and for each track that passed the above criteria, the following data were provided: the absolute time a track passed a line through the boresite perpendicular to the image direction, the flux value and detector identification for each detection recorded, and the in-scan velocity across the focal plane. No 100- μ detector values were included in the debris data base.

Figure 2.1 (extracted from Beichman et al. [2]) displays the focal plane detector suite. The absolute time given with each track is when the streak crosses the imaginary vertical line going through the boresite (denoted by the + symbol). Note that a detector can be up to 4.75 arcmin long and up to 1.51 arcmin wide. For this study, absolute time and position in the focal plane for each observation from a detector are required, and therefore the following calibration of the data from the debris data base was performed. The center of each detector belonging to a track was selected for a set of initial points, and a line was fit in a least-squares fashion to these positions. If the line went through a lit detector, then the calibrated focal plane position was taken to be the point on the line halfway through the detector on the line. If the line was off of the detector, then the nearest corner of the detector was chosen as the focal plane position. With the in-scan velocity provided in the data base, the relative time of the observed point on a detector was determined by calculating the distance of the point to the absolute reference time line along the track and dividing by the in-scan velocity. This method provides the number of seconds from the absolute reference time, and the absolute time of each detection in the track can thereby be determined. The image direction is perpendicular to the ecliptic plane, and therefore the declination direction is skewed from the image direction by the inclination of the ecliptic. Figure 2.1 shows that the image direction is horizontal from right to left. The right ascension direction is skewed from the cross-scan direction by the same amount, and since the detectors are longest in the right ascension direction and no information is contained in the data base concerning the resolution of an observation on a detector, the right ascension measurements can be more noisy than the declination due to the uncertainty of the position on the detector in the cross-scan direction.

Figure 2.1. The IRAS focal plane and suite of detectors (from Beichman et al. [2]).

An example of an IRAS track and the calibration procedure described is presented below. Table 2.1 gives relevant data pertaining to IRAS Track #664140. (The IRAS Track ID numbers listed here are artificial designators and do not correspond to other listings.) This track was collected on Day 258 of 1983, and an in-scan velocity of 4.46 arcmin/s was recorded. Table 2.1 shows that there were eight detections involved in the track, and for each detection the following data are given: time from the first detection, detector number, wavelength of the detector, the recorded flux (in Janskys), the calibrated position in the X (or cross-scan) and Y (or image) directions, and the boundaries of the detector in the X and Y directions. Position units are given in arcminutes on the focal plane from the boresite. The position data are plotted in Figure 2.2, where the graph has been oriented in a similar fashion to the map of the focal plane in Figure 2.1. The center of each detector is highlighted by the triangle symbol, and the calibration positions

are denoted by squares. Note that the curve fit to the calibrated positions is not a straight line since a line fit to the centers of the detectors would not go completely through Detectors 54 and 18. In these instances, the edge of the detectors are chosen as the calibrated focal plane positions.

Once the absolute focal plane position for each IRAS detection is determined, calibrated boresite pointing data are used to transform the data to inertial right ascension and declination measurements. Figure 2.3 (extracted from Beichman et al. [2]) shows the IRAS control axes with respect to the sun. The Y axis is the boresite axis with the angle ψ determining the scan rate. The angle θ completes the orientation of the focal plane in this reference system. During a viewing scenario, θ remained roughly constant, and ψ changed in a nearly linear fashion. If ψ and θ are known, then the inertial position of any point on the focal plane can be determined by first rotating the point on the focal plane to the solar reference frame and transforming this frame to the inertial frame using the known apparent ephemeris of the sun about the Earth. These values were determined for the entire mission by IPAC as a result of an intensive analysis of the IRAS onboard attitude sensors and stars observed by IRAS. An estimated 1-sigma accuracy of these values is 10 to 20 arcsec (or 4 to 8 mdeg) [4]. IPAC supplied the pointing for each time in the debris data base.

