NOTICES

REPORT NUMBERING SYSTEM — The numbering of technical project reports issued by the Naval Air Development Center is arranged for specific identification purposes. Each number consists of the Center acronym, the calendar year in which the number was assigned, the sequence number of the report within the specific calendar year, and the official 2-digit correspondence code of the Command Office or the Functional Directorate responsible for the report. For example: Report No. NADC-78015-20 indicates the fifteenth Center report for the year 1978, and prepared by the Systems Directorate. The numerical codes are as follows:

CODE	OFFICE OR DIRECTORATE
00	Commander, Naval Air Development Center
01	Technical Director, Naval Air Development Center
02	Comptroller
10	Directorate Command Projects
20	Systems Directorate
30	Sensors & Avionics Technology Directorate
40	Communication & Navigation Technology Directorate
50	Software Computer Directorate
60	Aircraft & Crew Systems Technology Directorate
70	Planning Assessment Resources
80	Engineering Support Group

PRODUCT ENDORSEMENT — The discussion or instructions concerning commercial products herein do not constitute an endorsement by the Government nor do they convey or imply the license or right to use such products.

19. KEY WORDS (Continue on reverse side if necessary and identify by block number) Corrosion fatigue, crack initiation, crack propagation, environment (dry air, 3.5% NaCl), loading (constant amplitude & spectrum), percent bolt load transfer, effect loading frequency, strain controlled tests, preconditioning, long term exposure testing.		
20. ABSTRACT (Continue on reverse side if necessary and identify by block number) This report contains the test results and raw fractographic data acquired under Phase II of the corrosion fatigue program for mechanically-fastened joints. The results presented in this Volume (IV) are evaluated in Volume III. Variables included in the Phase II test program were material (7075-T7651 and Ti-6Al-4V), environment (dry air and 3.5% NaCl), load spectra (F-16 400 Hr. and F-18 300 Hr.), type loading (strain-controlled, constant amplitude,

SECURITY CLASSIFICATION OF THIS PAGE(When Data Entered)

spectrum), stress level (a base-line stress; three alternate stresses), specimen conditioning (none; preconditioned), loading frequency (four loading rates), specimen type (strain controlled, compact tension and dog-bone), and bolt load transfer (0%, 20%, 40%). Most of the results herein are for 7075-T7651 aluminum alloy dog-bone specimens. These results were used to evaluate the corrosion fatigue analysis methodology for crack initiation and crack propagation in Volume III. Ti-6Al-4V alloy results herein are limited to un-notched strain controlled tests. Further titanium research conducted under Phase II, including experimental results and evaluations, is documented in Volume V.

FOREWORD

This program was conducted by General Dynamics, Fort Worth Division (GD/FWD), with Lehigh University (Dr. R. P. Wei) as a subcontractor/consultant. This report (Vol. IV) documents the test and fractographic results obtained by General Dynamics under Phase II of the "Development of Fatigue and Crack Propagation Design and Analysis Methodology in a Corrosive Environment for Typical Mechanically-Fastened Joints" program (NADC Contract N6226-81-C-0268). The program was sponsored by the Naval Air Development Center, Warminster, PA, with Mr. P. Kozel as the project engineer. Dr. S. D. Manning of General Dynamics, Fort Worth Division, was the Program Manager/Principal Investigator and Dr. R. P. Wei of Leigh University was a co-investigator.

Several General Dynamics personnel supported the Phase II test program. D. E. Gordon coordinated the overall testing effort, procured specimens, performed the strain-controlled and the constant amplitude tests, eddy current inspections and fractographic evaluations. S. B. Kirschner coordinated the dog-bone specimen spectrum tests and per-

formed fractographic evaluations and data analyses. Dog-bone specimen spectrum tests and specimen dimensional checks were performed by R. O. Nay. Corrosion fatigue testing support was provided by F. C. Nordquist, J. W. Hagemayer and H. C. Hoffman. Dr. R. P. Wei of Lehigh University also assisted in setting up the test plan and provided valuable technical support.

The following reports (NADC-83126-60-) were also prepared under the Phase II effort:

- o Volume III - Phase II Documentation
- o Volume V - Corrosion Fatigue Cracking Response of
Beta Annealed Ti-6Al-4V Alloy in 3.5%
NaCl Solution

S E C T I O N I

I N T R O D U C T I O N

This report documents the test and fractographic results acquired by General Dynamics under Phase II of the corrosion fatigue test program. The test matrix, test setup, test procedures, specimen details, data acquisition methods, etc., are described herein. Raw fractographic results and supporting details are also presented. However, the conclusions and recommendations for the Phase II test program, including the evaluation of the test/fractographic results are presented in Volume III [1].

Most of the test and fractographic results presented herein are for the 7075-T7651 aluminum alloy. Results are also presented for strain-controlled specimens made from Ti-6Al-4V alloy. However, the Ti-6Al-4V alloy test results and evaluations that were conducted by Lehigh University as a part of the basic titanium research effort under Phase II are documented in Volume V [2].

A brief overview of the corrosion fatigue program for mechanically-fastened joints is given in Section II. The

corrosion fatigue (CF) test program for the Phase II effort is described in Section III. In Section IV, testing procedures and data acquisition methods, including fractography, are described. Strain-controlled test results for the 7075-T7651 aluminum alloy and the beta-annealed Ti-6Al-4V alloy are presented in Appendices A and B, respectively. Constant amplitude test results for dog-bone specimens of 7075-T7651 aluminum alloy are presented in Appendix C. Dog-bone specimen spectrum fatigue test results and applicable fractographic data are presented for Tasks 4, 5 and 6 in Appendices D, E and F, respectively.

S E C T I O N I I

C O R R O S I O N F A T I G U E P R O G R A M
O V E R V I E W

The purpose of this section is to review the overall objectives of the corrosion fatigue program for mechanically-fastened joints and to put the results of this Volume (IV) into perspective.

The main objectives of this program were to:

1. Develop and verify an analytical methodology for predicting the TTCI and crack propagation life of mechanically-fastened joints in a corrosive environment.
2. Develop corrosion fatigue test/data-acquisition methods and guidelines for acquiring statistically-valid data needed to implement the analytical methodology.
3. Study the effects of various factors on the corrosion fatigue behavior of mechanically-fastened joints.

The Phase I effort, documented in Volumes I and II [3,4], was concerned with three tasks as follows:

- o Task 1 - Methodology and Data State-of-the-Art Assessment
- o Task 2 - Methodology Development
- o Task 3 - Test Plan Development

In Phase I the existing corrosion fatigue analysis methods were reviewed, the effects of various variables (i.e., stress level, R-ratio, loading frequency, environment hold-time, etc.) on TTCI and crack growth were experimentally investigated and evaluated for two different materials (7075-T7651 aluminum alloy and beta-annealed 6Al-4V Ti alloy), and a test plan was developed for the Phase II effort. The most suitable corrosion fatigue analysis methods for predicting the TTCI and crack propagation for mechanically-fastened joints were recommended in Phase I for evaluation in Phase II. Constant amplitude corrosion fatigue data were acquired under the Phase I effort.

