13. ABSTRACT *(Maximum 200 words)*

The Air Force Research Laboratory requires a method for predicting the relative life of O-rings produced by different manufacturers. O-rings manufactured to the same MIL-spec from different manufacturers usually use different material formulations. Differences in formulations can result in different properties as the O-rings age. The required test methods would be based on benchtop procedures capable of determining basic properties of new and aged seals, which affect sealing properties.

Two methods potentially capable of measuring the storage and loss moduli of O-rings under dynamic conditions were proposed. One method was based on measuring multiple rebounds of a pendulum dropped against the O-ring. The second was based on determining the force displacement response of O-rings squeezed between two parallel plates and excited over a series of frequencies ranging from 1 to 100 Hz. Test instruments were built to explore both methods. Silicone and nitrile O-rings from multiple manufacturers were aged under different temperature and pressure conditions for 168 and 504 hours to provide the test samples.

Computational methods were developed to analyze the data from these test methods. Two computer code versions were developed. The first was designed to run on a PC, and predicted the deformation and forces for O-rings for a variety of loading conditions. The second was a workstation version that automatically ran either of two finite element codes (MARC or ANSYS). The workstation versions have much more capability than the PC versions, but of course are more difficult to run.

13. ABSTRACT (Cont'd)

The test methods both proved capable of measuring the basic properties of the O-rings, with somewhat greater accuracy from the pendulum rebound method. Variations between different materials were determined. However, the aging method did not induce significant changes in each family of O-rings, preventing development of a true life prediction method.

The rebound test method has been retained and will be used in the future to determine fundamental properties of elastomer samples of non-standard geometries.

1.0 SUMMARY

Fluid leakage due to failed seals in military aircraft fuel and hydraulic systems can drastically effect equipment performance, component life cycle and military readiness. Equally important is the environmental damage caused by such leakage. A computational model to accurately assess the service life of various elastomeric seals in their various operational environments would have a profound impact on solving these problems.

Seal materials made by different manufacturers to the same specification do not necessarily use identical materials or processes. The requirement is that seals meet certain performance requirements. Under operating conditions changes, degradation and permanent deformation of the seal materials can and will occur. Operating conditions usually involve exposure to heat, pressure, vibration and operating fluids while the seals are compressed in a housing (gland). During exposure, relaxation and deformation of the seal can occur. The fundamental chemistry of the seal may change due to aging or operating fluid being absorbed into the seal material. All of these effects will change the performance characteristics of the seal. These changes will affect sealing performance.

Different materials and seal formulations are expected to respond differently under these aging conditions. The result is that the performance of seals from different manufacturers can vary significantly over time. A test method capable of distinguishing between seals made to the same specification would be of great value when choosing seal materials and manufacturers.

This program selected fluorosilicone and nitrile seals from three sources, and exposed them to artificial aging conditions up to 504 hours. After exposure, changes in weight and shape were measured and the mechanical behavior of these test seals was measured using dynamic methods. The methods involved the measurement of the decay of multiple rebounds by a pendulum striking test O-rings and the measurement of the force displacement-response of O-ring cyclically oscillated while compressed between two parallel plates.

Analysis of the rebound tests allowed determination of the storage and loss moduli of each O-ring material and the fundamental frequency associated with the first three bounces. Using this method, the basic material properties of new and aged O-rings could be determined and compared.

In a similar manner, during the parallel plate measurements, force-displacement curves were generated at discrete excitation frequencies and the results analyzed to determine storage and loss moduli for each sample at these discrete frequencies. Using this method, the basic material properties of new and aged O-rings were determined and compared.

Two forms were developed for the life prediction system: a personal computer (PC) version and a workstation version. The PC version runs in two modes: (1) a Visual Basic mode where the user is prompted for the inputs and (2) a DOS mode where the user must use DOS commands to complete a run. The DOS mode provides more flexibility but is considerably more difficult to use. The workstation versions include a modeling system based on the MARC finite element code and one based on the ANSYS finite element code. The ANSYS version currently lacks the versatility of the MARC version, but can readily simulate tests on O-ring samples. Each of the

1

four versions can simulate load histories and geometries to varying degrees of complexity, and can predict the history during a typical loading cycle. This can be combined with the long term properties to aid in predicting the O-ring life.

Three basic tests were examined for obtaining the properties of the life prediction system. These included: a pendulum rebound test, cyclic parallel plate compression tests and high pressure compression set tests. All of the tests were performed on the O-rings directly. Hence, little preparation is required. The pendulum rebound tests were the most successful. They can be automatically interpreted to obtain estimates for the seal dynamic properties. The cyclic parallel plate compression tests are interpreted manually; otherwise, the tests are as useful as the pendulum rebound tests. The high pressure compression set tests were difficult to interpret and provided little insight into the properties influencing the O-ring life.

2.0 INTRODUCTION

The primary technical objective of this program was to develop a predictive method for seal life, using measurements of critical initial or aged physical or mechanical properties of seals, that allow an accurate estimation of actual service life of military specification hydraulic, lubricating oil and fuel seals. The primary emphasis is to develop predictive methods for elastomeric O-ring seals and other elastomeric seal designs operating within the -54 to 177°C (-65 to 350°F) temperature range and at pressures within 0 to 34.5 MPa (0 to 5000 psi).

Input parameters to the predictive model include seal gland and O-ring geometry, pressure, seal material properties, and loading. The predictive method can be calibrated by measuring the aged properties of seals recovered from operational service as well as artificially aged seals. The test method selected assesses the stress relaxation and/or other changes in dynamic properties (storage and loss moduli, for example) that have occurred as a result of compression of the seal within the seal gland. The test method was selected from methods such as force/deflection evaluation of the O-ring or a dynamic relaxation experiment to assess the changes of viscoelastic properties within the seal. *The selected test methods can be performed using standard quality control laboratory equipment with a minimum of required modifications.*

The predictive models require physical property measurements and the life models require calibration. Hence, the life model must be compared to experience and experimental results, receiving further refinements over time.

Current military specification elastomeric seals such as MIL-P-25732 and MIL-P-83461 nitrile (butadiene/acrylonitrile) hydraulic seals and MIL-R-25988 fluorosilicone fuel seals have high compression set (permanent deformation) on long term aging in fluid. The high compression set, along with high temperatures in operation, and dynamic wear, cause the seal to leak excessively and require replacement. The problem is aggravated for nitrile hydraulic seals by the inclusion of a plasticizer in the seal formulation to obtain the -54°C low temperature flexibility. As this plasticizer is eventually replaced by ambient fluid in the seal, low temperature leakage results. Fluorocarbon elastomers such as MIL-R-83248 military specification seal have better long term compression set but lack the low temperature flexibility to meet a -54°C requirement. Military specification requirements are based on short term, 70 hour compression set tests in hydraulic fluid or fuel. This single point test is inadequate to separate good seals supplied by seal manufacturers from marginal seals and there has been no correlation developed that will accurately predict the actual service life of these seals.

The reliability of military aircraft fluid systems is generally limited by the capability of elastomeric seals such as O-rings to maintain effective sealing force. The actual sealing force experienced by the seal is a complex function of the initial squeeze of the seal in the gland, swelling experienced by the seal as a function of temperature and pressure, and the compression set of the seal. In order to anticipate service life limitations, it is necessary to predict the time period over which these seals will continue to perform their function. The widely accepted parameter used to evaluate the condition of used seals is compression set. Curves, such as those contained in Figure 2.1 have been used to estimate the life of seals of various materials which are subject to varying thermal environments. An example of compression set measurements for O-

rings is illustrated in Figure 2.2. However, work performed by United Technologies has shown a poor correlation of compression set measured with actual field service time accumulated by elastomeric seals. Results of eight MIL-R-25988 and MIL-R-83248 seals were taken from each of several components that had been removed from aircraft with varying numbers of flight hours. The data showed a very poor correlation between compression set and flight hours.

It is, therefore, necessary to develop a predictive method for seal life based on dynamic properties which will provide an improved correlation with service hours. This method can be developed with any military specification elastomer, such as MIL-R-25988. With the determination of additional material properties, the method could then be transferred to other military specification elastomers, such as MIL-P-25732 and MIL-P-83461.

The major variables which influence the life of an elastomeric seal are temperature, seal material, fluid, seal squeeze, pressure, and gland design. The model to be developed must predict the life of a seal based on these input variables. In order to correlate the model with actual service conditions, it is desirable to assess the condition of the seals at intermediate stages within the overall life.

Two types of variables affect seal performance, dimensional variables and basic material properties. Dimensional variables directly influence the ability of the seal to mechanically close the sealing gap and establish the required sealing force. Changes in dimensions, such as creep, result in distortion and the relaxation of the seal. These effects can and will compromise the ability of the seal to close the seal gap and maintain sealing force. Shifts in material properties are more subtle, but affect sealing performance nonetheless. Changes in the stiffness of the material and response to the applied forces will affect the performance of the seal. Dimensional changes are easy to measure, while shifts in properties are difficult to determine. Despite these difficulties, development of methods of measuring, analyzing and predicting properties shift would be of significant value. Seals obtained from different manufacturers and made to a common specification are not usually the identical seal formulation. As a result, the response to applied conditions may not be the same as well as properties changes as the seal ages. Development of test and predictive methods would allow selection of seals expected to give superior lifetime performance.

Many test methods exist for the determination of fundamental properties of elastomeric materials. These properties include the storage and loss moduli, which control the stiffness and damping of the elastomeric components. Poisson's ratio, the ability of the material to resist volume change as a load is applied, is another basic property. These properties are usually determined using specific test methods, such as Thermo Mechanical Analysis (TMA) or Rheological Dynamic Analysis (RDA). These instruments usually require sample coupons of a specific shape such as disks or flat bars. The analytical tools supplied with the instruments depend on analysis of specific shapes; this prevents analysis of finished products such as O-ring seals.

As mentioned previously, compression set has been used to assess the condition of elastomeric components with little success. The difficulty of using compression set and similar methods which measure external, geometric changes is that the method is insensitive to fundamental

4

changes in material properties and behavior. Measuring the bulk distortion of test pieces provides no insight toward the strain distribution within the test piece and certainly no information about the distribution of stress in the material. Fundamental properties, such as storage and loss moduli, will change due to aging, exposure to solvent, and other environmental effects. The shift of these and other basic properties does affect the dynamic response of the parts and their ability to meet performance requirements. Test methods are required which can measure basic property shifts with pieces of differing geometries.