Mathematically, if (x,y) denotes a focal plane position, and $\mathbf{w}$ denotes a unit vector in the IRAS focal plane coordinate frame $\mathbf{w} = (-x, y, z)$ (with $z^2 = 1 - x^2 - y^2$), then one can derotate the vector $\mathbf{w}$ using the boresite reference angles ψ and θ for the specified time

$$\mathbf{v} = R_3(-\theta) R_2(-\psi) \mathbf{w} \quad ,$$

and calculate angles ψ' and θ' in the sun-reference coordinate frame depicted in Figure 2.3 for the point (x,y). These angles are calculated as $\theta' = \tan^{-1} [v(2)/v(1)]$ and $\psi' = \cos^{-1} [v(3)]$ and can be transformed to the inertial coordinate frame using the position of the Sun with respect to the inertial frame.

Figure 2.2. Plot of data in Table 2.1 providing an example of an RSO streak across the IRAS focal plane (units are in arcminutes).

2.2 PROBLEMS WITH REDUCTION AND SCREENING OF THE DATA

A significant problem with the way the debris data base has been collected is that if even one detector in a track is falsely lit (as is possible from the radiation sources mentioned above or because a detector is behaving in a noisy fashion), then the fit of the line to all the detections in the track can be thrown off, and the calibrated positions of each of the other detectors can be in error. In fact, this is entirely possible. Most of the detectors in the focal plane have a measured response for the mean rms noise floor of 0.15 to 0.2 Jy, and some of the detectors exhibited a measured mean rms noise value of > 0.3 Jy [2]. A histogram of the Noise Equivalent Flux Density (NEFD) of the detectors is given in Beichman et al. and reproduced below in Figure 2.4. These data were collected on-orbit to estimate the 1-sigma noise for a single sample. Since the debris data base had used a noise floor of 0.1 Jy (in the hope of gathering all the orbital debris data), it is opened up to the possibility of a large amount of spurious data with no means of screening the tracks metrically.

Figure 2.3. The IRAS spacecraft control axes (X , Y , and Z) as referred to the sun and North Ecliptic Pole [labeled $X(S)$, $Y(S)$, and $Z(S)$], (from [2]).

An excellent example of a track plagued by this problem is shown in Table 2.1. Detectors 22 and 15 both have flux values close to 0.2 Jy. This is dangerously close to the noise floor for both of these detectors, as shown in Figure 2.4. If these were spurious detections, then the calibration procedure plotted in Figure 2.2 would be very different for the remaining data points in the track. This would alter each of the calibrated positions as well as the in-scan velocity, which affects the absolute time. The track presented in Table 2.1 has been correlated to the known geosynchronous RSO SSC #14158, and it was observed by IRAS at a range of over 35,000 km. An independent orbit for this RSO has been calculated, and metric residuals determined by comparing the orbit with the calibrated inertial positions are shown in Table 2.2. The two low-flux detections at the end of the track could contribute to the large deviation in the position data compared to the orbit. The biases are most likely due to boresite pointing error.

Unfortunately, tracks like this example are not rare. Combinatorial statistics from the IRAS debris data base are shown in Table 2.3. More than 47% of the observations involve flux values < 0.6 Jy, and more than 77% have flux values of < 1 Jy. Moreover, more than 26% of the tracks have an in-scan velocity < 4 arcmin/s, and these tracks are more likely to be astronomical objects rather than RSOs. (The typical geosynchronous RSO will have an in-scan velocity between 4.5 and 4.6 arcmin/s.)

The noisy response functions from the detectors make it difficult to screen out bad data using the radiometric flux measurements. A 3-sigma value for confidence in the flux measurements implies that most measurements have an uncertainty of 0.6 to 1 Jy. These figures question the reliability of tracks of small-sized objects (such as debris), where flux values < 1 Jy are typical. Moreover, the sensitivity of the

detectors precludes screening tracks by temperature (as determined by ratios of flux measurements from the different wavelength passbands) since uncertainties of this level can produce temperature deviations as much as 50% for faint targets.

Figure 2.4. Histograms of NEFDs under quiescent conditions (from Beichman et al. [2]). The detector number is indicated in each box.