The Phase II effort, data acquisition and methodology evaluation, included three tasks:

- o Task 4 - Experimental Methodology Development and Evaluation
- o Task 5 - Acquisition of Data for Prediction of Environmentally-Assisted Crack Growth in Aircraft Joints
- o Task 6 - Prediction Methodology Evaluation and Verification

The objectives of the Phase II effort were to: (1) develop and evaluate suitable experimental methods and specimens for acquiring corrosion fatigue data for mechanically-fastened joints, (2) acquire corrosion fatigue data needed to implement the predictive methods recommended under Phase I, (3) evaluate the effectiveness of the CF analysis methodology for predicting the fatigue life of mechanically-fastened joints under spectrum loading, and (4) evaluate the effects of various factors (e.g., loading frequency, R-ratio, stress level, load transfer, load spectra) on the TTCI and crack propagation in mechanically-fastened joints.

In Phase I it was found that the corrosion fatigue behavior of the Ti-6Al-4V alloy was very complex [3]. For this reason, the Phase II effort was mainly concerned with the demonstration and evaluation of the corrosion fatigue

methodology for 7075-T7651 aluminum alloy. In Phase II, the Ti-6Al-4V alloy investigations were limited to the development of a better understanding of the corrosion fatigue crack growth mechanisms and the effects of loading frequency were emphasized [2].

This volume (IV) documents the Phase II experimental test program conducted and includes the raw test and fractographic results. Phase II test/fractographic results presented in this Volume (IV) are evaluated in Volume III [1] and the conclusions and recommendations are also presented.

S E C T I O N I I I

P H A S E I I T E S T P R O G R A M

3.1 INTRODUCTION

The purpose of this section is to describe what was tested under Phase II of the corrosion fatigue program for mechanically-fastened joints and to discuss overall test objectives. Detailed test procedures and methods for acquiring the experimental results are discussed in Section IV. A preliminary test plan for the Phase II effort was developed under Phase I and it is described in Volume I [3]. The preliminary test plan was periodically adjusted during the course of the Phase II effort so that future tests could build on the Phase II test results and needs.

3.2 PHASE II TEST OBJECTIVES

The main objectives of the Phase II test program were to:

1. Develop and evaluate suitable experimental methods and specimens for acquiring corrosion fatigue data for mechanically fastened joints (Task 4).

2. Acquire statistically-valid corrosion fatigue data needed to implement and "tune" the corrosion fatigue analysis methodology for spectrum loading applications (Task 5).

3. Provide statistically-valid experimental data for evaluating the effects of various factors (e.g., loading frequency, R-ratio, stress level, load spectra, and percent bolt load transfer) on the time-to-crack-initiation (TTCI) and time-to-failure (TTF) in fastener holes (Task 5).

4. Provide key experimental results for Ti-6Al-4V alloy for developing a better understanding of basic mechanism and the effects of loading frequency on fatigue crack growth (Task 5).

5. Provide corrosion fatigue test results for crack initiation and crack growth in fastener holes that can be used to evaluate the accuracy of analytical methodology described in Volume I [3] (Task 6).

3.3 TEST PROGRAM PHILOSOPHY

The corrosion fatigue behavior of mechanically-fastened joints is complex. Therefore, the following philosophy was reflected in the Phase II test program:

- o Minimize the number of test variables to isolate the effects of corrosion fatigue.
- o Use test replications to acquire statistically-valid data.
- o Consider the most fundamental elements of a mechanically-fastened joint (i.e., single hole, straight bore, protruding head fastener and fastener load transfer).
- o Develop a better understanding of the corrosion fatigue behavior of straight-bore holes - with and without: fasteners and load transfer through the fasteners.
- o Due to the complexity of corrosion fatigue, state-of-the-art analytical corrosion fatigue methodology should be developed and verified in progressive steps with increasing structural complexities. Develop

understanding and data for simple joints before considering more complex joints.

- o Build on the test data and understandings from the Phase I effort.
- o Develop and verify the corrosion fatigue analytical methodology for 7075-T7651 aluminum alloy.
- o Develop a better understanding of the corrosion fatigue mechanisms for Ti-6Al-4V alloy [2].

3.4 TEST MATRIX AND DATA SET DESIGNATIONS

This section describes what was tested in Phase II. Key test variables reflected in the test program and testing rationale are also discussed in this section. However, detailed testing procedures and data acquisition methods are discussed in Section IV.

The Phase II corrosion fatigue program test matrix included 253 test specimens as noted in Table 1. Specimen details are shown in Figs. 1-3. A summary of the test variables used in Phase II is shown in Table 2.

TABLE 2 PHASE II TEST VARIABLES

MATERIAL	- o 7075-T7651 ALUMINUM ALLOY - o Ti-6Al-4V ALLOY
ENVIRONMENT	- o DRY AIR - o 3.5% NaCl SOLUTION
TYPE LOADING	- o STRAIN-CONTROLLED - o CONSTANT AMPLITUDE SPECTRUM
LOAD SPECTRA	- o F-16 400 HR. (HI-LO BLOCKS) - o F-18 300 HR. (RANDOMIZED) - o F-18 300 HR. (HI-LO BLOCKS)
LOADING FREQUENCY AND HOLD TIME	- o CONSTANT AMPLITUDE (0.3 Hz TO 20 Hz) - o SPECTRUM (FAST, SLOW, X-SLOW) - o HOLD TIME (0 s TO 2.33 s)
TEST SPECIMENS	- o UN-NOTCHED AXIAL (STRAIN-CONTROL) - o COMPACT TENSION - o DOG-BONE WITH CENTER HOLE
FASTENER HOLE	- o OPEN (W/O BOLT) - o WITH BOLT
BOLT HOLE FINISH	o POLISHED
BOLT TYPE	o STEEL PROTRUDING HEAD (CAD-PLATED) (e.g., NAS 6207)
BOLT LOAD TRANSFER	- o 0% LT - o 20% LT - o 40% LT
STRESS LEVEL	- o BASELINE STRESS - o OTHER
SPECIMEN PRECONDITIONING	- o NONE - o PRETEST AND PRESOAK IN 3.5% NaCl

Test plans for Tasks 4, 5 and 6 are shown in Tables 3-7. For tracking purposes, tests are defined by I.D. number and by data set. The total number of specimens tested under each data set and other testing details are shown in Tables 3-7.

3.4.1 Coding System for Tests

A coding system was devised to concisely describe the key test variables used in Tables 3-7 and to facilitate test identifications. The coding system used in this report is shown and illustrated in Table 8.

In Tables 3-7 tests are also identified by "data set number" so that test specimens can be grouped and identified by the applicable data set number. This system is used throughout this report.

3.4.2 Materials

Two materials were used for the Phase II testing: 7075-T7651 aluminum alloy and Beta-annealed Ti-6Al-4V. These materials are of particular interest because several Navy aircraft in service include these materials in the airframe and such materials are susceptible to corrosion fatigue. The 7075-T7651 aluminum alloy material was supplied as 0.50-inch plate. The Ti-6Al-4V material was in the form of 0.875-inch thick plate. These materials were

from the same plates used for the Phase I testing. Material properties for these materials are presented in Volume I [3].