The solution to these limits is to develop shape-independent test methods and analytical tools to extract the material properties of components such as O-ring seals. Two methods were examined, developed and evaluated. One method attempted to measure and analyze multiple rebounds against a seal. A standard pendulum tester, typically called an Izod or Charpy impact test was adapted for this approach. In the second method, the O-ring was squeezed between two parallel plates, similar to the squeeze applied to an O-ring seal during typical operating conditions. This O-ring could be vibrated at a series of fixed frequencies and amplitudes while the force-displacement response was measured. Using analytical methods designed for the test, basic properties could be extracted from the data.

When used with new and aged seals, it was anticipated shifts in properties which might affect seal performance could be measured.

O-SEAL LIFE VS TEMPERATURE
NATIONAL SEAL DIV. FEDERAL MOGUL
Figure 2.1 Temperature Effects on O-Ring Seal Compression Life

DEFLECTION $= t_o - t_1$ RETURN   COMPRESSION SET $= t_o - t_1$

ORIGINAL THICKNESS t_o t_1 SPACER BAR   RECOVERED THICKNESS t_1
EXAMPLE: $t_o = 0.200$ $t_1 = 0.150$ $t_1 = 0.190$

COMPRESSION SET (AS PERCENT OF ORIGINAL DEFLECTION)

$$C = \frac{t_o - t_1}{t_o - t_1} \times 100$$

$$C = \frac{0.200 - 0.190}{0.200 - 0.150} = \frac{0.010}{0.050} \times 100 = 20\% \text{ Compression Set}$$

(ASTM normally requires
deflection equal to $1/4$ t_o)

Compression Set is generally determined in air and reported as the percent deflection by which an elastomer fails to recover after a fixed time under a specified squeeze and temperature. As expressed 0% indicates no relaxation has occurred whereas 100% indicates total relaxation; the seal just contacts mating surfaces against which it no longer exerts force. Compression set may also be stated as a percent of original thickness. However, percent of original deflection is more common.

Figure 2.2: Definition of Compression Set

7

3.0 APPROACH

During operation, properties of seals change as already mentioned. Over the service life, the seal must maintain adequate contact pressure to maintain a sealing as these properties change. Obviously, the primary failure mode of seals is leakage. Dynamic seals must control leakage under conditions where relative motion and wear occurs at the sealing interface. Under these conditions, the dynamic properties as well as static properties are critical to the performance of the seal. A method which could accurately assess changes of critical properties and predict the limits of satisfactory seal performance would minimize occurrences of in-flight failure by allowing effective and timely replacement of seals. Examples of critical properties and conditions include: dimensional changes caused by creep and compression set; physical property changes due to aging of the material; and material loss due to wear and abrasion.

Current military specification elastomeric seals such as MIL-P-25732 and MIL-P-83461 nitrile (butadiene/acrylonitrile) hydraulic seals and MIL-R-25988 fluorosilicone fuel seals have high compression set (permanent deformation) on long term aging in fluid. The high compression set, along with high temperatures in operation, and dynamic wear, cause the seal to leak excessively and require replacement. Military specification requirements are based on short term, 70 hour compression set tests in hydraulic fluid or fuel. This single point test is inadequate to separate good seals supplied by seal manufacturers from marginal seals and there has been no correlation developed that will accurately predict the actual service life of these seals.

Therefore it is necessary to develop a predictive method for seal life based on a dynamic property, such as stress relaxation, which should be more sensitive to material properties changes during aging and which will provide an improved correlation with service hours. This method is designed to be used with any military specification elastomer, such as MIL-R-25988, MIL-P-25732 and MIL-P-83461. For the development of the predictive method MIL-R-25988 and MIL-P-83461 seals were each selected from three different manufacturers. These seals were subjected to laboratory aging conditions which involved exposure to elevated temperature and fluid at a nominal operating pressure. The MIL-R-25988 seals were exposed to JP-8 jet fuel at 900 psi pressure and 121°C or 149°C. Similarly, the MIL-P-83461 seals were exposed to hydraulic fluid at 27.6 MPa pressure and 107°C or 135°C. At each temperature fluid aging was done for nitrile and fluorosilane seals for 168 and 504 hours. Following exposure, changes in the dimensions and weight of the seals were measured and the seals were sent for dynamic testing.

Development of a successful method for predicting seal life requires the following key elements:

- Predictive model of seal performance
- Selection of testing methods and measurement of critical properties of initial and aged samples
- Correlation and refinement of predictive model results with test data

Current life prediction methods are highly dependent on the compression set tests. These tests are difficult to interpret accurately, and are not dependable for predicting the life of a seal. A direct correlation between properties and aging may provide the designer with a more accurate prediction of the seal life. Based on these considerations two models were developed for predicting seal life: (1) a simple PC model for design calculations and (2) a more complex

workstation model for detailed analysis. The PC model is discussed in Section 6.2 and the workstation model in Section 6.3.

The computational models require material test data to establish the parameters used in the mechanical response of the seal. Single point measurements, such as compression set and durometer (hardness), are insensitive to changes in material properties. Dynamic methods, such as measurement of storage and loss moduli by torsional rheology, are very sensitive to material properties shifts. However, while this method works well for rectangular test coupons, it is impractical for the testing of O-rings.

Tensile and compressive testing of O-rings to determine force-deflection response at different strain rates and temperatures should be sufficient. The effect of environmental aging of the materials can be established using initial and aged test coupons in a parallel testing effort. The dynamic properties of these samples, including storage (G') and loss (G") modulus can be determined by torsional rheology using a Rheometrics rheological dynamic analyzer (RDA).

4.0 MATERIALS SELECTION

Military specification seals were selected based on the service experience of the Air Force. Seals causing the most significant field problems were identified through consultation with the Materials & Manufacturing Directorate, Air Force Research Laboratory. The military (and commercial) aircraft experience of United Technologies Hamilton-Standard was also considered. The military specification seal types selected were evaluated using the life prediction method selected during Task 1.

MIL-P-25988 fluorosilicone fuel seals used in military and commercial fuel controllers were selected as one candidate for this program. Hamilton-Standard experience has shown these seals to be the current service life limiting factor in aircraft fuel system sealing applications. Leakage of aircraft fuel systems is particularly troublesome due to the potentially catastrophic consequences. MIL-P-25732 and MIL-P-83461 were considered as examples of nitrile hydraulic seals. Based on the experience of Hamilton-Standard, MIL-P-83461 seals were selected for evaluation.

To determine the effect of differences between seal compounds (materials) used by different manufacturers, each type of seal was obtained from three sources. Two sizes of MIL-R-25988 fluorosilicone seals, 25988/2-007 and 25988/2-214 were selected for testing and evaluation. A single size of the nitrile seal, MIL-R-83461/1-214, was selected for evaluation. In addition, MS28774-214, fluoropolymer backing rings were selected for use with the M83461 seals. The seal distributor, Sealing Solutions, obtained single batches of each type of seal from the manufacturers listed below. Certificate of conformance documents were obtained for each lot of seals to verify basic requirements.

MIL-R-25988 (fluorosilicone)	Parco Company Parker International Seal
MIL-P-83461 (nitrile)	Parco Company Parker Wynn's Precision
MIL-28774 (fluoropolymer)	Tetrafluor

JP-8 jet fuel was selected as the test fluid for the MIL-R-25988, fluorosilicone O-rings. The JP-8 fuel was obtained from the Air Force via Wright-Patterson labs. Brayco Micronic 882 (MIL-H-83282) hydraulic oil was selected as the test fluid for the MIL-R-83461 nitrile O-rings. Brayco Micronic 882 was supplied by the Hamilton-Standard division of UTC.

5.0 AGING METHODS

To develop methods for characterizing changes of properties in elastomeric materials such as O-rings, methods to artificially age samples were required under controlled, accelerated conditions. To develop the required aging capabilities, fixtures, environmental conditions and processes first needed to be defined for each O-ring material.

5.1 Test Conditions

Conditions were identified that simulated the actual operating environment that the O-rings would experience. For example, actual gland dimensions were selected to provide the proper squeeze on the seal. Exposure temperature, pressure and fluids were selected to simulate real world conditions. A second set of conditions with increased test temperature was selected to accelerate the process. The following conditions were selected:

Seal	Size	Temp (°C)	Pressure (MPa)	Fluid	Time (hrs)
MIL-P-25988	-007, -214	121	6.2	JP-8	168
MIL-P-25988	-007, -214	121	6.2	JP-8	504
MIL-P-25988	-007, -214	149	6.2	JP-8	168
MIL-P-25988	-007, -214	149	6.2	JP-8	504
MIL-P-83461	-214	107	27.6	Brayco Micronic 882	168
MIL-P-83461	-214	107	27.6	Brayco Micronic 882	504
MIL-P-83461	-214	135	27.6	Brayco Micronic 882	168
MIL-P-83461	-214	135	27.6	Brayco Micronic 882	504

JP-8 fuel and Brayco Micronic 882 hydraulic oil, as stated previously, were the test fluids.

5.2 Test Fixtures

Test fixtures were required that were capable of subjecting test O-rings to the conditions described above for the required test period. Fixtures were designed using the gland dimensions for the –007 and –214 O-rings described by the SAE Aerospace Standard, AS4716. The fixtures were designed to each hold 8 O-rings. Examples of the test fixture designs are illustrated in Figures 5.1 and 5.2.

Each fixture was assembled in a pressure vessel to provide containment and these were attached to a manifold which was constructed in a Blue M, Model IGF 6680F-4, forced air oven. The manifold was constructed using stainless steel 304 tubing and pressure fittings capable of handling 34.5 MPa at temperatures above 149°C. Pressure was supplied by an Enerpac P-39 hand pump capable of supplying a maximum of 68.9 MPa of pressure. The assembly is illustrated in Figures 5.3 and 5.4.

5.3 Aging Procedure

The aging procedure of the test seals required well-defined methods for installation, measurement and aging of the test seals to ensure repeatability of the procedure. These methods are described below.

Prior to installation on the test fixtures, O-rings were examined for defects and deformities. Those showing obvious damage were rejected. The thickness and width of each O-ring was measured at 3 points using a digital micrometer and the average taken. The weight of each O-ring was measured to 4 decimal points. Each O-ring was given a unique ID relating to supplier, aging conditions and position in the aging fixture and the data was recorded.

O-rings were assembled wet with test fluid onto the aging fixtures, shown in Figure 5.1 and 5.2, using mounting tools designed to minimize damage to the O-rings. The mounting tools are shown in Figure 5.5. If an O-ring was damaged during assembly, a substitute was used and the above data revised to reflect the change. During assembly of the M-25988/2-007 O-rings, breakage of about 15% of the test pieces was noted. After the assembly of the O-rings, the collars were assembled onto the fixtures and the assemblies were placed into the containment vessels. The completed test fixtures were then connected into the pressure manifold inside the Blue M forced air furnace.