TABLE 2.2**Metric Residuals from Comparing an Independent RSO Orbit with IRAS Track #664140**

Time (Days from 1983) Object# ra bias ra σ dec bias dec σ			
258.5704843985 14158 -16.5 11.8 -11.8 2.4			

TABLE 2.3**Combinatorial Statistics from the IRAS Debris Data Base****(In-scan velocity limits are given in arcmin/s and flux limits are given in Janskys)**

Category	Number	Percentages
Observations (Total)	519988	
Tracks (Total)	138902	
Days	277	
Tracks with In-Scan Velocity < 4	36321	26.15%
Tracks with In-Scan Velocity ≥ 4 and < 6	41222	29.68%
Tracks with In-Scan Velocity ≥ 6	61359	44.17%
Observations with Flux Value < 0.6	244454	47.01%
Observations with Flux Value ≥ 0.6 and < 1.0	156960	30.19%
Observations with Flux Value ≥ 1.0 and < 1.5	65085	12.52%
Observations with Flux Value ≥ 1.5	53489	10.29%

It appears then that only a metric confirmation (of a track with an orbit of a known RSO) can be made on tracks containing flux values < 0.6 Jy, and observed RSOs with flux values > 1 Jy are generally bigger than small (centimeter-sized) debris. It will be demonstrated that IRAS did see a large number of known RSOs from ranges of 1000 km to the geosynchronous orbit range of 35,000 km, but one cannot say with any measure of confidence what type of debris was seen (or how many debris measurements are available).

2.3 THE METRIC ERROR BUDGET FOR THE REDUCED DATA

The timing estimate for each detection is made by estimating the response function near 1-sec boundaries and taking the absolute time to fall at the peak of the response function [2]. The error from this procedure should be no worse than 10 msec, which translates into an ephemeris error of at most 70 m. This affects the accuracy of the data in a worst-case scenario as follows: at 1000-km range, a 70-m ephemeris error will produce an observed angle error of 4 mdeg.

For tracks with no erroneous measurements, a bias in the reduced right ascension and declination measurements will be induced by the error in boresite pointing (4 to 8 mdeg). For worst-case scenarios, the standard deviation of the individual error can be up to 0.7 arcmin (12 mdeg) in the in-scan direction and up to 2.5 arcmin (42 mdeg) in the cross-scan direction. If the track contains data from four or more separate detectors, then the bias error will remain the same, but the standard deviation of the error can be smaller by a factor of 2. If there are one or more false detections in a track, then the error from a good measurement can increase to 5 arcmin (or 83 mdeg) in the cross-scan direction, but most likely these tracks will show up with large standard deviations because the track is skewed to include the erroneous data.

A summary of the metric error budget for IRAS observations is provided in Table 2.4. This table shows the error source, a worst-case estimate for the error, when the worst case can be realized, a normal-case estimate, and assumptions assumed for the normal-case error. In each category, the root of the sum of the squares (rss) of the errors is provided. Table 2.4 shows a worst-case metric error for an individual IRAS observation is 80.7 mdeg with a normal case 10.8 mdeg.

TABLE 2.4
The Metric Error Budget for IRAS RSO Observations

Error Source	Worst Case	Worst-Case Description	Normal Case	Normal-Case Description
Time Error	4.0 mdeg	10-msec error at 1000-km range	0.4 mdeg	10-msec error at > 10,000-km range
IRAS Ephemeris	5.7 mdeg	100-m error at 1000-km range	0.3 mdeg	40-m error at > 10,000-km range
Pointing Error	8.0 mdeg	upper pointing error limit	4.0 mdeg	lower pointing error limit
Focal Plane Position	80.0 mdeg	4.75-arcmin position error due to erroneous parts of the track	10.0 mdeg	1/2-arcmin position error
Total Error	80.7 mdeg		10.8 mdeg	

3. THE PRECISE IRAS PLATFORM EPHEMERIS

To perform a precise metric analysis of IRAS observations, a precise ephemeris of the IRAS platform is necessary for any time of interest. This was not a prime requirement for IPAC and for performing an analysis of inertially fixed point sources and other slowly changing astronomical data from IRAS, but a precise platform ephemeris is critical in analyzing the metric accuracy of RSO detections. To obtain a precision ephemeris for IRAS, it was necessary to collect metric measurements of IRAS throughout the 10-month operational life. The archives of NAVSPASUR and the SSC¹ were utilized to obtain all of the available tracking data on IRAS throughout 1983. Precision orbits were fit to the data using 8-day arcs with 1-day overlaps. A special perturbations orbit determination routine, called DYNAMO, was used for this job with an accurate model of the gravitational and nongravitational forces acting on IRAS. Attributes of the DYNAMO orbit determination package are given in Figure 3.1.