The 7075-T7651 aluminum alloy was emphasized in the Phase II test program and the test results were used to evaluate the corrosion fatigue methodology under Task 6.

The corrosion fatigue behavior of the Ti-6Al-4V alloy was found to be very complex in the Phase I effort [3]. Therefore, the Phase II experimental effort for this alloy was mainly concerned with developing a better understanding of the corrosion fatigue mechanisms and, in particular, the effects of loading frequency on crack growth. Test results for the strain-controlled specimens are presented in this report and the compact tension test results and evaluations, are presented in Volume V [2].

3.4.3 Test Specimen Design

Three specimen designs were used in the Phase II investigations. The test specimen details are shown in Figs. 1 - 3. Types of tests conducted with these specimens are shown in Table 1.

The hour-glass specimens shown in Fig. 1 is commonly used in strain-controlled experiments, where large strain

amplitudes are required. This specimen geometry is less susceptible to buckling than the commonly used longitudinal specimen. In our experiments, we felt that the NDI detectability of small cracks would be improved by using the hour-glass design specimen at low strain amplitudes also. All strain-controlled tests in both 7075-T7651 aluminum alloy and beta-annealed Ti-6Al-4V were conducted with the particular specimen geometry shown in Fig. 1.

All Ti-6Al-4V crack growth investigations conducted in Phase II were accomplished with the compact tension specimen shown in Fig. 2. This is the identical specimen design that was used for Ti-6Al-4V crack growth investigations in Phase I [3].

All of the constant amplitude and spectrum loaded stress controlled tests were conducted on the dog-bone specimen shown in Fig. 3. The same specimen design was used for both no-load transfer and load-transfer testing. Considerable experience has been obtained on this specimen design from previous investigations [5-7].

To minimize the effects of fastener hole quality (e.g., scratches in the bore) fatigue crack initiation, all fastener holes in the dog-bone test specimen were polished. Also, all steel fasteners were cad-plated to minimize the corrosive effects between dissimilar metals.

Most dog-bone specimens had a nominal hole diameter of 7/16 inch and a few specimen had a hole diameter of 1/2 inch. Specimen dimensions in the test section and hole diameters were measured and results were recorded.

A 7/16 inch diameter fastener hole was typically used so that the same dog-bone specimen design could be used for both no-load transfer tests as well as for 20% and 40% load transfer tests.

3.4.4 Environments

Specimens were tested in both dry air and 3.5% NaCl solution at room temperature. Several specimens tested in Tasks 4 and 5 were preconditioned (pretested and presoaked in 3.5% NaCl). Test chambers used for obtaining these environments plus the preconditioning procedure are discussed in Section IV.

3.4.5 Type Loading

The Phase II tests included three different types of loading: (1) strain-controlled, (2) constant amplitude and (3) spectrum. Strain-controlled tests were performed with un-notched specimens (Fig. 1) to acquire the data needed to implement the strain-life approach for making time-to-

crack-initiation predictions for loaded and unloaded fastener holes. Constant amplitude tests were performed using both compact tension specimens (Fig. 2) and dog-bone specimens (Fig. 3). Spectrum tests were also performed using dog-bone specimens.

3.4.6 Load Spectra

Corrosion fatigue tests were performed using three different load spectra: (1) F-16 400 Hour (Hi-Lo Blocks), (2) F-18 300 Hour (Randomized) and (3) F-18 300 Hour (Hi-Lo Blocks). Details of these test spectra are discussed in Section 4.6.

Dog-bone specimens of 7075-T7651 aluminum alloy were fatigue tested using the F-16 400 hour block spectrum to acquire experimental results for "tuning" corrosion fatigue analysis predictions for the time-to-crack-initiation (TTCI) and time-to-failure (TTF) in fastener holes.

Fatigue tests were also performed under Task 6 using dog-bone specimens and two variations of the F-18 300 hour spectrum. These tests provided results for evaluating the corrosion fatigue analysis predictive methodology for the time-to-crack-initiation and crack propagation for mechanically-fastened joints.

3.4.7 Loading Frequency

Tests were performed using different loading frequencies (ref. Tables 3-7) so that the possible effects of frequency and environment exposure time on the time-to-crack-initiation and crack growth could be assessed for the two alloys considered. Particular emphasis was placed on acquiring dog-bone specimen (7075-T7651) fatigue test results for three different loading frequencies: (1) Fast = flight hours/2 days, (2) slow = 8000 flight hours/16 days and (3) x slow = 8000 flight hours/90 days.

3.4.8 Bolt Load Transfer

Three different load transfers were used: (1) 0% both with and without a fastener in hole, (2) 20% load transfer, and (3) 40% load transfer. The percent bolt load transfer is defined as the percentage of the total input load to the dog-bone specimen (Fig. 3) reacted by the single bolt in the test section. The test setup used to obtain the 20% and 40% load transfers is described in Section 4.5.

All bolts were loaded in double shear to minimize the effects of bending and to focus attention on key variables: environment, load spectra, stress level, loading frequency and % bolt load transfer.

3.4.9 Stress Levels

Dog-bone specimens were fatigue tested at four different stress levels in Task 4, including 34 ksi, 32 ksi, 30 ksi and 28 ksi (gross). Task 4 was mainly concerned with developing and evaluating the experimental and corrosion fatigue data acquisition methods that would be used to conduct the fatigue tests under Task 5. Another objective of Task 4 was to determine a suitable baseline stress level that would be used for the corrosion fatigue tests of Tasks 5 and 6. After testing several dog-bone specimens at different stress levels, we selected a baseline stress of 28 ksi (gross). We selected a stress level that would assure fatigue cracking in a reasonable test and environmental exposure time.

4.1 INTRODUCTION

The purpose of this section is to describe and discuss the essential elements of the Phase II test program (e.g., test specimen preparation test setups test spectra, and testing procedures). Also, the data acquisition procedures are discussed, including eddy current techniques, fractographic analysis methods and data extrapolations. Test results are presented in Appendix A-F.

4.2 SPECIMEN PREPARATION FOR TESTING

4.2.1 Strain - Controlled

Strain-controlled specimens (hour-glass type) shown in Fig. 1 were manufactured for both 7075-T7651 aluminum alloy and beta-annealed Ti-6Al-4V alloy. Specimens for the aluminum alloy and for the titanium alloy were machined from plate stock 0.50 inch and 0.875 inch thick, respectively.

After machining, all specimens were mechanically polished

in the hour-glass area to obtain a surface finish of 8 μ inch r.m.s. or better. All polishing was conducted parallel to the longitudinal axis of the specimen. Specimens were polished to help minimize the effects of manufacturing defects, such as small surface scratches, on the test results. Residual stresses were produced by the surface polishing. However, this result was considered more acceptable than the surface scratches for the test objectives intended.

4.2.2 Dog-Bone Specimen

All dog-bone specimens tested in Phase II were machined from 7075-T7651 aluminum alloy, 0.50 inch thick plate material. Specimen details are shown in Fig. 3.

After machining, a straight-bore center hole was drilled using the modified Winslow spacematic drill. This automatic drill unit maintains rotation during retraction to minimize surface scratches caused by the drilling operation.