The test system was evacuated using a mechanical pump to remove air from the system for 5 minutes and was then backfilled with test fluid. (JP-8 or Brayco 882) The system was pressurized to full test pressure at room temperature to check for leaks. When the integrity of the system was confirmed, the pressure was lowered to 100 psi and the oven was programmed to heat to the test temperature. During the heating cycle, typically 8 hours, the test pressure was checked periodically to avoid an over-pressurization condition. When the test temperature was reached, the test pressure was checked every 4-12 hours and adjusted to maintain the test pressure within 10%. Tests were continued for the programmed test time, followed by an overnight cooling of the oven with the samples under pressure.

After cool down, residual fluid pressure was relieved and the test fixtures were removed from the oven. One fixture was disassembled at a time and the O-rings were removed, dried, measured and weighed. Sample recovery and measurement occurred in the 6 hours following depressurization. Following measurement each O-ring was stored in a marked, fluid filled polyethylene bag prior to testing. Samples were usually taken for rebound testing within 48 hours of collection and dynamic modulus testing within 7 days of collection.

6.0 LIFE PREDICTION METHOD

Many levels of modeling are available in the analysis of polymeric seals. The material can be modeled as elastic using large strain rubber elasticity. Linear damping effects can be included by using a viscoelastic model. Nonlinear, time dependent effects can be included by using creep models, and all of the above can be combined using viscoplastic models.

Large strain rubber elasticity has been understood for over fifty years[1,2]. Polymers are generally assumed to be isotropic. The response is usually described in the principal strain directions and the strain measure is taken to be the stretch ratios. Each of the principal stresses are then found by taking the derivative of the elastic potential with respect to the strain components, where the elastic potential is given by

$$W = \frac{G}{2}(\lambda_1^2 + \lambda_2^2 + \lambda_3^2 - 3) \qquad (1)$$

The λ_i are the principal stretch ratios, $i=1,2,3$, and G is the shear modulus. In rubber elasticity the volume is conserved, or

$$\lambda_1 \lambda_2 \lambda_3 = 1 \qquad (2)$$

which makes the Poisson ratio, ν, one half (for small strains and under ideal conditions). For a Poisson ratio of one half the shear modulus and Young's modulus are related by

$$E = 3G \qquad (3)$$

Additional terms have been added to the elastic potential and are commonly incorporated. In particular the Mooney-Rivilin[1] model is common,

$$W = C_1(I_1 - 3) + C_2(I_2 - 3) \qquad (4)$$

where

$$I_1 = \lambda_1^2 + \lambda_2^2 + \lambda_3^2 \qquad (5)$$
$$I_2 = \lambda_1^2\lambda_2^2 + \lambda_2^2\lambda_3^2 + \lambda_3^2\lambda_1^2 \qquad (6)$$

are invariants. For many polymers an adequate approximation of the mechanical response results from

$$C_1 = G/2 = E/6 \qquad (7)$$
$$C_2 = C_1/4 \qquad (8)$$

The formulations above require that only the Young's modulus for small strains must be measured. The fact that the material is incompressible, (i.e. the volume is conserved) means that the hydrostatic component of the stress tensor cannot be evaluated directly from the strains, and hence becomes an additional unknown in the governing equations. This additional unknown is balanced by the assumption that the material is incompressible. A better match between measured response can be achieved by the addition of higher powers in the terms I_1-3 and I_2-3.

Viscoelasticity is commonly used to approximate the time dependent response of polymers. Normally the constitutive relation is written in integral form[3],

$$\varepsilon_{ij} = \int_{-\infty}^{t} J_{ijkl}(x, t-\tau)\frac{\partial \sigma_{kl}}{\partial \tau}d\tau \qquad (9)$$

or equivalently

$$\sigma_{ij} = \int_{-\infty}^{t} G_{ijkl}(x, t-\tau)\frac{\partial \varepsilon_{kl}}{\partial \tau}d\tau \qquad (10)$$

where G_{ijkl} are the moduli, J_{ijkl} are the compliances, x is the position vector, t is the time, ε_{ij} is the strain tensor, and σ_{ij} is the stress tensor. The moduli are generally taken in the form of an N term Prony series[4],

$$G_{ijkl} = G_{ijkl}^{\infty} + \sum_{n=1}^{N} G_{ijkl}^{n} e^{-t/t^{n}} \qquad (11)$$

where G^{∞}_{ijkl}, G^{n}_{ijkl} and t^{n} are material parameters.

Permanent set in polymers is not generally a linear effect, and it may not be possible to represent it using viscoelastic equations. Such representations may require the use of a nonlinear creep theory. Polymer creep models are generally borrowed from those used for metals. Generally a power law is assumed,

$$\dot{\varepsilon} = A\sigma^{n} \qquad (12)$$

and the creep deformation is assumed to be incompressible. Hence, the constants A and n in equation (6) are sufficient for characterizing the three dimensional response of the isotropic material, and are generally temperature dependent.

The above formulations separate the nonlinear time dependent (creep) and nonlinear time independent (plasticity) response of the material, but at sufficiently high temperatures plasticity and creep become difficult to separate. Viscoplastic constitutive laws have been developed, based on the concept of overstress. The concept of overstress was first defined by Krempl[6], and recently extended to large strains[7]. These extensions have been shown experimentally to be applicable to polymers.

6.1 Material Response Description

The viscoelastic properties for polymers are usually represented by a storage (shear) modulus, G', and a loss (shear) modulus, G''. These are found by measuring the torsional load required for an enforced sinusoidal twist of a thin rectangular cross-section. The ratio of the in-phase torsional shear stress and the corresponding shear strain gives the storage modulus, while the ratio for the out-of-phase stress and strain gives the loss modulus. For an isotropic material represented by equation (10) only one stress and one strain component are present. Under these conditions equations (10) and (11) become, respectively,

$$\tau = \int_{-\infty}^{t} G(x, t-t')\dot{\gamma}(t')dt' \qquad (13)$$

and

$$G = G^{\infty} + \sum_{n=1}^{N} G^{n} e^{-t/t^{n}} \qquad (14)$$

20

where $\dot{\gamma} = d\gamma / dt'$.

Assume an imposed sinusoidal stain

$$\gamma = \gamma_0 \sin \omega t \qquad (15)$$

where γ_0 is the shear strain amplitude, and ω is the frequency. Substituting equations (14) and (15) into equation (13) results in

$$\tau(t) = G^\infty \gamma_0 \sin \omega t + \sum_{n=1}^{N} G^n \gamma_0 \{ \frac{\sin \omega t}{1 + (\omega / t^n)^2} + \frac{1 / (\omega / t^n) \cos(\omega t)}{1 + (\omega / t^n)^2} \} \qquad (16)$$

The storage and loss moduli are given by the coefficients of $\gamma_0 \sin \omega t$, and $\gamma_0 \cos \omega t$, respectively.

Then

$$G' = G^\infty + \sum_{n=1}^{N} \frac{G^n}{1 + 1 / (\omega t^n)^2} \qquad (17)$$

and

$$G' = \sum_{n=1}^{N} \frac{G^n / (\omega t^n)}{1 + 1 / (\omega t^n)^2} \qquad (18)$$

Note that for very low frequencies

$$G' = G^\infty \qquad \text{and} \qquad G'' = 0 \qquad (19)$$

while for very high frequencies

$$G' = G^0 \qquad \text{and} \qquad G'' = 0 \qquad (20)$$

where $G^0 = G^\infty + \sum_{n=1}^{N} G^n$.

Hence, G'', must have at relative maximums at some frequencies. This can be found by setting the derivative of G'' with respect to frequency equal to zero. The result is G'' is a relative maximum when

$$\sum_{n=1}^{N} \frac{G^n [1 - (\omega t^n)^2]}{[1 - (\omega t^n)^2]^2} = 0 \qquad (21)$$

For one term in the Prony series, the frequency at which the maximum in G'' occurs is at

$$\omega = 2\pi f = 2\pi / t^1 \qquad (22)$$

Relaxation tests can be used to find the parameters in equation (14). In a relaxation test the torsional strain is suddenly applied, and then held. The torsional stress, required to hold the strain, is measured as a function of time. The initial measure of stress to strain is an estimate for G^0 in equation (20). The long term, steady state ratio of stress to strain is G^∞. The parameters G^n

21

and t^n in the Prony series can be found by: least squares techniques, the use of inverse Laplace transforms, or by trial and error.

Long term creep tests can be analyzed in a similar manner. For example, consider a Prony series consisting only of the term n equal to one. If a shear stress, τ_0, is suddenly applied at time equal to zero and then suddenly released at time t_0, the strain history is given by

$$\gamma = \begin{cases} \dfrac{\tau_0}{G^1}(1+\dfrac{t}{t_0}) & 0 < t < t_0 \\ \dfrac{\tau_0}{G^1}(\dfrac{t}{t_0}) & t_0 < t < \infty \end{cases} \tag{23}$$

Both relaxation and creep data reduction can be useful for the initial interpretation of various compression set tests. Since compression set tests are sometimes performed at higher temperatures to accelerate the tests, we must be able to project the results to lower temperatures. This can be accomplished by noting, if the mechanism producing the permanent strains has not changed over the temperature range of interest, then the rates will be proportional to $exp(-Q/RT)$ (where Q is a heat of reaction, R is the gas constant, and T is the absolute temperature.)

6.2 PC O-Ring Code

Salita has developed a simple finite element based code for NASA[8,9] to aid in describing the response of the Shuttle solid rocket O-ring seals. The code geometric input can be used to describe in general piston and rod seals, as shown in Figure 6.1. Face seals (Figure 6.1), though, can only be approximately modeled. The code includes the ability to model transient gap motion and pressure transients. The material model, although approximate, can include time dependent material response.

However, the computer code was designed to simulate the Space Shuttle solid rocket seals during launch; thus it included specific pressure and gap launch transients. Those portions of the code had to be modified to include more general transient loads. Three loading functions were added. Each was classified according to a type. Type 0 ran the program with a suddenly applied pressure after the gap was closed. This was a test mode the program originally contained. Type 0 also suddenly changed the gap simultaneously. In type 1, the gap and pressure change after a specified time, and then revert back to the original state an additional time later. The most useful loading type is type 2, which includes a sinusoidal variation in the pressure and the gap. The pressure variations with respect to the gap can only be in phase or 180 degrees out of phase. The last type, type 3, includes an exponential decay or rise in the pressure and gap. Again, for type 3, the pressure and gap change by the same ratio at all times. Several other minor changes were made to accommodate a more general O-ring design analyses.