The IRAS focal plane was cooled to 3 to 4 deg Kelvin using a liquid helium cryostat, which sublimated and vented as the operation period proceeded. This produced a small thrust on the platform of IRAS, which had to be modeled in the orbit-fitting procedure. This was modeled as a thrust in the along-track direction whose value was constant and estimated as a free parameter for each day of the weekly fit. To avoid correlation between the estimation of the along-track thrust effect and scales for the effect of atmospheric drag and the effect of solar radiation pressure, the area-to-mass ratio and scales were held fixed and constant throughout. Earthshine pressure was also included in the nongravitational force model for IRAS. The gravitation model included the geopotential to degree and order 20, the sun and moon, and solid Earth and ocean tides.

Table 3.1 presents the results of comparing adjacent weekly fit 1-day overlaps over the entire time period of interest, from Day 26 to 334, 1983. The average and maximum magnitude errors for the differenced position vectors are displayed for each day that an overlap test was performed. Most of the 1-day overlaps show an average magnitude error of about 60 m with a maximum of 100 m, but there are occasional instances where the average is as large as 500 to 700 m with a maximum error of close to 1 km. The data tabulated actually represent a worst case since the comparisons are made at the ends of each fit interval, which have the largest error. To show a typical weekly fit comparison result, the errors for 1-min spacing in the radial, along-track, and cross-track components for the Day 138 overlap are plotted in Figure 3.2. Note the comparison of the plots of the Day 250 overlap errors shown in Figure 3.3, which represent the worst case from Table 3.1. In Figure 3.3 large amplitudes in the 1-min sampling of the component errors are seen.

The reason for the large anomalies in Table 3.1 is not well understood, but it can be speculated that they are tied to the ability of the orbit-fitting procedure to model the thrust from the cryogen depletion. Figure 3.4 shows a plot of the daily fit along-track thrust value, which was used to model the cryogen depletion effect for IRAS. The value plotted over the 10-month life of IRAS is the thrust value in 10^{-6} dynes. Although the noise in the fit is extensive for the first week, the thrust value settles down to nearly a constant value, and the noisier aspects of the plot can be correlated to the periods in Table 3.1 with the

¹ We thank J. Liu and B. Morris for providing the data.

largest overlap errors. Also, the cryogenic effect on the orbit is seen dying down to nothing after the liquid helium has been entirely depleted (after Day 322). The difficulty the orbit-fitting procedure has in determining an accurate thrust value on certain days may be tied to the number and accuracy of the observed data used in the fit or else correlated nongravitational effects such as changes to the platform attitude.

The estimated error for the accuracy of the position of IRAS for an arbitrary time during the mission is 40 m, and values enlarged by an order of magnitude are likely in worst-case scenarios. As discussed in Section 2 and shown in Table 2.4, a 100-m ephemeris error during a worst-case observation scenario of 1000-km range will produce an angle error on the order of 5.7 mdeg.

4. THE AUTOMATIC ANALYSIS DATA FLOW

The IRAS metric data were analyzed with automatic software in the MSX Surveillance Data Analysis Center (SDAC) called the Metric Pipeline. Its job is to characterize the accuracy of metric data supplied to the pipeline. It utilizes Uncorrelated Target (UCT) processing to tag the data, independent metric observations from the U.S. Air Force Space Surveillance Network (SSN), and analytic orbit determination to provide an initial orbit as a front end for follow-on precision orbit determination. Residuals of the test data from the precision orbit determination are then isolated and sent to a data base for the analyst to consider pass statistics. Figure 4.1 illustrates the data flow.

First, a UCT processor is invoked to attempt to correlate every metric observation to the known RSO catalogue, and any observation that does not correlate will be removed from additional processing. The UCT processor utilizes an algorithm referred to as "Elsets-to-Observations" correlation, which uses a series of filters with a known catalogue of RSO element sets to correlate the observations. A data flow is given in Figure 4.2. The coarse filter is used to weed out most of the element sets very quickly, and the UCT processor is able to do this by keeping all of the element sets in memory and using a quick propagator to determine rough pointing from the proper sensor for comparison with an observation at the time of interest using coarse tolerances. The few that pass the coarse filter are sent to a fine propagator to determine an RSO element set that best agrees with the observation to within fine tolerances.