Fastener holes were drilled per General Dynamics fastener installation standard M198 [8]. Standard hole diameters for the dog-bone specimens are shown in Table 9.

After drilling, the center hole in each specimen was mechanically polished using a split mandrel and metallographic polishing paper to obtain better than an 8 μ inch r.m.s.

TABLE 9 STANDARD HOLE DIAMETERS

Nominal Hole Dia. (Inch)	Hole Diameter (Inch)	
	Min	Max
1/4	0.2500	0.2540
7/16	0.4375	0.4425
1/2	0.5000	0.5050

Ref. General Dynamics Standard M198 [8].

surface finish. The purpose of the polishing was to minimize the effects of fastener hole quality on the fatigue test results. Also, we wanted to obtain test results that would be compatible as close as possible with the smooth un-notched strain-controlled data acquired.

After polishing the center hole of each specimen, the hole diameter, width and thickness of each specimen in the test section were measured. Results are recorded on the fractographic data sheets for each specimen in Appendices D-F.

4.2.3 Preconditioning

Selected dog-bone specimens from Tasks 4 and 5 were preconditioned as follows:

1. One block of the F-16 400 hour block spectrum was applied to the test specimen in lab air at a maximum spectrum stress of 28 ksi (i.e., peak load in spectrum produces 28 ksi stress on gross section of test specimen).

2. The specimen was then soaked in a 3.5% NaCl solution at room temperature for 72 hours.

3. Specimens were then cleaned and dried using the procedure described in AGARD report 695 [9].

4. If the preconditioned specimens were not fatigue tested immediately, they were stored at room temperature in a plastic bag with desiccant until tested.

Specimen preconditioning was considered to complement the AGARD program effort [9] and to further evaluate the effects and of preconditioning on the time-to-crack-initiation and crack growth in fastener holes.

4.2.4 Fastener Type and Installation

Dog-bone specimens were fatigue tested with or without fasteners installed in the center hole. All fasteners used were cad-plated steel with a protruding head. NAS-6207 (7/16" dia.) and NAS-6208 (1/2" dia.) bolts were used where applicable. The standard minimum and maximum fastener diameter after cad-plating are 0.4360"/0.4370" and 0.4985"/0.4995" for the NAS-6207 and NAS 6208 bolts, respectively.

Some dog-bone specimens were tested with a NAS bolt and mating nut installed in the center hole with no-load transferred through the bolt (i.e., 0% LT). In this case a steel washer was used under the nut and the nut was installed "finger-tight".

4.3 ENVIRONMENTAL CHAMBERS

Two different environments were considered in the Phase II testing: dry air and 3.5% NaCl solution both at room temperature. Three basic environmental chamber designs were used to simulate the environment for the strain-controlled tests, for the no-load transfer dog-bone specimen tests and for the load transfer dog-bone tests. The environmental chamber designs used and the environment simulation procedures for the Phase II test program are described and discussed in the following subsections.

The salt water solution for the Phase II tests was prepared by dissolving reagent grade NaCl in triply-distilled water. The average solution pH was about 6.5 over the duration of each test. All Phase II salt water tests were performed in a constant immersion environment with periodic changing of the 3.5% NaCl solution to keep the solution fresh.

4.3.1 Strain-Controlled Tests

The environmental chamber for both dry air and 3.5% NaCl solution consisted of tygon tubing with an inside and outside diameter of 1/2 inch and 3/4 inch, respectively. A short piece of tubing, less than 2.00" in length, was first slipped over the strain-controlled specimen (Fig. 1) in the test section. The tubing was short enough to prevent any interference with the extensometer device. The tubing was

sealed at both ends with polysulfide sealant after mounting. The mounted environmental chamber is shown in Fig. 4. For the dry air tests, desiccant was poured into the container before sealing the top. In the 3.5% NaCl solution experiments the salt water solution was added at an opening near the top of the chamber after the container had been sealed.

4.3.2 No-Load Transfer Dog-Bone Tests

Details of the environmental chamber used for the no-load transfer tests are shown in Fig. 5. This type of chamber was successfully used in the Phase I test program [3]. A chamber was mounted to each side of the dog-bone specimen over the center hole of the test section. The two chambers were clamped together to seal them against the specimen. The environmental chamber system described above was used for both constant amplitude and spectrum fatigue tests in Phase II.

The hole in the chamber allowed access for eddy current detection probes during testing to monitor fatigue crack initiation. A cork was placed in the hole when the chamber was in use. Environmental chambers were also used for dry air environment tests by placing desiccant crystals in the chamber.

Fig. 4 Environmental Chamber and Test Setup for Strain-Controlled Tests

Fig. 5 Environmental Chamber Used for NO - Load Transfer Dog-Bone Tests

4.3.3 Load Transfer Dog-Bone Tests

The environmental chamber was an integral part of the loading bars used to transmit the ram loading directly to the bolt in the dog-bone specimen. Two loading bars, with the test specimen in the middle, were bolted together with a single 7/16" diameter steel bolt (clad plated) with a washer under the nut. An environmental chamber was formed in each loading bar by a counterbore (1.50" diameter and 0.10" deep) on the side facing the test specimen. A sealing groove with a rubber "O" ring surrounded the counterbore to seal the environmental chamber. A small torque was applied to the nut -- just enough to seal the environmental chambers against the surface of the test specimen. The loading bar assembly and details of the chamber are shown in Fig. 6.

Desiccant crystals were placed in the chambers to simulate a dry air environment. A 3.5% NaCl solution was added to the environmental chambers to simulate a salt water environment. Provisions were made in the chamber for draining the solution and for adding a fresh solution without disassembling the two loading bars.

4.4 STRAIN-CONTROLLED TESTS

Strain-controlled experimental procedures were developed in three stages: (1) calibrate strain-controlled specimen and ram loading, (2) evaluate environmental simulation methods, and (3) verify the time-to-crack-initiation (TTCI) acquisition method. Elements of the experimental methodology development

Fig. 6 Details of Integral Environmental Chamber Used In Loading Bar for Bolt Load Transfer Tests

are described in Fig. 7.

Experimental procedures were developed and verified for acquiring strain-controlled fatigue crack initiation data in dry air and in a 3.5% NaCl solution. Strain-controlled tests were conducted on fifty 7075-T7651 aluminum specimens and thirty beta-annealed Ti-6Al-4V alloy specimens as part of Tasks 4 and 5 (see Tables 1, 3 & 4). The experimental procedures used to acquire the crack initiation data are described in this section.

A total of 30 strain-controlled experiments were conducted on the beta-annealed Ti-6Al-4V alloy. Since the same experimental procedures developed for the aluminum alloy worked equally well for the titanium alloy, only one titanium specimen was needed for Task 4 (ref. Tables 1, 3 and 4). This specimen was used to conduct a strain survey. Crack initiation data was obtained for 29 test specimens.