The modified code can be used on a workstation or on a PC. On the PC there are two versions: a Visual Basic version and a DOS version. The DOS version will run on any PC that has MS-DOS or a DOS prompt, but requires the user to edit a file containing the input to run the program. A sample input file is shown in Figure 6.2. The Visual Basic version, which should

run on most PC's has labeled entries for each of the parameters shown in Figure 6.2. The first entry in the data is a title for the case being run. The geometric inputs for the PC version include: gap, gland width, gland height, offsets at the sides of the gland, the cross-section diameter of the O-ring, the inside diameter of the O-ring gland, the unstretched diameter of the O-ring. The material properties include the Young's modulus, the relaxation time and the relaxation factor. Loading includes the applied pressure, the back pressure, and the coefficient of friction between the gland and the O-ring. The loading also includes a type (discussed above) together with the variations in the applied pressure and the gap, and the time period for the loading. The last entries include the number of time steps and the time step.

The output resulting from Figure 6.2 is illustrated in Figures 6.3 through 6.5. Figure 6.3 displays the deflected shape at a particular transient time. Figure 6.4 plots the transient history of the footprint of the O-ring on the walls of the gland, while Figure 6.5 gives the transient normal force history on each wall. If friction is present, then a plot of the tangential wall forces can also be obtained.

There are several limitations to the PC code. The code was developed on workstations and main frames using Fortran. When moved to the PC a Fortran to C translator was used and the C code was compiled. Hence, when an error occurs during execution (usually this occurs because of input data problems) the message only references locations in the C code, if the debugger is used. This means that code errors can only be accurately traced on a computer where the Fortran is compiled directly. A Fortran compilation on a PC would remove this problem. If an error occurs with a C compiled version then the most likely error is an O-ring configuration that cannot react the loads against the walls. This will happen when a large gap develops between higher and lower pressure regions in the gland. The PC version uses the graphic interface package Grafic. The PC version of Grafic is still experimental and cannot make hardcopies of the deformed shape, but does store postscript files of the load and footprint histories. Finally, if friction is present, it may take an extra time step to release nodes from a wall.

A complete description of the Visual Basic version is included in Appendix A, and similar discussion for the DOS version is in Appendix B. Each Appendix is self-contained so that they can be copied and separated from the report.

6.3 Workstation Codes

Two versions of finite element based workstations were developed. One to be used with MARC and the second with ANSYS. Each uses a minimum amount of input from the user.

6.3.1 MARC Version

The MARC version is based on the nonlinear finite element code distributed by MARC Analysis Research Corporation in Palo Alto, California. It includes contact and friction formulations along with large strain rubber viscoelasticity as in equations (4) and (13). A general Prony series can be included as in equation (11). The transient motion of the contact surfaces (i.e., the gland surfaces) and the pressure history can be quite general. The code developed for use with the

23

MARC version includes a Fortran routine that generates the MARC input from user inputs. The user is either prompted for the inputs, or the program can be run using a redirected input file.

Figure 6.6 is an example of a redirected input file. The inputs include a title followed by the inside and minor O-ring diameters. The material properties include the storage modulus, $tan\delta$ (i.e., the ratio of the loss modulus to the storage modulus) and the frequency where the loss modulus is a maximum. The friction coefficient between the O-ring and the gland is entered next. The next three sets of entries describe the O-ring geometry. The next several entries describe the loading. The applied internal pressure and the external (back) pressure are entered next, followed by the mean and maximum compression squeeze. The squeeze is defined as the change in cross-section diameter divided by the cross-section. The next entries are the pressure change over one cycle and the phase angle with respect to gland surface motion. The last two sets of entries include the number of cycles to simulate, the frequency of oscillation, and the number of load steps for the gland motion, pressurization, and the number of load steps per cycle.

MARC user subroutines were written for the gland motion and pressure loading history. A mesh was generated and stored. This mesh is then used for the runs that are generated. A Unix script has been written that automatically runs the program to make the MARC finite element model and then run the MARC finite element code.

Figures 6.7 through 6.13 illustrate some of the results that can be obtained. Figure 6.7 is a face seal that is subject to transient motion of the gland faces. Figures 6.8 and 6.9 illustrate the stresses and the deflections at two different times with nodes and elements shown. Figure 6.10 shows a rod seal while Figure 6.11 demonstrates the deflections and stresses at a later time with only elements shown. Finally Figure 6.12 illustrates a piston seal. Figure 6.13 displays the stresses and deflections at a later time without any mesh definition included. Note that this last case does not display the current location of the gland surfaces.

The MARC version readily runs cases with gland motion but can have numerical instability problems with large pressure loading. This instability can represent a real physical instability or could be numerical in nature. A buckling analysis can aid in determining the source of the instability.

A complete description of the MARC version is included in Appendix C. The Appendix is self-contained so that it can be copied and separated from the report.

6.3.2 ANSYS Version

The ANSYS version cannot simulate the diverse problems that the MARC version can, but the ANSYS version can readily model the parallel plate cyclic tests. To perform these simulations, an ANSYS 5.4 macro was written which prompts the user for geometric and material data, generates a model of a viscoelastic rubber O-ring, and runs a compression and decompression cycle using rigid compression surfaces. This simulation is particularly useful for interpreting the parallel plate tests.

After entering ANSYS, the user needs to type oring at the command line which executes the macro oring.mac. The user is then prompted for a job name and title. Geometric data is then requested (see Figure 6.14) which includes the major diameter and minor diameter. The major diameter is the inner diameter plus half the cross-section diameter. Loading requirements are entered next. These include the compression displacement and compression velocity. Material properties requested include the instantaneous shear modulus, G^0, the infinite time shear modulus, G^∞, and the relaxation time, t^1.

Once the user completes the entry of geometry and material variables, the macro generates the geometry and the mesh, defines the rigid surfaces, and executes three load steps. Several material parameters are currently set by the macro (although they can readily be modified by editing the macro). These parameters are as follows:

G = G(inf.)   (The global elastic shear modulus is set equal to G(inf.) in the viscoelastic model)

ν = 0.475   (Poisson's ratio)

μ = 0.0   (Friction coefficient - Zero friction assumed)

The load steps are set up to run a compression, hold, and decompression:

ANSYS returns a warning during the simulation indicating that the viscoelastic elements have not been tested with the large strain option. The test cases completed indicate this should not be a problem.

A complete description of the ANSYS version is included in Appendix C. The Appendix is self-contained so that it can be copied and separated from the report.

7.0 TEST METHODS

Determination of fundamental properties of plastic and elastic materials normally requires the use of dedicated instruments using samples with specific shapes and dimensions, such as rectangular bars and cylindrical disks. Simple tests, such as TMA (Thermal Mechanical Analysis) only determine basic characteristics, such as softening point or coefficient of expansion.

More sophisticated methods are required to extract fundamental properties, such as elastic and loss moduli. Examples of the type of instrumentation required to perform this type of testing includes the RDA II (Rheological Dynamic Analysis) from Rheometrics Corp. and the DMA 982 or 983 (Dynamic Mechanical Analyzer) from TA Instruments. A different method, described in ASTM D945, requires the use of the Yerzley mechanical oscillograph. Since the test methods required by these instruments require samples of specific shapes, these samples must be provided by removal from existing parts, where possible, or the preparation of special samples for testing. Removal of sample pieces from parts, such as, O-rings or seals, results in destruction of the part. This prevents monitoring of changes in material properties of a part due to aging or other effects.

Simple tests do exist, where the effect of impact on elasomeric samples can be measured. Examples of these methods include ASTM D1054, where a pendulum can be dropped against a rubber sample and both the penetration into the sample and the subsequent rebound height measured. In ASTM D2632, the rebound height of a ball dropped on a flat sample can be measured. For example, in ASTM D1054, since the energy of the pendulum is proportional to the verticle component of the displacement of the pendulum, it may be expressed as 1 – cos of the angle of displacement, and impact resilience, R, is readily determined from the equation:

$$R = 100 \times (1 - \cos \text{ angle of rebound}) / (1 - \cos \text{ of original angle})$$

The value R is commonly called percentage rebound. In both these methods, portions of irregular speciments could be included in the test. The energy imparted by the test system and the rebound energy can be calculated. However, a calculation method for determining basic viscoelastic properties is not possible using these methods. Additional information must be collected describing the dynamics within the test and calculation methods for extracting the basic properties would have to be developed.

7.1 New Test Methods

The material models require methods that are sensitive to subtle and continuous changes in materials properties. In general, dynamic methods, which cyclically excite the elastomer are more sensitive to changes in the material than single event testing. Methods that use cyclic excitation include torsional rheology using the RDA instrument and Dynamic Mechanical Analysis (DMA). Examples of single event testing include tensile testing, hardness testing by durometer and simple rebound testing. The significant difference between cyclic testing versus single point methods is that the material can be excited over a frequency to reach a steady state condition. Other methods of dynamic testing exist, where the sample can be excited by a single

38

pulse and a frequency dependent response is measured. A stress relaxation test using a torsional sample in the RDA is one example. It may be possible to measure and analyze the response of an elastomer sample excited by a rebound test. Proposed methods included:

1. Modified DMA or RDA testing of O-rings.
2. Dynamic analysis of rebound testing of O-rings,
3. Cyclic compressive testing of O-rings between parallel plates.

Each method would be developed and applied to new and laboratory aged O-rings. Analysis of the results would be used to determine changes in basic properties, such as storage and loss moduli.

7.2 Modified Rheometer or DMA Methods

For this type of test, the O-ring specimen would be deformed between two parallel plates using a known amount of squeeze and compressive force. One plate would oscillate the O-ring around the center axis and the axial force-displacement response measured by the second plate. Implementation of this method with existing equipment would be relatively simple; however, the analysis of the results would be difficult. The effects of slip, distortion and the interaction of a preload force normal to the direction of cyclic stress presented a serious analytical challenge. This approach was not explored further in favor of less difficult analytical models and more direct test methods, as requested by the Air Force.

7.3 Rebound Test Methods

Rebound testing is based on existing methods of exciting rubber or plastic samples by the dropping of a sphere or hammer of known mass a fixed distance onto the sample and observing the rebound response of the sample. Since the mass and height of falling element is known, the kinetic energy imparted to the test sample can be calculated. Standard tests exist for this type of testing ASTM D256, D1054, D2632 and D3574. However, these tests have limits in that the continuous response of the sample following impact is not measured. Each method was reviewed as the possible basis for a dynamic test. D256 uses a standard pendulum to measure the impact resistance of samples and D1054 measures the rebound height of a pendulum dropped on a rubber sample. D2632 and D3574, test H, measure the rebound height of a ball dropped onto a flat rubber surface or on a foam material, respectively.