What remains are sets of observations that have tags associating them with known RSOs. As shown in Figure 4.1, each set of IRAS metric observations on a particular object will follow a multistep procedure to characterize the metric accuracy of the data. All other SSN metric data on the particular RSO within, say, ± 20 revolutions of the object's orbit will be retrieved. The most recent element set on the object from the RSO catalogue data base will be retrieved. The element set will be fit to the SSN metric data using a least-squares algorithm tied to an analytic propagation model. This is done using a software package called ANODE, and its attributes are provided in Figure 4.3. ANODE is able to produce a good starting estimate for a DYNAMO orbit fit (see Figure 3.1). Pass statistics from the precision orbit of the target compared to the IRAS metric data form the basis for assessing the quality of the data.

Much of the challenge in automating the pipeline procedure is to stop, check, and restart the orbit-fitting algorithms in case of failure or nonconvergence. In some instances, ANODE and DYNAMO can fail to converge due to the presence of bad or mistagged data or because there was a maneuver during the fit interval. In cases of nonconvergence, a result produced by ANODE or DYNAMO can be worse than the catalogue initial conditions. Force modeling is determined automatically, and ANODE and DYNAMO are both asked to fit free parameters to model nongravitational effects such as atmospheric drag and solar radiation pressure. In cases of sparse data for the orbit fit, the orbit-fitting software may be unable to determine a good orbit. To restart the orbit-fitting routines effectively, ten subintervals of the basic arc of data are utilized to avoid maneuver windows or tracks of bad data. These subintervals are outlined in Table 4.1. DYNAMO is not asked to fit an orbit for an RSO for which ANODE could not converge. If the DYNAMO orbit is still unable to converge with the provided data in one of the ten intervals, then the orbit is left for an analyst to work with interactively.

5. COROLLARY DATA TO SUPPORT THE ANALYSIS

In this section, the corollary data required to support the automatic metric pipeline will be outlined, and the source of the data in our processing will be specified. The SDAC automatic metric pipeline requires the IRAS observations in terms of right ascension and declination, a catalogue of RSO element sets for each day of the IRAS mission, and independent SSN metric observations on every object observed by IRAS.

A first pass of the UCT processor on the IRAS RSO detections was performed in late 1992 using catalogues of element sets for 1983 from the Millstone Hill radar archives [5]. However, these catalogues contain mostly deep-space satellites, and many of the satellites above the IRAS altitude and with a period < 225 min were not included. Moreover, Millstone does not routinely receive SSN metric data on these low- to midaltitude satellites. NAVSPASUR was requested to complete both the required element set data and the SSN metric data. Complete catalogues of RSO element sets for each day of 1983 (totaling over 4500 element sets per day) and archived metric data on all tracked objects for the year (totaling more than 570 Mbytes) were provided.²

The metric data from the NAVSPASUR archives from 1983 were not of the same quality that are available for the 1995 SSN. This fact clearly demonstrates the quality calibration work done over the past 12 years to enhance the SSN metric data and (as a by-product) the element set catalogue. The optical sensors in use during 1983 included GEODSS and the Baker-Nunn cameras. The latter produced poor quality angle data on the order of 10 to 30 mdeg, while GEODSS produced angle data with 5- to 10-mdeg accuracy, 1 sigma. Radar sites in use included the Millstone Hill radar, the ALTAIR radar, and Pirinlik, Turkey (the FPS-79). Pirinlik data were of poor quality, with range errors on the order of 60 to 100 m; Millstone data had a range quality of 5 to 10 m, with angle accuracy of 5 to 20 mdeg; and ALTAIR data were somewhat worse.

The density of the archived metric data provided by NAVSPASUR was smaller than when each object was tracked, to save on resources. To trim the amount of archived data, NAVSPASUR consolidated measurements from the tracks and made Earth-centered state vectors out of some of the tracks of observations. This has the effect of causing the precision orbit program to produce orbits of a poorer quality. Many of the orbits computed for characterizing the metric accuracy of an IRAS track are of a similar quality to the IRAS ephemeris itself, about 40 to 100 m. Thus, the reference orbits also contribute to the metric error budget as a bias in the residuals.