4.4.1 Experimental Procedures

Total strain-controlled fatigue tests were performed on a closed loop hydraulic MTS machine (MTS Model 810.13, 22 kip capacity) controlled by fully reversed ($R' = \epsilon_{\min} / \epsilon_{\max} = -1$) sinusoidal strain amplitude waves. This system was used in conjunction with a 406.11 controller, 436.11 Control unit, Model 436.11 FG functional generator, 6 GPM hydraulic supply

Fig.7 Elements of Strain-Controlled Experimental Methodology Development

and a digital indicator Model 430.41. Hydraulically operated grips (Model 641.92) were used. These grips are self-aligning to relieve possible bending stresses in the test specimens.

The aligning grips assured that the test machine axis was coincident with the specimen axis. For test specimens with strain gages, alignment was checked by observing the strain gage readings after the specimen was installed under zero applied load. Only very small strains were observed after installation in the test machine.

Normally, diametrical strain measurements are made on the hour-glass specimen. However, since many of the tests were conducted in a 3.5% NaCl environment, a two-inch gage length extensometer was mounted outside of the environmental chamber (Fig. 4). Extensometer voltage output (axial deformation) was measured as a function of axial strain in the reduced section of the specimen. These measurements were made by correlating extensometer voltage readings to strain gage readings for strain gages mounted axially in the minimum area section of the test coupon. Calibration curves based on these measurements are presented in Appendix A.

Strain surveys and strain-controlled specimen calibration tests were conducted to experimentally determine the relationship between ram load, axial strain and axial deformation (over 2.00" gage length). The test setup is shown

in Fig. 8. Four axial strain gages and an extensometer were mounted on the calibration specimen as shown in Fig. 9.

The instrumented specimen shown in Fig. 8 was statically loaded in tension and compression using a selected range of loads. Strain and extensometer measurements were taken at selected load levels. Typical results are presented in Appendix A for the 7075-T7651 aluminum alloy.

Calibration curves for 7075-T7651 aluminum alloy and Ti-6Al-4V alloy, respectively, were used to select extensometer voltages to obtain a specified strain value in the Task 5 experiments. The shape of the calibration curves were similar for both beta-annealed Ti-6Al-4V and 7075-T7651 aluminum alloys.

The environmental chamber used and simulation procedures for both dry air and 3.5% NaCl solution are described in Section 4.3.1.

In our experiments, most specimens were tested at a maximum total strain amplitude greater than .7% and at a test frequency of .5 Hz. This frequency was low enough to plot stress-strain hysteresis loops using the x-y recorder. For the long-life fatigue specimens, the frequency was increased to 2 Hz and 5 Hz to allow a large number of cycles to be accumulated in a reasonable period of time. During these

Fig. 8 Setup for Strain Surveys Using Strain-Controlled Specimen

Fig. 9 Strain Gage Locations for Strain-Controlled Specimen

tests, test frequencies were lowered to .5 Hz at fixed intervals to make x-y plots. A few specimens were tested at several different frequencies corresponding to one strain amplitude value to investigate the effect of frequency on fatigue crack initiation.

During the constant strain tests, individual stress-strain hysteresis loops were recorded on a Moseley Model 7000A x-y recorder. All recordings were made at frequencies less than 1 Hz. An example of the type of traces obtained are shown in Fig. 10. After recording the first few cycles, traces were obtained at periodic intervals, until testing ceased.

From the slopes of the stress-strain hysteresis loops, the elastic strain amplitude, $\Delta\epsilon_e/2$, and plastic strain amplitude, $\Delta\epsilon_p/2$, could be determined. This technique is also illustrated in Fig. 10.

The area enclosed by the hysteresis loops was measured using a polar planimeter. Using this technique, areas could be measured to the nearest 0.01 square inch.

Continuous load-time and strain-time records were obtained with a Gould Brush 2200 two-channel strip chart recorder. Typical traces are shown in Fig. 11.

Fig. 10 Typical Stress-Strain Hysteresis Loops Recorded on a Moseley Model 7000A x-y Recorder

Fig. 11 Typical Load-Time and Strain-Time Traces Obtained with a Gould Brush 2200 Two-Channel Strip Chart Recorder

4.4.2 NDI Monitoring for Crack Detection

Early monitoring of experimental methodology specimens was accomplished with eddy current techniques. These techniques, used in fastener hole inspections, are described in Volume I [3]. For surface inspection, an eddy current pencil probe (NDT Product Engineering, MP-20 micro-probe) was used to inspect for early fatigue cracks in the reduced section of the specimen. Since scanning had to be performed manually instead of automatically, there was some loss of sensitivity. This monitoring was compared to crack detection as observed from the decrease in maximum tensile load with cycling. The decrease in the maximum tensile load, due to load shedding, was found to be more sensitive than eddy current techniques for determining macroscopic crack initiation. Therefore, the load shedding technique was used to determine the TTCI for Tests under Task 5 (Ref. Table 4) for both 7075-T7651 aluminum alloy and beta-annealed Ti-6Al-4V.

In the 7075-T7651 aluminum alloy material, after the first few cycles, the maximum tensile stress remained relatively constant until a fatigue crack was initiated. A calibration curve was established between the decrease in maximum tensile stress and crack depth. After tensile load decreases of different percentages were observed during fatigue testing, specimens were then overloaded in tension to failure. Fatigue crack sizes were then measured. The results are

presented in Appendices A and B. Cycles to crack initiation for test specimens in Task 5 were defined in terms of cycles completed before a 2% drop in maximum tensile stress occurred.

Cyclic softening occurred in the beta-annealed Ti-6Al-4V alloy at higher strain amplitudes. Both the maximum tensile stress and compressive stress decreased as a function of cycling. The percentage decrease in maximum compressive stress was used to measure cyclic softening occurring and thus allowing the effects of "load shedding" and cyclic softening to be separated in the measurements of maximum tensile stress. The onset of a 0.010 inch deep fatigue crack was defined as the number of cycles when the maximum tensile stress showed a 2% greater decrease than the maximum compressive stress.

4.5 DOG-BONE SPECIMEN TESTS

Dog-bone specimens with a center hole were tested in three basic configurations: (1) open hole, (2) bolt in hole but no bolt load transfer and (3) load transferred directly through the bolt to the specimen. All dog-bone specimens tested in Phase II had the same basic specimen design shown in Fig. 3. Details of the dog-bone fatigue tests performed, including test setup, experimental procedures, etc., are described below.

All spectrum fatigue and constant amplitude

stress-controlled tests were performed on servo-controlled hydraulically-actuated load frames. The test setup used for the no bolt load transfer tests is shown in Fig. 12. This setup was used for both constant amplitude and spectrum fatigue tests. Details of the environmental chamber are described in Section 4.3.2.

Specimens for the spectrum fatigue tests were run continuously until failure or to a specified time. Occasional stops were made for testing adjustments, measurements or equipment maintenance/repair.

The test setup for the bolt load transfer tests is shown in Fig. 13. A loading bar with an integral environmental chamber was used to transfer the ram load to the bolt in the center hole of the dog-bone test specimens. Two independent but synchronized rams were used to load the test specimen. One ram applied load directly through the lug and of the specimen while the other ram applied loads directly to the loading bar as shown in Fig. 13. The environmental chamber used is described in Section 4.3.3.

The percentage of load transfer (LT) through the bolt is defined as a percentage of the total applied ram load to the specimen lug end. We used two different percentages of LT for the load transfer tests, i.e., 20% LT and 40% LT.