Dynamic analysis of a rebound type test would require continuous measurement of the behavior of the system, to determine the position of the energy imparting component during multiple rebound events. This approach not only allows the analysis of a series of impacts and rebounds but also allows direct measurement of decay within the test system. Three approaches were considered:

1. A standard ball drop test, described in D2632, could be observed using a video recorder and a reference grid. Motion of the ball during multiple rebounds would be analyzed using the video recording. A problem with this method is the inability to control the path of the

bouncing ball. A second problem is the contact surface between the ball and the O-ring is not conducive to reproducible impacts. Alternative approaches were considered.

2. Modification of the ball drop test using a flat washer or disk in place of the ball was considered. The disk might be guided by a stiff guide wire. However, a difficulty exists for controlling the impact of the disk with the O-ring. To provide a reproducible test, the disk must land flat with each impact. This method was deferred as additional methods were considered.

3. Instrumentation of a standard pendulum to measure position was examined. Position of the arm and hammer could be measured using a mechanically coupled encoder or the position could be determined using the video camera and grid method described above.

7.3.1 Pendulum Test Method and Hardware

The advantages of the pendulum method are obvious when compared to methods using free falling spheres. Commercial test instruments, including surplus equipment at UTRC, were available for modification. The behavior of this type of pendulum is well undestood. The moving element, or hammer, travels in a fixed path, so multiple rebounds and reproducibility between experiments is possible. Incorporation of an encoder to determine hammer position would be a relatively simple task. A pendulum rebound system was selected by UTRC for further development for rebound testing of elastomer samples. The test instrument is shown in Figure 7.1. This instument is based on a single beam Wiedemann-Baldwin impact tester.

The use of a pendulum system to impart a known amount of energy is described in a number of ASTM test methods, such as D1054, D256 (Izod and Charpy methods) and D3998 (Kravitz pendulum). The advantage of a pendulum system is the potential and kinetic energy in the pendulum can be determined if the mass and geometry of the pendulum are known and the position of the pendulum is measured as a function of time. From postion-time measurements the velocity and kinetic energy can be derived. If a system rebounds against a known sample for multiple events, until complete decay occurred, the dynamics of excitation and energy dissipation can be analyzed if a satisfactory model for the behavior was developed.

The following modifications were made to the instument. The sample holder was replaced with a rigid steel anvil, designed to hold the O-ring under test against a flat surface. The face of the pendulum was fitted with a hammer of known curvature. The pendulum weight distribution was determined. The fixed release mechanism at the top of the pendulum was attached to a movable arm, providing release points from 15 to 150 degrees in 15 degree steps. The axial shaft from which the pendulum swings was fitted with a low mechanical resistance, linear potentiometer. The potentiometer was connected to a regulated 10 V power supply. The output of the potentiometer was connected to a zero gain buffer amplifier with high input impedance. The position of the pendulum beam was calibrated vs. output voltage. This output was connected to a multi-channel A-D data acquistion unit running on a MS-DOS/Windows based computer. Details are shown in Figure 7.2a and 7.2b.

7.3.2   Pendulum Test Software

The pendulum tests are transient and highly nonlinear. The nonlinearities are due not only to the contact during the impact of the hammer with the O-ring but also are introduced by the large amplitude motion of the pendulum. Accurate models of the test would require simulations using finite element codes. This would be well beyond the capability of the ordinary PC's envisioned for use with the pendulum impact tester. Hence, a simple method for interpreting the data from a pendulum tester needs to be developed.

Several inputs are required to reduce the data from a typical pendulum impact test. The data can be placed into three categories: the characteristics of the pendulum, the geometry of the O-ring, and the location of the pendulum as a function of time. The pendulum can be described by: the inertia, I; the length from the pendulum pivot to the impact point, L; the length from the center of gravity to the pivot, r; and the chord impact length, c_l. The chord length, c_l, divided by the circumferential length is the fractional length over which the impact occurs. If the hammer were larger than the entire O-ring the ratio would be one. Usually the ratio is much smaller than one. The geometry of the O-ring includes the major diameter (inside diameter plus half the cross-section diameter), D, and the minor (or cross-section) diameter, d. The input data from the test includes the angular position of the hammer as a function of time, collected at a sample rate high enough to determine the time the hammer is in contact with the O-ring.

The center of mass of the pendulum arm can be found by balancing. The inertia can be found by the measuring the small amplitude frequency, f, and then using:

$$I = \frac{mgr}{4\pi^2 f^2} \qquad (24)$$

The radius of gyration, k, can be used in place of the inertia, if the mass is known, and can be found from the definition:

$$k^2 = I / m \qquad (25)$$

The motion of the pendulum can be adequately described by considering the conservation of energy. The energy, E, is given by:

$$E = \frac{1}{2} I \dot{\theta}^2 + mgr(1 - \cos\theta) \qquad (26)$$

where θ is the angular position, $(\ )=d/dt$ is the derivative with respect to time, and g is the acceleration of gravity. The energy can be found for each impact by determining the maximum angle before the impact (where the angular velocity vanishes.) The energy is then given by:

$$E = mgr(1 - \cos\theta_{max}) \qquad (27)$$

The angular velocity at the beginning of the impact is a maximum and can be found by setting θ equal to zero in equation (26) as:

41

$$\dot{\theta}_{max} = \sqrt{2E/I}$$ (28)

The impact will now be considered as a mass moving at some initial speed into a linear spring and mass in parallel. This is only a rough approximation and later work can refine the description of the impact. The ratio of the velocity before the impact divided by velocity after the impact is related to the fraction of critical damping, ζ, by:

$$\zeta = \ln(\dot{\theta}_{before} / \dot{\theta}_{after})$$ (29)

The time of impact, dt, (which can be extracted from the data if the sampling rate is sufficiently high) is one half cycle and can be used to find the natural frequency, ω, (in radians per second) as in:

$$\omega = \pi / dt$$ (30)

The effective stiffness, K, can now be found from:

$$K = m(\omega k / L)^2$$ (31)

while the effective damping constant, c, is:

$$c = 2\zeta m\omega(k / L)^2$$ (32)

The $tan\delta$ for the O-ring material can now be found by dividing force constant by the spring force:

$$\tan\delta = \frac{\omega c}{K}$$ (33)

The problem now is to translate the effective spring constant into a shear modulus. The shear modulus will be proportional to the effective spring constant and inversely proportional to the distance over which the impact occurs (i.e. the chord length, c_l) or:

$$G^* = \alpha K / c_l$$ (34)

where

$$G^* = \sqrt{G'^2 + G''^2}$$ (35)

From a simulation of an O-ring squeezed between two parallel surfaces, an approximate value for the constant α is:

$$\alpha = 3.70$$ (36)

42

Equations (34) and (36) are only an estimate, and a more accurate representation is required. The storage and loss moduli can now be found from:

$$G' = G^* \cos\delta \qquad (37)$$

and

$$G'' = G^* \sin\delta \qquad (38)$$

A more accurate interpretation can be found by determining the energy as the area under the load deflection curve for the O-ring squeezed between two parallel surfaces as a function of the deflection. Since the energy input is known and the deflection can be found from accurate experimental data, the effective modulus could be found. Unfortunately, with the current pendulum test hardware, it was not possible to determine the deflection to a sufficient accuracy. Improvement of accuracy and resolution of the pendulum hammer position and deflection would be required to provide a better interpretation.

A description of the software used to interpret the pendulum test data is included in Appendix E, along with a complete listing.

7.3.3 Discussion of Pendulum Rebound Test Results

Master data describing the history and dynamic testing results for O-rings is shown in Table 7.1 for the MIL-R-25988 fluorosilicone O-rings and in Table 7.2 for the nitrile O-rings. The aging history, compression set data, dynamic parallel plate testing and dynamic pendulum testing results are all reported in these tables. Testing was limited to the larger, AS 568 size -214, O-rings. Significant breakage occurred with the smaller, size -007 samples, limiting the number of specimens available for testing. Due to limited resources, a decision was made to concentrate on the developing and calibrating the larger pendulum hammer that would be used with the –214 O-rings. Calculations were made to determine the fundamental frequency (Rebound_Freq_n)), the storage modulus, G' (Gpn) and loss modulus, G" (Gppn) of the first three rebounds (n) for each measured sample. The mean values of three rebound tests per sample are shown in the table.

For each manufacturer, preliminary tests were run on new O-rings. Tests were run on dry specimens, followed by tests on new O-rings which had been wet with test fluid. JP-8 was used for the fluorosilicone seals and hydraulic oil for the nitrile seals. Dry samples were run only for reference purposes. Since all the aged O-rings were stored and tested wet, the new, wet samples provided the baseline reference to determine property shifts. A comparison of the storage and loss moduli for new and aged O-rings is shown in Figures 7.3 and 7.4. This data has been grouped by manufacturer.

Examination of the data for the fluorosilicone O-rings indicates that significant scatter exists across the data for each manufacturer's seals. No significant trends in property shifts were seen over the course of the aging experiments. Either the property changes due to aging were insignificant or the test method was insensitive to property shifts. However, results were generally reproducible for individual samples. This suggests that the method, within inherent mechanical and instrumental limits, is sound. As mentioned in Section 7.3.2, an improvement

43

of accuracy and resolution of the instrumentation would be required to provide a better interpretation.

Examination of the results of the rebound testing of the nitrile O-ring shows similar results. Although the range of the data (moduli in MPa) is reasonable for the type of material under test, no trends are evident. Either the aging method is insufficient to generate significant differences in the samples, or the test method is limited in sensitivity.

7.4 Cyclic Parallel Plate Test

Under actual use conditions, O-ring seals can be considered to be trapped between two parallel plates with some nominal level of compressive strain. Under actual use, the seal is trapped in a groove, called a gland. Typical O-ring seal configurations were previously shown in Figure 6.1. Under these conditions, the stress induced in the seal material provides a nominal sealing force. Under actual use, however, differential pressure exerted on the seal creates a more complex situation which deforms the seal material. The complex stress induced in the seal that is trapped in the gland structure provides the required sealing force, if the seal behaves as designed.

However, it may be possible to determine changes of relative sealing force between samples with different aging histories and between different materials, by cyclically exciting the compressed seals and analyzing the stress-strain response.

7.4.1 Parallel Plate Test Hardware

In practice, the seals could be held between two parallel plates and excited by cyclically varying the spacing between the plates. For testing of the seals, this was accomplished by use of a pair of circular plates which were installed in a high cycle rate MTS 820 servohydraulic tester. The test samples were compressed to 80% of their relaxed height and allowed to relax for 2-3 minutes. Each sample was then oscillated between 70-80% of the original seal height at frequencies from 1 Hz to 60 Hz and the force-displacement response was measured.