²The authors thank Robin Smith and the NAVSPASUR archives for providing the data.

6. RESULTS

A summary of the results from processing all of the IRAS data from the debris data base is shown in Table 6.1. The total number of RSO tracks based on a precision metric correlation, the number of days, the number of distinct satellites, the average and standard deviation of the tracks per day, and pass statistics for the tracks are tabulated. In this section, the following results are displayed: the average and standard deviation of the bias errors in both right ascension and declination for the tracks and the average and standard deviation of the standard deviations in both right ascension and declination for the tracks. All values for the statistics are given in millidegrees. As seen in Table 6.1, the average right ascension and declination bias errors are small, but there are large standard deviations for these values. Thus, the tracks sometimes exhibited very large biases (> 30 to 50 mdeg) and other times had smaller values. The average standard deviation in right ascension was about 10.9 mdeg, while the value for declination was considerably better (7.0). There is also a large value (close to 13 mdeg) in the standard deviation of these results in both right ascension and declination.

IRAS saw a wide variety of objects, including noncircular low-altitude orbits with apogees higher than the IRAS orbit. The metric error budget for IRAS data, which includes time and IRAS ephemeris errors, can be smaller for certain classes of objects. The time and errors from the IRAS ephemeris can be negligible for objects in geosynchronous orbit because the observation range exceeds $35,000$ km. Unfortunately, precision reference orbits for these objects are difficult to produce because of the lack of good quality angle-tracking data from the independent SSN sensors. Accurate range data is of less value for geosynchronous orbits if the angle tracking data have a metric accuracy of 10 mdeg or more. Nevertheless, it is interesting to consider all of the IRAS tracking data on geosynchronous RSOs. The data are tabulated in Table 6.2, showing that IRAS saw a large number of geosynchronous objects with much better declination accuracy and slightly better right ascension accuracy. The nature of the bias errors do not change for this category of objects, which suggests that the pointing and reference orbit errors may be the chief contributors.

The results in Table 6.2 are not as good as one might expect, due in part to a number of tracks plagued by some of the issues outlined in Section 2.2. Table 6.3 shows two sample IRAS tracks on the geosynchronous orbit SSC #13900. The IRAS track numbers are, respectively, #547347 and #547348. Table 6.3 shows the absolute time, the residuals in right ascension and declination, the detector number (for mapping on Figure 2.1), the wavelength of the detector (in microns), the range from IRAS, and the flux (in Janskys). Recall from Section 2.2 that noise values for most of the detectors were on the order of 0.2 Jy and can be as much as 0.3 Jy. All of the flux values for Track #547347 are greater than three times the noise floor, and the standard deviation of the data in right ascension is roughly 4 mdeg and about 2 mdeg in declination. Now consider Track #547348 and notice the small $60\text{-}\mu$ detector values (0.32 , 0.14 , and 0.29 Jy). These may corrupt the metric accuracy considerably by skewing the direction and the in-scan velocity and, consequently, the calibrated metric positions. However, when noticing the absolute time, the time at Detector 50 in Track #547347 and the time at Detector 50 in Track #547348 are only 0.071 sec apart. At a rate of 4.58 arcmin/s, the object would travel a distance of 0.32 arcmin, which leads one to believe that these two detections are part of the same detection and track. The same is true for Detectors 54 and 42. If we

reject Detectors 37, 14, and 9 from Track #547348 and merge data from Detectors 54, 50, and 42 into Track #547347, then this leaves Detector 29 from Track #547348, which does not fit. Its flux value is much lower than the other 12- μ values for this object, and we conclude that it is not part of the track of this RSO. Unfortunately, examples such as this are not rare in the IRAS data, and these will contribute to larger biases and standard deviations. Since most of the analysis was done automatically, there was little attempt to screen out all of the bad tracks from the overall statistics, although obvious metric outliers were removed.