Fig. 12 Test Setup for No-Bolt Load Transfer
Dog-Bone Specimen Tests

Fig. 13 Test Setup for Bolt Load Transfer Dog-Bone Specimen Tests

A special hardware interface was used for all dog-bone tests to continuously monitor each load frame and to assure proper load control. This system provided a permanent record of test events.

Eddy current measurements were periodically made in the center hole of the test specimen for all constant amplitude tests. Spot check measurements were also made during the spectrum fatigue tests to determine the time to initiate a crack size of 0.01" in the fastener hole. The eddy current probe was inserted directly into the fastener hole without disassembling the environmental chamber. For the no-load transfer tests the cork in the hole at the side of the environmental chamber was removed to permit eddy current measurements to be made. In the case of the bolt load transfer tests, the bolt through the loading bar and environmental chamber was removed to make eddy current measurements.

The eddy current technique, described in Volume I [3] provided backup information on the TTCI for the spectrum fatigue tests. This technique was used to complement the fractography - particularly for those tests when the 3.5% NaCl environment might affect the fatigue markings on the fracture surface.

4.6 TEST SPECTRA

Three test spectra were considered in the Phase II testing of 7075-T7651 aluminum alloy dog-bone specimens: (1) F-16 400 hour (hi-lo block), (2) F-18 300 hour (random) and (3) F-18 300 hour (hi-lo block).

The F-16 400 hour (hi-lo block) spectrum used for the Phase II testing is a wing-root bending spectrum. This preliminary development spectrum has been used extensively at the General Dynamics, Fort Worth Division for F-16 development tests and other structural research programs [5-7]. We selected this spectrum for use in the Phase II effort because this spectrum marks well fractographically and we have considerable experience in reading the fractographic data. The F-16 400 hour (hi-lo block) spectrum is referred to herein as spectrum "A".

Samples of the load history for the F-16 400 hour spectrum are shown in Fig. 14. A breakdown of the load history by load points for the F-16 400 hour and F-18 300 hour test spectra are compared in Table 11.

The F-18 300 hour spectrum, supplied by the Naval Air Development Center (Warminster, PA) for this program, is a modified wing spectrum. This spectrum was modified for Phase II testing purposes as follows. The maximum compressive load in

Note: The maximum gross stress on test specimen cross section scaled to maximum load in each spectra.

the spectrum was limited to the same percentage of the maximum tension load as that for the F-16 400 hour spectrum (i.e., 35% of maximum tension load). This modification of the F-18 300 hour spectrum was made so that the dog-bone specimens could be fatigue tested in load frames without special lateral support required.

Two variations of the F-18 300 hour spectrum were considered: (1) loads randomized for each 300 hour block and (2) loads ordered in the same sequence for each 300 hour block (hi-lo). The first spectrum variation is referred to herein as the "F-18 300 hour (randomized)" spectrum or spectrum "B" and the second variation is referred to as the "F-18 300 hour (Hi-lo block)" spectrum or spectrum "C". The hi-lo block version of the F-18 300 hour spectrum was formatted the same way as the F-16 400 hour (hi-lo block) spectrum.

Strip chart printouts of the load history for spectrum B and C are shown in Fig. 15 and 16, respectively.

4.7 FRACTOGRAPHIC ANALYSIS

4.7.1 General Procedure

Dog-bone fatigue specimens were prepared for fractographic evaluation as follows. Unbroken specimens were first broken open to display the fracture surface. All

Fig. 15 Strip Chart Trace of Load History for F-18 300 Hour (Random) Spectrum ("B")

Fig. 16 Strip Chart Trace of Load History for F-18 300 Hour (Block) Spectrum ("C")

fracture surfaces were then cleaned to prepare the specimens for fractographic analysis. All shear lips were ground off without damaging the fracture surface. Specimens were then cleaned ultrasonically in acetone. A cellulose-acetate tape was softened using acetone and then pressed firmly against the fracture surface to remove surface dirt or residue. This cleaning process was repeated several times for best results.

After thoroughly cleaning the fracture surface, the fracture specimen was then mounted onto the microscope stage using a piece of clay to hold it in place. A fractographic evaluation was performed then for the largest fatigue crack in each fastener hole. The final size of the fatigue crack on each size of the fastener hole was measured and results were recorded on the fractographic data sheets (e.g., ref. Appendices D-F).

Fractographic evaluation were made using an X, Y micrometer stage with a bench stereo microscope at magnifications of 15X to 120X. The number of load points at specimen failure were translated into the bench marks at failure using the applicable load spectra. Fractographic measurements were then taken at the end of each block back to a minimum crack size of 0.010", where possible. In some cases, fractographic measurements could not be traced to the desired minimum crack size due to poor surface markings for

the smaller crack sizes. The fractography provided the means for defining the time-to-crack-initiation (TTCF) for $a_0 = 0.01$ " in the fastener holes.

Crack size versus time measurements and other pertinent details were recorded on the fractographic data sheets. This includes, in most cases, a photograph of the fracture surface, specimen dimensions, crack origins, peculiarities, number of load points at failure, etc.

Sample fractographic surfaces are shown in Fig. 17 with crack growth markers corresponding to loads $\geq 80\%$ of the maximum load in the F-16 400 hour spectrum ("A"). Similarly, sample fractographic surfaces with crack growth markers corresponding to loads $\geq 90\%$ of the maximum spectrum load are shown in Figs. 18(a) and 18(b) for the F-18 300 hour (random) spectrum ("B") and the F-18 300 hour (block) spectrum ("C"), respectively.

4.7.2 Crack Initiation Origins

Following fatigue testing, each failed specimen was carefully examined to determine, if possible, the primary origin of failure. Many specimens had multiple crack origins making failure analysis difficult.

Fig. 17 Sample Crack Growth Markers Corresponding to 80% + Loads for F-16 400 Hours Spectrum ("A")

Fig. 18 Sample Crack Growth Markers Corresponding to
90% + Loads for F-18 300 Hour Spectrum:
(a) Random Spectrum ("B"); (b) Block Spectrum ("C")

Fatigue crack origins were cataloged as follows: B = bore of hole, C = corner of hole, S = surface away from hole and I = internal flaw. Results are presented in Appendices D-F.

4.8 EXTRAPOLATION OF FRACTOGRAPHIC RESULTS

In some cases, the fractography could not be reliably read down to the selected reference crack size for time-to-crack-initiation (i.e, $a_0 = 0.010"$) for the dog-bone specimens. In such cases, the fractographic results were extrapolated to estimate the time-to-crack initiation (TTCI).

Three different extrapolation methods were considered to estimate the TTCI for $a_0 = 0.01"$: (1) linear extrapolation, (2) least squares fit of power law and (3) least squares fit of exponential function. Extrapolations were estimated for each of the three methods and the results were compared for consistency.