In the experimental test setup, the MTS servohydraulic tester was driven by an external sinusoidal source and the relative position of the plates determined using a simple LVdt position sensor. The output of the sensor was used to provide feedback control of the servohydraulic hardware and also used as one of the measured outputs. A load cell was placed in series with the static (reference) plate to measure force output. The plates were ported to relieve gas pressure from the cavity between the two plates and the seal. Based on prior testing of various types of elastomeric specimens, this configuration generally gives good results in the 0.1-60 Hz range with small displacements, typically under 0.100 inches. (2.54 mm) The parallel plate tester is shown in Figure 7.5.

To acquire data, two methods were used. Initially, due to limitations of available digital data acquisition hardware, a Techtronix Model DSA 602A recording oscilloscope was used for data acquisition. Digital data acquisition hardware available at the start of testing was limited to less than 100 Hz per channel and contamination of data was a concern. Samples were oscillated between 70-80% of relaxed height at 1, 5, 10, 20 40 and 60 Hz. The force and displacement

output from each test was printed and set aside for analysis. This method provided an adequate method for recording data. However, it made analysis difficult due to the manual method of data analysis. Later samples, (for example, the nitrile O-ring seals) were tested using similar methods, and data acquisition was provided using Strawberry Tree data acquisition hardware and a 486 computer running Workbench for PC software. This data acquisition method provided a sufficient bandwidth of 500-2000 Hz per channel depending on hardware configuration.

The parallel plate test is not linear because of the area changes and, hence, is difficult to interpret. The most accurate interpretation would be to use the MARC or ANSYS workstation software to simulate the test. This would automatically include the nonlinear effects.

7.4.2 Parallel Plate Test Software

The results from the cyclic parallel plate tests consist of the maximum and minimum loads for each cycle. The input conditions include: the mean squeeze (i.e., the mean displacement across the cross-section diameter divides by the diameter) and the change in the squeeze. Typically the tests were performed at mean of 25 percent with a variation of 5 percent above and below the mean.

A relatively simple method for interpreting the data would be to take the contact area as the contact area at the mean squeeze and the induced strain as the strain at the center of the O-ring cross-section. A MARC finite element model for an elastic O-ring with a typical ratio of major-to-minor diameters was used to find the contact area and the strain as a function of the squeeze. The area ratio is defined as:

$$A_R = \frac{A_c}{\pi D d} \qquad (39)$$

where A_c is the contact area, D is the major diameter., and d is the minor diameter. A least squares fit to the results of the simulation (for all but the first point) is shown in Figure 7.6a. The least squares fit for the area ratio is:

$$A_R = 1.823S + 0.0958 \qquad (40)$$

where S is the squeeze. In a similar manner the strain is given by:

$$\varepsilon = 1.270S - 0.040 \qquad (41)$$

and is shown in Figure 7.6b. The strain range can now be found from:

$$\varepsilon_{p-p} = \varepsilon_{max} - \varepsilon_{min} \qquad (42)$$

where the peak-to-peak squeeze is twice the maximum minus the mean squeeze.

The effective modulus can now be found from:

$$G^* = \frac{F_{max} - F_{min}}{3\pi DA_R \varepsilon_{p-p}}$$
(43)

where use has been made of equation (3).

The phase angle between the median force and the median displacement times can be used to find δ (recall that the ratio of G' to G'' is $tan\delta$) as:

$$\delta = \pi f (t_{up} + t_{down})$$
(44)

where t_{up} is the time the median force leads the mean squeeze, and t_{down} is the lead time going down. The storage and loss modulus can be now be found from equations (37) and (38). Of course,

$$\tan \delta = G'/G''$$
(45)

The above data reduction can be readily completed using a PC spreadsheet.

7.4.3   Discussion of Cyclic Parallel Plate Test Results

Results from analysis of the Parallel Plate Cyclic compressive testing for fluorosilicone and nitrile O-ring seals are shown in Tables 7.1 and 7.2. Preliminary baseline tests were made using new O-ring samples from each manufacturer in both the dry state and with each O-ring wet with the appropriate fluid. The new, wet samples were used for a reference baseline for each manufacturer. The storage modulus, G' (Gp_n) and loss modulus, G'' (Gpp_n) are reported in units of MPa at four frequencies in Tables 7.1 and 7.2. As shown by the test data, the results mirror the results from the rebound pendulum methods. Although the results generally gave acceptable results in terms of the absolute range of material properties, the scatter and the lack of relative change within each data set between new and aged samples indicates the aging method is insufficient to generate significant differences in the samples and the test method limited in sensitivity. A comparison of the storage and loss moduli for new and aged O-rings is shown in Figures 7.6 and 7.7. This data has been grouped by manufacturer.

7.5 Compression Set Testing

When elastomeric materials are subjected to continuous, long-term compression, creep and relaxation can occur within the sample, resulting in permanent deformation of the sample. This phenomenon is called compression set and was previously discussed in Section 6. The definition of compression set is shown in Figure 2.2.

7.5.1   Compression Set Test Hardware

As described in Section 5.2, prior to dynamic testing, the O-ring seals were subjected to an aging process using simulated operating conditions. During aging, the seals were compressed in fixtures similar to actual operating hardware. Examples of the test fixtures are shown in Figures 5.1 and 5.2. During the aging process, the weight change and compression set were determined.

Prior to installation in the aging fixtures, the weight of each O-ring sample was recorded. The small diameter of each specimen was measured manually at 6 points using a digital micrometer. The technician responsible for measurement used an optical magnifier of approximately 10X to determine that negligible deformation of each sample occurred during the measurement method. Three points were collected along the short axis of the O-ring (thickness) and 3 points were collected across the small diameter along the long axis (width) Following each aging cycle, the samples were recovered, weighed and measured within 1-2 hours of removal from the aging fixture. The results were averaged and reported in Tables 7.1 and 7.2.

7.5.2   Reduction of Compression Set Test Data and Comparison of Results

The initial and final width and height of each O-ring tested was measured and tabulated in a spreadsheet. Three measurements were made and averaged and the initial and final mass were entered in a separate spreadsheet. An example is shown in Figure 7.9. As can be seen from Figure 7.9, it is difficult to note any correspondence between supplier and the permanent changes due to aging. Figures 7.9 through 7.17 summarize this data. Note that mass measurements were not made for all the specimens. Two aging times were considered: 168 hours or 7 days, and 504 hours or 21 days. The nitrile seals were tested at 107°C and 135°C, while the fluorosilicone seals were tested at 121°C and 149°C.

In general, the width permanently decreased and the height increased for the nitrile seals, while for the fluorosilicone seals both the width and the height permanently increased. The nitrile seals generally exhibited a mass increase, as did the low temperature fluorosilicone tests. However, the high temperature fluorosilicone seals exhibited a mass decrease. This indicates that there may have been a change in the fluorosilicone seals between 121 and 149°C. Table 7.3 averages compression set data over all suppliers.

In general, the changes should increase in absolute value with temperature and time. Since the pressure dominates over the squeeze [the squeeze can relax over time, but the loads cannot as shown in equation [(23)], the width changes must be considered over the height or mass changes. Yet the fluorosilicone shows no discernable trends. The height changes should be steady if relaxation has dominated. Again the fluorosilicone does not show a proper trend. The nitrile seals were consistent in both the height and width.

The reduction of the data can be illustrated by considering the nitrile seals. The 10°C increase in temperature for the 168 hour tests increased the width change by 2.4 times, while the increase in temperature at 504 hours increased the width change by 1.4 times. Hence, take the increase to be about 2 times for the 10°C change. The change in the width will vary as $exp(-Q/RT)$. For this case then, Q/R is about 7000 R. Taking a creep law that includes time hardening

$$\dot{\varepsilon} = A_0 e^{-Q/RT} p^n t^m = A e^{-Q/RT} t^m \qquad (46)$$

where A_0, n and m are constants. For our case, the pressure is a constant and the term $A_0 p^n$ is a constant A. The constants can be evaluated by noting that over a change in time the permanent changes again differed by a factor of two. This makes m about 0.6. Obviously, the reduced data

47

is not accurate, and provides only an estimate of the permanent changes at other temperatures and times. Unfortunately, only one pressure was applied for each seal, and so an estimate for the stress exponent cannot be found. Time hardening is also not a good approximation of creep. In general, the compression set data did not provide sufficiently accurate data to provide a procedure for determining the life. It appears that a better estimate for the long time behavior can be discerned from the $tan\delta$, or possibly from the G' and the G'' data.

7.6 Comparison of Results

As was originally believed, the compression set data proved to be a poor prediction of changes in physical properties of O-ring seals, and, therefore, is not a good method for predicting seal life.

However, the data scatter and lack of trends observed for both the pendulum rebound test and for the cyclic compression testing was unexpected. In both cases, the level of scatter was found to be as severe as the scatter for compression set results. No trends were determined for either method to correlate the change in physical properties of each manufacturer's seals as a result of the aging process. All tests, however, were carried out with wet O-rings, and the plasticization of the seals by the fluid may obscure slight material changes.

Table 7.3 Compression Set Data Averaged Over Suppliers.

8.0 DISCUSSION OF RESULTS

The original intent of the research program was to develop a simple benchtop test method capable of distinguishing changes in aged O-ring seals which might serve to project relative life between manufacturers. Fluorosilicone and nitrile O-ring seals were each obtained from 3 manufacturers and artificially aged. Three different methods were explored to measure changes in the seals which might serve to predict seal performance and life,

1. Compression set,
2. Dynamic rebound,
3. Cyclic compressive force-displacement response.

Changes in seal dimensions and weight were measured as a function of the aging processes to determine whether compression set might prove a useful prediction method. Previous work and these results confirmed that compression set was incapable of distinguishing between good and poor seal materials.

Using the remaining two test methods, fundamental principles of operation were established. Preliminary hardware, test methods and analytical tools were designed and developed. However, with the current level of development, limited by the scope and funds available for the program, test methods capable of determining subtle changes of seal properties were not successfully developed.

The dynamic rebound test has potential for measuring basic rubber properties between multiple samples. However, the level of sophistication required to differentiate the expected changes of properties is beyond the capability of both the current method and the test hardware. This method could be developed into a benchtop test method that the military requires. Development of this method to provide required capabilities would require a program more focused than the current effort. It is recommended and suggested that a focused activity using a limited number of well characterized elastomeric seal samples could concentrate on refining both the hardware and the analytical software.

The cyclic compressive force-displacement method also has potential similar to the rebound method; however, development of this method into a suitable benchtop test is not expected. The cost of servohydraulic test equipment, such as the MTS, Instron or similar equipment, is incompatible with the goal of developing a simple benchtop method for evaluating seals.

9.0 SUMMARY OF LIFE PREDICTION METHOD

Two methods were examined for estimating the life of O-ring seals. The first is based on the use of PC's and the second on workstations. The PC version will be coupled to the pendulum test data, while the workstation version will be coupled with the cyclic parallel plate tests. There is no reason they cannot be reversed, but the pendulum test is particularly simple and provides a good match to the PC version. A summary of the life prediction method for the PC and workstation codes is given below.