During the course of the pipeline processing of the IRAS metric data, there were instances where ANODE indicated that the IRAS track contained good data, but the follow-on DYNAMO orbit would not converge. In these cases, the analyst is forced to interactively work with DYNAMO to produce a good reference orbit. Reasons for DYNAMO's failure to converge include bad observations in the SSN data set or data mistags, an attempt to fit nongravitational parameters that could not be supported by the data, and ANODE's failure to provide a good enough initial orbit. In other instances, correlation tolerances were passed in the UCT processor using an existing element set, but ANODE was not able to converge well enough to satisfy goodness-of-fit requirements for the automatic pipeline to proceed onto a follow-on

DYNAMO orbit. In each of these instances, the user is forced to look at the data interactively. For the IRAS data, these instances occurred between 10% and 15% of the time because the data on some satellites are sparse or noisy and some satellites performed maneuvers outside windows where they were observed. Some interactive solutions have been obtained for this study, but many remain. Therefore, the totals given in Tables 6.1 and 6.2 may not indicate all the known RSOs that IRAS observed. It is estimated that the total in Table 6.1 can be increased by about 100 or 150.

7. SUMMARY

An automatic procedure has been used to process all potential RSO observations from IRAS. Required corollary and auxiliary data include a catalogue of RSO element sets updated for each day during IRAS operation, independent metric observations from sensors in the SSN for each object that IRAS observed, and a precision IRAS ephemeris. The latter was calculated in-house using SSN metric data on IRAS throughout 1983. A procedure of metric calibration was outlined and a metric error budget was formulated. The results illustrate the following points.

1. Although IRAS was pointing away from the Earth in a configuration conducive to astronomical observation, RSOs were seen on the average of four tracks per day. IRAS observed nearly 400 distinct RSOs with representatives from most satellite orbit classes, except those with apogee height less than the height of IRAS.

2. Even though the data base of potential detections contains nearly 139,000 tracks, an absolute metric correlation with known RSOs was made for nearly 1200 tracks (or $< 1\%$). It is speculated that there may be as much as an additional 1% of the data base that is comprised of uncorrelated satellites (debris and uncatalogued objects), but more than 97% of the data base is uncertain and many of the detections may be spurious.

3. Metric calibration of the tracks of observations is difficult because of the potential for erroneous detections corrupting the in-scan velocity and direction and, consequently, the absolute position. It is estimated that (for tracks without erroneous observations) the accuracy of the right ascension is 10 mdeg and the declination is 3 mdeg. These are comparable to GEODSS metric accuracy values for 1983.

APPENDIX A

IRAS TRACKS CORRELATED TO KNOWN RSOs IN THE CATALOGUE

This appendix lists all of the IRAS tracks correlated to known RSOs, for which a precision metric comparison to an orbit determined from independent SSN metric data was made. The following data are provided for each track: The absolute time of the first detection in the track, the correlated RSO SSC object number, the standard deviation (per unit weight) from the DYNAMO fit to independent data, and the right ascension and declination biases and standard deviations. The Sigma value indicates a goodness-of-fit criterion, and the results can be scaled by that value. If the orbit is fit to the data so that the residual errors are on the order of the weights on the data, then the Sigma value would be 1.0. If it is more, then the orbit errors are worse than the weights; if it is less, then they are better than the weights. Statistics from the IRAS data where the Sigma value is greater than 10 are suspect.

Track#	time (Days from 1983)	Object#	Sigma	ra bias	ra sd	dec bias	dec sd

13. ABSTRACT (Maximum 200 words) The Infrared Astronomy Satellite (IRAS) was launched and operated during a 10-month period in 1983. The orbit was close to the MSX orbit design, but the science data were collected in a mode where the focal plane was pointing directly away from the Earth. The Space Research Institute at Groningen, Netherlands, collected approximately 139,000 tracks of data that had focal plane motion different than astronomical sources, and the IRAS Processing and Analysis Center (IPAC) determined the boresite pointing of IRAS to within 20 arcsec. This report will focus on the nonastronomical detections from IRAS, many of which are Resident Space Objects (RSOs). In particular, the focus of the study is on how many are correlated to the known RSO catalogue for 1983 and the calibration and characterization of the metric accuracy for the correlated data. This study was undertaken to prepare for analysis of RSO detections from the MSX satellite, and in particular, so that automatic analysis tools designed for analysis of surveillance experiment data could be tested. The supporting analysis tools, required corollary data, and metric calibration procedure will be described, and the results of the accuracy of the IRAS ephemeris and metric RSO detections will be presented.