Linear extrapolations were based on the two smallest consecutive crack sizes that could be fractographically read. Extrapolations based on the assumed power law and exponential functions were determined using a least squares fit form of

Eqs. 1 and 2 to the three smallest consecutive crack sizes shown on the fractographic data sheet, respectively.

$$a(t) = At^B \quad (1)$$

$$a(t) = \hat{a}(0) \exp (Qt) \quad (2)$$

In Eqs. 1 and 2, $a(t)$ is the crack size at any time t ; A , B , $a(0)$ and Q are empirical constants. The applicable constants were determined using the least square fit form of Eqs. 1 and 2 given by Eqs. 3 and 4, respectively.

$$\underbrace{\ln a(t)}_Y = \underbrace{\ln a}_b + \underbrace{B}_m \underbrace{\ln t}_X \quad (3)$$

$$\underbrace{\ln a(t)}_Y = \underbrace{\ln \hat{a}(0)}_{b'} + \underbrace{Qt}_{mX} \quad (4)$$

STRAIN-CONTROLLED TEST RESULTS FOR
7075-T7651 ALUMINUM ALLOY

A.1 INTRODUCTION

Raw test results for Tasks 4 and 5 are presented in this Appendix. These results are evaluated and discussed in Volume III [1].

A.2 TASK 4 TEST RESULTS

Task 4 was concerned with the development of experimental methodology for requiring strain-controlled data for dry air and 3.5% NaCl environments. The strain-controlled data is needed to implement the strain life approach for making time-to-crack-initiation (TTCI) predictions for mechanically-fastened joints. Details of the strain life approach are discussed in Volumes I [3] and III [1]. Results from the Task 4 effort are presented herein.

A.2.1 Stress Strain Hysteresis

Typical behavior of the stress-strain hysteresis plots are shown in Fig. A1. A slight drop in the maximum tensile and compressive stresses occurred during the first few cycles followed by stable behavior after approximately 25 cycles.

Fig. A1 Stress-Strain Hysteresis Loops During Fatigue Cycling .

A.2.2 Strain Survey

Strain surveys were performed to experimentally quantify the relationship between ram load, axial strain and axial deformation (over 2.00" gage length). Four axial strain gages and an extensometer were mounted on the calibration specimen as shown in Figs. 9 and 10.

Strain survey results are presented in Table A1. Axial load versus axial strain results are plotted in Fig. A2. In Fig. A3 the axial load versus axial deformation is plotted. The relationship between strain at the neck-down area and the constant diameter area is shown in Fig. A4. The axial load versus axial strain relationship obtained is plotted in Fig. A5.

A.2.3 Specimen Calibration and Load Shedding Results

Plots for the maximum tensile load versus number of cycles and the maximum tensile stress versus number of cycles are shown in Figs. A6 and A7, respectively. Results are shown in Fig. A6 for three specimens immersed in 3.5% NaCl solution. In Fig. A7, results are plotted for specimens have total strain amplitudes ranging from $\Delta\epsilon_{T/2} = 0.65\%$ to $\Delta\epsilon_{T/2} = 1.70\%$. In general, very little change in compressive or tensile loads was observed until a

fatigue crack had initiated. Compressive and tensile loads were relatively stable for both low and high strain amplitude specimens until crack initiation occurred (Fig. A7). Once a fatigue crack had formed, the tensile load dropped rapidly while the compressive load stayed relatively constant. The fatigue crack allows a crack opening displacement to meet the required strain limit with a smaller tensile load. In compression, larger loads were required to strain the material to the required value. Little difference was observed in the behavior of specimens tested at different total strain levels.

A calibration curve was established between the decrease in maximum tensile stress and crack depth. After tensile stress decreases of different percentages were observed, specimens were loaded to failure. Fatigue crack sizes were then measured. The results of these tests are shown in Fig. A8. Cycles to crack initiation for test coupons in Task 5 were defined in terms of cycles completed before a 2% drop in maximum tensile stress occurred. From Fig. A8, a 2% decrease corresponds to a 0.010 inch fatigue crack. This is the same crack size used to define the number of cycles to initiate a crack depth of 0.010", Ni, for the stress-controlled tests of Phase I [3].

A.3 TASK 5 TEST RESULTS

Using the experimental procedures developed and evaluated under Task 4, the required strain-controlled data for Task 5 was

Fig. A8 Decrease in Maximum Tensile Stress as a Function of Crack Size in Strain-Controlled Specimens (7075-T7651 Aluminum)

obtained. The experimental data acquired under Task 5 provided the information needed to make time-to-crack-initiation predictions for mechanically-fastened joints under Task 6. Results presented herein are evaluated in Volume III [1].

Strain-controlled results for Task 5 are shown in Tables A2 and A3 for dry air/lab air and for 3.5% NaCl environments, respectively. Results are presented for: strain amplitude (total, elastic and plastic), area under the hysteresis loop, load frequency, and 2Ni cycles to initiate a crack depth of 0.010 inch.

A plot of cyclic strain versus initiation life in 7075-T7651 aluminum is shown in Fig. A9 for dry air and a 3.5% NaCl environment.

The possible effect of test frequency on crack initiation in a 3.5% NaCl environment was examined. Most of these studies were conducted at lower strain amplitudes where the test coupons were exposed to a salt water environment longer. Four frequencies were used: .1 Hz, .5 Hz, 2.0 Hz, and 5.0 Hz. Test results are shown in Fig. A10 and results are evaluated in Volume III [1].

STRAIN-CONTROLLED TEST RESULTS FOR
BETA-ANNEALED TI-6AL-4V ALLOY

B.1 INTRODUCTION

Raw test results for Tasks 4 and 5 are presented in this Appendix. These results are evaluated and discussed in Volume III [1].

B.2 TASK 4 TEST RESULTS

Typical stress-strain hysteresis plots are shown in Figure B1. Monotonic and cyclic stress-strain properties for this material and basic material properties are given in Volume I [3].

Both the maximum tensile and compressive stresses decreased with cycling with the largest decrease during the first few cycles (Fig. B1). The decrease in the maximum tensile and compressive stresses with cycling was accompanied by an increase in the width of the hysteresis stress-strain plots (increase in plastic strain increment) and also the area enclosed by the hysteresis loop (increase in plastic work).

The strain-controlled specimens (Fig. 1) for this material were calibrated using the same procedure developed for the 7075-T7651 aluminum alloy. Extensometer voltage output (axial

Fig. B1 Stress-Strain Hysteresis Loops During
Fatigue Cycling for Beta-Annealed
Ti-6Al-4V ($\Delta\epsilon/2 = 1.06\%$)

deformation) was measured as a function of axial strain in the reduced section of the specimen. These measurements were made by correlating extensometer voltage readings to strain gage readings for strain gages mounted axially in the minimum area section of the test specimen. A calibration curve based on these measurements is shown in Figure B2. This calibration curve was used to select extensometer voltages to obtain a specified strain value for the Task 5 experiments.

B.3 TASK 5 TEST RESULTS

Strain-controlled results for Task 5 are presented in Table B1 for lab air, dry air and 3.5% NaCl solution environments. The $2N_i$ reversals are for a crack depth of 0.010 inch. N_i was defined as the number of cycles in which a 2% decrease was observed in the maximum tensile stress compared to the maximum compressive stress.

The total strain amplitude versus $2N_i$ reversals to crack initiation ($a_0 = 0.010$ inch) is plotted in Figure B3 for lab air, dry air and 3.5% NaCl environments.