9.1 Pendulum Test and PC Code

Three steps are required for estimating the life of an O-ring using the PC software. The pendulum test data must be gathered and interpreted. A model must be generated, and then an estimate for the long term response developed. The first two steps are readily completed, but the last will depend on a comparison across several design choices to determine which design will have the longest life.

9.1.1 Interpretation of Pendulum Data

The data from the pendulum test will consist of $\tan\delta$ or G' and G''. The most important of these is the loss modulus, G'', as it represents the permanent deformation that could occur. In the PC code there are two parameters: 1) the relaxation factor which can be set to $\tan\delta$. And 2) the Young's modulus which can be taken as 3 times the storage modulus, G' as in equation (3). The relaxation time is a third constant, but we only have the storage and loss moduli. If the data for the first bounce is used for G' and G'' then we set the relaxation time to the period for the first bounce, or we must look through the remaining data for an estimate of the frequency where G'' is a maximum, and set the time equal to the period while using the values for G' and G'' at that frequency. If there is no discernable maximum then set the relaxation time to the period for the first bounce frequency, or, if possible, use a bounce with a frequency near the loading frequencies. This step will ensure that the correct response will result for that frequency.

9.1.2 PC Code Modeling

Once the properties have been determined, all that remains is obtaining the data for the O-ring and gland geometry and the loading. The geometric inputs are readily determined from the proposed design. Variations in the design geometry can be readily entered and evaluated. The loading will consist of a mean squeeze and mean pressure, and variations about the mean. The frequency of the variations must also be determined. The variations in the footprints and the wall forces should be examined to determine if the seal is likely to leak. Higher normal wall forces are desirable. High frictional forces will increase the erosion rate. Smaller footprints are more susceptible to leaking due to surface roughness.

9.1.3 Long Term Response PC Prediction

If the long term response is desired, then the appropriate relaxation time must be used, and only a long time steady state case needs to be run. The long term relaxation time is difficult to

determine from typical compression set data as discussed in Section 7.5; hence, it may only be possible to determine the steady wall forces, and footprints. For accurate steady state estimates, the long time G' and G'' must be known, or equivalently a long time relaxation test must be performed.

9.2 Pendulum Test and PC Code

Again, three steps are required for estimating the life of an O-ring using the workstation software. The cyclic parallel plate data must be gathered and interpreted. A finite element model must be generated, and then an estimate for the long term response developed. The greater power of the finite element analyses means that models can also be generated to analyze the experimental data, and greater fidelity can be added to the model as desired.

9.2.1 Interpretation of Cyclic Parallel Plate Data

The data from the cyclic parallel plate test will again consist of $tan\delta$ or G' and G''. The workstation code directly interprets the values for G' and $tan\delta$ at the frequency where G'' is a maximum. If a relative maximum cannot be found then a frequency should be chosen that is close to the loading frequency for the simulations. This will ensure that the correct response will result for the loading frequency.

9.2.2 Workstation Code Modeling

Once the properties have been determined all that remains is the data for the O-ring and gland geometry and the loading. The geometric inputs are readily determined from the proposed design. Face seals can also be modeled, which can be an aid in evaluating the cyclic parallel plate tests. Variations in the design geometry are not as easily evaluated because of the increase in computational times, but this is balanced by the more accurate models that can be examined. The loading again consists of a mean squeeze and mean pressure, and variations about the mean. The frequency of the variations must also be determined. The workstation allows for a phase angle to be introduced between the squeeze variations and the pressure variations.

9.2.3 Long Term Response Workstation Prediction

If the long term response is desired then the appropriate relaxation time must be used. Again the long term relaxation time is difficult to determine from typical compression set data as discussed in Section 7.5. For accurate steady state estimates, the long time G' and G'' must be known, or equivalently, a long time relaxation test must be performed. Because of the greater generality of the finite element code, the models generated can be readily modified to include nonlinear response parameters, such as creep properties in equations (12) and/or (46).

10.0 CONCLUSIONS

Benchtop procedures capable of determining basic properties of new and aged seals were examined and developed. In conjunction with the test methods, analytical models were developed with the intent of predicting sealing properties of aged O-ring seals.

Two methods potentially capable of measuring the storage and loss moduli of O-rings under dynamic conditions were explored. One method was based on measuring multiple rebounds of a pendulum dropped against the O-ring. The second method was based on determining the cyclic force- displacement response of O-rings squeezed between two parallel plates. The O-rings were excited over a series of frequencies ranging from 1 to 100 Hz.

Two computational methods were developed for the analysis of data generated by these test methods. The first was designed to run on a PC, and predicted the deformation and forces for O-rings for a variety of loading conditions. The second was a workstations version that automatically ran either of two finite element codes (MARC or ANSYS.)

Both test methods proved capable of measuring the basic properties of the O-rings, with somewhat greater accuracy from the pendulum rebound method. Variations between different materials were determined. However, the aging method did not induce significant changes in each family of O-rings, preventing the successful development of a true life prediction method.

The rebound test equipment and method has been retained and will be used in future efforts to determine fundamental properties of elastomer samples with non-standard geometries. An application for a patent covering the test hardware, test method and analytical software has been submitted to the UTRC legal department for filing.

APPENDIX A
VISUAL BASIC CODE USER'S MANUAL

The Visual Basic version can be used on most PC's. It provides the user with a simple interface that prompts the user for the data entries and execution.

Double click on the program "vboring.exe" and a screen will appear with the data entries run labeled. Enter a title to identify the case to be run. Proceed to the next data entry line and enter the gland dimensions as shown in Figure A.1. On the next line enter in order: the minor or cross-section diameter, the stretched inner diameter, followed by the unstretched inner diameter. Proceed to the next line and enter the Young's modulus (use three times the storage modulus), the relaxation time (which is the period for the frequency where the loss modulus is a maximum, or if that is not known the period for the loading frequency), and last enter the relaxation factor (which can be taken to be the long term shear modulus divided by the short term modulus.) At the end of this line enter the file name without an extension (i.e., the job ID.) Skip to the next line and enter the applied pressure, the back pressure and the coefficient of friction. Move down one line to enter the loading type. This is usually a 2 for sinusoidal loading. Type 3 is exponential decay, while type 1 is step loading, and type 0 is used for program tests. The next three entries on the line are the change in the pressure, the change in the gap and the frequency. In the last line enter the number of time steps and the time step.

Hit the execute button to run the program. This will first run the Fortran program "make_input" which uses the Visual Basic input and converts it to an input file for the modified O-ring deformation program developed by Salita (Ref. 8.) The output from the O-ring deformation is stored in a file with the job ID and an '.out' appended. Next the Visual Basic program executes the Fortran program "plotit.f." The program plotit will ask the user how often the deformed plots should be completed. An entry of 5 will plot every fifth step. Program plotit first presents the deformed plots through increasing time. Hit the X key to get to the next plot. The last three plots present in order: the footprint history, the normal force history on each wall, and, if friction is present, the last plot is the frictional forces on each wall. Hard copies (in the form of postscript files) cannot presently be made of the deformed plots. Footprint and force history plots can be made by hitting the H key. Only one plot can be made per run because of incompatibilities between the graphics subroutines and DOS. The user will have to close the DOS window to complete the run. If no hard copies are requested, then the program exits normally.

The O-ring deformation code was written in Fortran and translated to C, and the C code was compiled using Gnu C. Hence, if the O-ring deformation program exits with an error,(usually as a segmentation fault) then the most likely explanation is that an improper model was generated. Any messages will refer to the C code and it will not be possible to identify the exact source of the error. As an example, an O-ring that does not seal and has pressure applied will exit with an error. But since the error message refers to the C code that was generated from the Fortran code, it cannot be readily traced.
Fig. A.1 PC Code Gland Geomerty

APPENDIX B
DOS CODE USER'S MANUAL

The DOS version can be used on more PC's than the Visual Basic version, since it requires less computing capability, but it is also more difficult to use. On older machines the user first needs to exit windows, on machines with Windows '95 choose the MS-DOS prompt under the Programs menu.

Once in DOS type 'copy template.dat' followed by the job name. Append the job name with '.dat' and hit 'enter'. This copies a previous file to the new input data file. Next type 'edit' followed by the job name. Again append the job name with '.dat' and hit 'enter'. Once in the editor a form similar to Figure B.1 will appear on the screen. The data already entered is a previous test case used to check the program. Erase the text in the first line, by highlighting and then using cut under the edit theme, or by backspacing through the line. Enter a title that identifies the case to be run. Proceed down two lines and enter the gland dimensions as shown in Figure B.2 by erasing the previous entries and typing the appropriate quantities. Skip down another two lines and enter in order: the minor or cross-section diameter, the stretched inner diameter, followed by the unstretched inner diameter. Skip down two lines and enter the Young's modulus (use three times the storage modulus), the relaxation time (which is the period for the frequency where the loss modulus is a maximum, or if that is not known the period for the loading frequency), and last enter the relaxation factor (which can be taken to be the long term shear modulus divided by the short term modulus.) Skip another line and on the next line enter the applied pressure, the back pressure and the coefficient of friction. Move down two lines to enter the loading type. This is usually a 2 for sinusoidal loading. Type 3 the is exponential decay. Type 1 is step loading, and type 0 is used for program tests. The next three entries on the line are the change in the pressure, the change in the gap and the frequency. In the last line enter the number of time steps and the time step.

Exit the editor by entering the File menu, choosing save, and then re-enter the File menu and choose exit. At the DOS prompt, type "runoring" followed by the job name. This will execute the file runoring.bat, which is shown in Figure B.3. This file will first run the compiled Fortran program "make_input" (see the listing after this appendix) which uses the file from the editor and converts it to an input file for the modified O-ring deformation program developed by Salita (Ref. 8.) The output from the O-ring deformation is stored in a file with the job name and an '.out' appended. Runoring.bat next stores the job name in jobid.tmp and then executes the program Fortran program plotit.f (see the listing at the end of this appendix). The program plotit will ask the user for how often the deformed plots should be completed. An entry of 5 will plot every fifth step. Program plotit first presents the deformed plots through increasing time. Hit the X key to get to the next plot. The last three plots present in order: the footprint history, the normal force history on each wall, and if friction is present, the last plot is the frictional forces on each wall. Hard copies (in the form of postscript files) cannot presently be made of the deformed plots. Footprint and force history plots can be made by hitting the H key. Only one plot can be made per run because of incompatibilities between the graphics subroutines and DOS. The user will have to close the DOS window to complete the run. The last step in runoring.bat is to delete the jobid.tmp file.

After completing a run it is possible to replot the results since the output has been stored. At the DOS prompt, type plotit. The program will ask for the job name and then ask for the plot frequency as described above. A postscript file of one of the history plots can be obtained here also.

The O-ring deformation was written in Fortran and translated to C, and the C code was compiled using Gnu C. Hence, if the O-ring deformation program exits with an error,(usually as a segmentation fault when an improper model is generated), then any messages will refer to the C code and it will not be possible to identify the exact source of the error. As an example, an O-ring that does not seal and has pressure applied will exit with an error. But since the error message refers to the C code that was generated from the Fortran code, it cannot be readily traced.

APPENDIX C
MARC MODELING USER'S MANUAL

MARC workstation modeling provides the experienced user of finite element codes with a significant increase in capability. Users with less experience may want to simulate tests that cannot be completed with the simpler PC versions.

The first step is to write a file containing the O-ring geometry, material properties, and loading conditions, as shown in Fig C.1. A job name must be chosen, and can consist of any number of characters. It must be appended with an '.inp'. The first line of the file is a title.

The second line contains the major and minor diameter. The major diameter is the inside diameter plus the cross-section radius. The minor diameter is the cross-section diameter. Line 3 contains the storage modulus and line 4 contains $tan\delta$. Line 5 is the frequency at which lines 3 and 4 apply. If line 5 is the frequency at which the $tan\delta$ is a maximum, the accuracy at other frequencies will be significantly increased. Line 6 contains the friction coefficient.

The gland geometry now follows. Line 7 contains the type of gland (type 1 is a piston seal, type 2 is a rod seal and type 3 is a face seal, as shown in Figure C.2.) The gland width and depth are entered on line 8. For a definition of the geometric dimensions see Figure C.3. On line 9 the inner diameter and the initial gap are entered. If zeros are entered for the quantities on line 9 then software will automatically assign values to each so that the O-ring just touches the inside of the gland and the top of the O-ring just touches the gland.

The loads are entered next. Line 10 contains the internal and external pressure. Line 11 must contain the mean squeeze, and line 12 the maximum squeeze. Line 13 has the pressure change, the phase angle with respect to the gland motion. On line 14 the number of cycles to be simulated, and the frequency are entered. The last line, line 16, contains information on the number of increments required to apply the mean squeeze, then the mean pressure, and lastly the cyclic loads.

The user can now run the simulation by typing "run_oring" followed by the job name. The script run_oring is included as Figure C.4. The first line echoes the job name to the ACSII file jobname.txt. Next the compiled Fortran program "make_model" is run which generates the MARC input data. The file jobname.txt is no longer needed and is next removed. Two subroutines, that describe the pressure (forcem.f) and gland motion (motion.f) history needed for the MARC finite element code, are now stored in a file with the job name followed by '.f'. Now the MARC program can be run. The program is automatically brought up, told the data file name (generated by the Fortran program "make_model.f") and told to run in background mode. The question asked by the MARC shell script is answered. If the job name is incorrect the MARC shell script will continue to ask for an answer, and the user must terminate it by holding down the Control key and the C key. The last line of the script deletes the file that contains the subroutines forcem.f and motion.f.

During the run the MARC code will store a log of the run in a file with job name appended by '.log'. Output is written in the file with the job name appended by '.out', and data for post processing is in the file with the job name followed by '.t16'.

Listings of the subroutines forcem.f, and motion.f are attached at the end of this appendix. The subroutines have three basic sections. The first programs the squeeze. The second brings the pressures to the mean pressures, and the last performs the cyclic loading. The listing for make_model.f follows. It generates each data block for the MARC input file. Many of the lines are the same for each run, and some of these are stored in several files appended with '.inp'. The finite element mesh is also stored for a unit cross-section radius. The mesh is translated according to the major radius, and rotated to accommodate the three O-ring types. There is an additional rotation of 45 degrees to minimize the effects of mesh distortion on the results.

A summary of the user input data is sent to the screen and also to a file with the job name appended with '.sum'. A list of files used by make_model.f is included as Figure C.5.

During the MARC runs, one persistent error occurs. At high pressure loadings the simulation detects instabilities (either buckling or numerical) and will terminate with one or more messages indicating that the third invariant of particular elements is negative. This indicates that the loading increments (or total load) cannot be accommodated without turning elements inside out. Although this is an indication of a true physical instability, it is more likely to be numerical in nature.

APPENDIX D
ANSYS MODELING USER'S MANUAL

The O-ring ANSYS version cannot simulate the diverse problems that the O-ring MARC version can, but the ANSYS version can readily model the parallel plate cyclic tests. To perform these simulations, an ANSYS 5.4 macro (see the listing at the end of this appendix) was written which prompts the user for geometric and material data, generates an axisymmetric model of a viscoelastic rubber o-ring, and runs a compression and decompression cycle using rigid compression surfaces.

Directions:
1. Enter ANSYS
2. Type 'oring' at the command line (executes the macro 'oring.mac')
3. Answer the following prompts:
   - Job Name   (This will be the name of the database file containing the model)
   - Title   (This will be listed at the bottom of all of the output plots)
   - Major Diameter   (see Figure D.1 below)
   - Minor Diameter   (see Figure D.1 below)
   - Compression Displacement   (Total compression of the O-ring (see Figure D.1))
   - Compression Velocity   (Velocity of the rigid surfaces into the O-ring during compression only)
   - Instantaneous shear modulus   (G(0) in the viscoelastic constitutive model)
   - Shear modulus at infinite time   (G(inf.) in the viscoelastic constitutive model)
   - Relaxation time factor   (λ in the viscoelastic constitutive model)

Model Execution:
Once the user completes the entry of geometry and material variables, the macro generates the geometry and the mesh, defines the rigid "target" surfaces, and executes three load steps. Several material parameters are currently set by the macro (although they can readily be modified by editing the macro). These parameters are as follows:

$G = G(inf.)$ (The global shear modulus is set equal to G(inf.) in the viscoelastic model

$v = 0.475$ (Poisson's ratio)

$\mu = 0.0$ (Friction coefficient - Zero friction assumed)

The ANSYS automesher is invoked to generate the mesh in the O-ring. It currently uses 60 higher-order viscoelastic elements around the periphery of the circle defining the cross-section. The axisymmetric option is turned on to fully account for the true stress state in the O-ring. The large deformation option is also invoked to account for large strain and large displacement effects.

The load steps are set up to run the following sequence of compression, hold, and decompression:

Load Steps

1. Compression: time = Δ/v (in 10 - 30 substeps)

                              Δ = compression displacement

                              v = compression velocity

Hold: time = $5*\lambda$ (in 10 substeps)

Decompression: time = $1*\lambda$ (in 10 - 30 substeps)

The solver is automatically executed for each load step and the basic stress and displacement output is written to the results file '*.rst' for every substep. During compression, the rigid surfaces are compressed from both sides at a rate of 'v/2. This is equivalent to a compression velocity of 'v' in the case where only one of the surfaces moves.

ANSYS returns a warning during the simulation indicating that the viscoelastic elements have not been tested with the large strain option. The test cases completed indicate this should not be a problem.
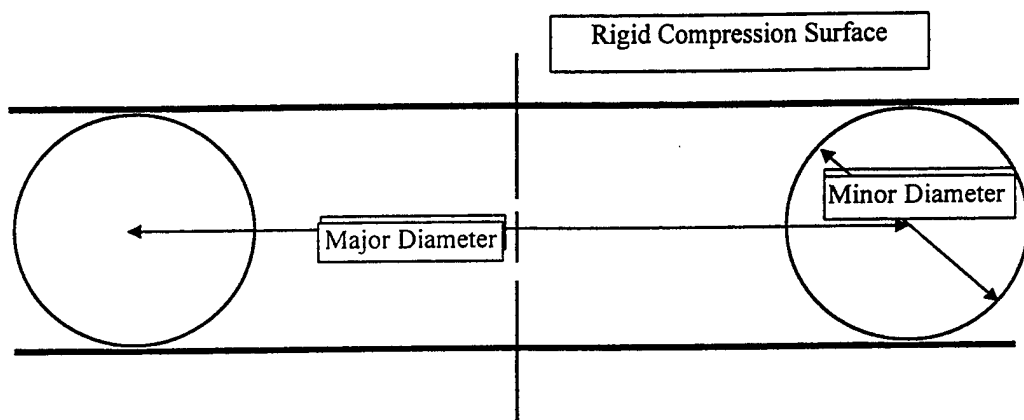

Figure D.1 Geometry of the O-Ring Model

```
!
! ANSYS Macro File - Creates a model of an oring with flat contact surfaces
!                    on each side.  The oring is compressed by one or both of
!                    these surfaces until it reaches a user-defined displacement.

APPENDIX E
PENDULUM TEST REDUCTION SOFTWARE

The software for interpreting the pendulum test data provides the user with a simple and effective way to obtain estimates for the O-ring material properties. The code was written in Fortran 77 and a listing of the code is included at the end of this appendix. Parameters are set at the top of the main program followed by declarations for each variable in the main program. All variables must be declared if the implicit none statement at the fifth line of the program remains. Declaring all variables allows the programmer, and subsequent users, to describe each variable, and removes many potential errors, making debugging a simpler task. After the declarations some constants the user may want to redefine are set. The program then asks the user for the job name. This is a unique name, that will be appended by extensions for various files associated with the test being analyzed. The program then asks the user for the initial angle, and echoes the job name and the angle to standard output. The program next opens an output file, on unit 12 as a file with the job name appended by .out, and writes the job name and the initial angle.

Next the data for the pendulum characteristics are read from a file named 'pendulum.dat' (an example is shown in Figure E.1) and echoed to standard output. The geometry for the O-ring is stored in a file separately by the user (se, for example, FigureE.2.) Now the user supplies the name of the O-ring data file. The O-ring data consists of the major (inside diameter plus cross-section radius) and minor diameter (cross-section diameter.)

The software is now ready to read the transient angle for the pendulum arm. The data is stored in a file with the job name appended with a .txt or .TXT. If the file is improperly named the program writes a warning message and stops. The first two lines of the data include a title, and column headings. Now the program can read the time and the signal strength, which is proportional to the angle. A count of the number of data points is also completed. The initial data is at the starting angle, allowing the proportionality constant to be found. The signal strength is next converted to angle.

The initial energy is found next by using the initial angle. The program now begins the loop over each bounce after writing the column headings. The loop over each bounce consists of first finding the next minimum in the angle, and then interpolating to find the times when the angle is past zero (i.e., in contact with the pendulum.) The next maximum can now be found form the data. It is now possible to find all the parameters for the O-ring properties using equations (24) through (38) in section 7.3.2. The results are sent to standard output and unit 12 for each bounce.