The effect of test frequency on crack initiation in both dry air and 3.5% NaCl environment were examined. Results are plotted in Fig. B4.

The change in the plastic strain amplitude versus $2N_i$ reversals to initiate a crack depth of 0.010 inch was

investigated. Results are plotted in Figs. B5 and B6.

A plot of the plastic work per unit cycle versus $2N_i$ reversals to initiation ($a_0 = 0.010$ inch) for this alloy is shown in Figure B7. The area of the hysteresis stress-strain curve was measured from the loop in which the plastic strain amplitude was maximum.

APPENDIX C

CONSTANT AMPLITUDE TEST RESULTS FOR DOG-BONE SPECIMENS (7075-T7651 ALUMINUM ALLOY)

C.1 TASK 5 TEST RESULTS

Constant amplitude test results for preconditioned dog-bone specimens (open hole; Fig. 3) are presented in Table C1 for both dry air and 3.5% NaCl environments. These stress-controlled tests were conducted under Task 5 (Ref. Table 6) for selected stress ranges ($\Delta\sigma$). The number of cycles to initiate a crack size of 0.010 inch, N_i , and the number of cycles to failure, N_f , are shown in Table C1.

C.2 TASK 6 TEST RESULTS

Twelve stress - controlled tests were performed under Task 6 (Ref. Table 6) for two different percentages of bolt load transfer (i.e., 20% and 40%). Tests were performed in dry air and in a 3.5% NaCl solution environment. Results are presented in Table C2.

Table C1 Constant Amplitude Stress-Controlled Test Results

APPENDIX D

SPECTRUM FATIGUE TEST RESULTS AND FRACTOGRAPHIC DATA
FOR TASK 4 (7075-T7651 ALUMINUM ALLOY)

Spectrum fatigue test results for the dog-bone specimens (Fig. 3) tested under Task 4 are summarized in Table D1. Fractographic data sheets are also presented in this appendix.

The maximum positive load in spectrum "A" (F-16 400 hour block spectrum), 100% load level, was scaled to a test load that would produce the desired gross stress on the specimen cross section. All other loads, positive and negative, were "scaled" to the 100% load level.

Fatigue loading frequencies for spectrum "A" were selected such that the spectrum loads corresponding to 8000 equivalent flight hours could be applied to the respective test specimen in a selected number of days (24 hours a day continuous testing). Three loading frequencies were considered in task 4: (1) F = fast (8000 flight hours/2 days), (2) S = slow (8000 flight hours/16 days) and (3) M = medium (8000 flight hours/8 days).

Notes for Table D1

- (a) Testing anomaly
- (b) Ref. Table 8 for description code
- (c) Linear extrapolation from two smallest consecutive crack sizes from fractographic data sheet
- (d) Extrapolation based on power law (Eqs. 1 and 3)
- (e) Fractography not read for this specimen for various reasons (e.g., testing anomaly, not 28 ksi baseline stress surface crack away from hole).
- (f) Fatigue crack origins: B = bore of hole, C = corner of hole and S = surface crack away from hole.
- (g) Time to initiate crack depth of 0.010" in fastener hole (determined from fractographic results).
- (h) Time-to-failure
- (i) Time spent in crack growth

APPENDIX E

SPECTRUM FATIGUE TEST RESULTS AND FRACTOGRAPHIC DATA
FOR TASK 5 (7075-T7651 ALUMINUM ALLOY)

Spectrum fatigue test results for the dog-bone specimens (Fig. 3) tested under Task 5 are summarized in Table E1. Fractographic data sheets are also presented in this appendix.

The maximum positive load in each load spectra, including overloads, was considered to be the 100% load level. The maximum positive test load for each spectra was selected to produce the desired gross stress on the specimen cross section. All other loads positive and negative in each respective test spectra were "scaled" to the 100% load level. As a result, "overloads" in the F-18 300 hour spectrum were treated as 100% load levels rather than a percentage greater than the 100% load level.

Fatigue loading frequencies for all spectrum tests, including the F-18 300 hour spectrum, were based on the test rates set for the F-16 400 hour spectrum tests. Loading rates were selected to complete 8000 equivalent flight hours of the F-16 400 hour spectrum in a selected number of days (24 hours a day continuous testing). Three basic loading frequencies were considered: (1) F = fast (8000 flight hours/2 days), (2) S = slow (8000 flight hours/16 days) and (3) Δ = extra slow (8000 flight hours/90 days). Accordingly, test machine frequency multipliers (FM) were set for the three basic frequencies: Fast (FM = 250), slow (FM = 40) and extra slow (FM = 1). The frequency multipliers can only be translated into actual frequency measurements for constant amplitude loading.

Notes: (a) Ref. Table 8 for description code.

(b) Fatigue crack origins: B = bore of hole, C = corner of hole and S = surface crack away from hole.

(c) Time to initiate crack depth of 0.010" in fastener hole (determined from fractographic results).

(d) Time-to-Failure (TTF)

(e) Time spent in crack growth.

(f) Extrapolation based on power law (Eqs. 1 & 3)

(g) Linear extrapolation.

(h) Testing anomaly

(i) Diameter measurement not recorded.

APPENDIX F

SPECTRUM FATIGUE TEST RESULTS AND FRACTOGRAPHIC DATA
FOR TASK 6 (7075-T7651 ALUMINUM ALLOY)

Spectrum fatigue test results for the dog-bone specimens (Fig. 3) tested under Task 6 are summarized in Table F1. Fractographic data sheets are also presented in this appendix.

The maximum positive load in each load spectra, including overloads, was considered to be the 100% load level. The maximum positive test load for each spectra was selected to produce the desired gross stress on the specimen cross section. All other loads positive and negative in each respective test spectra were "scaled" to the 100% load level. As a result, "overloads" in the F-18 300 hour spectrum were treated as 100% load levels rather than a percentage greater than the 100% load level.

Fatigue loading frequencies for all spectrum tests, including the F-18 300 hour spectrum, were based on the test rates set for the F-16 400 hour spectrum tests. Loading rates were selected to complete 8000 equivalent flight hours of the F-16 400 hour spectrum in a selected number of days (24 hours a day continuous testing). Three basic loading frequencies were considered: (1) F = fast (8000 flight hours/2 days), (2) S = slow (8000 flight hours/16 days) and (3) Δ = extra slow (8000 flight hours/90 days). Accordingly, test machine frequency multipliers (FM) were set for the three basic frequencies: Fast (FM = 250), slow (FM = 40) and extra slow (FM = 1). The frequency multipliers can only be translated into actual frequency measurements for constant amplitude loading.

Notes For Table F1

- (a) Ref. Table 8 for description code
- (b) Fatigue Crack Origins: B = bore of hole, C = Corner of hole and S = surface crack away from hole
- (c) Time to initiate crack depth of 0.010" in fastener hole (determined from fractographic results)
- (d) Time-to-failure
- (e) Time spent in crack growth
- (f) Extrapolation based on power law (Eqs. 1 and 3)
- (g) Linear extrapolation from two smallest consecutive crack sizes from fractographic data sheet
- (h) Diameter measurement not recorded
