13. ABSTRACT (Maximum 200 words) Applying the analytic technique, two antenna designs were found for which the radiation Q was below the limit determined by Chu for electrically small antennas. The simplest design is a turnstile antenna comprised of two perpendicularly oriented collocated electric dipoles that are phased to support circular polarization, for which the radiation Q is slightly less than a single electric dipole. The most intriguing antenna design consists of four spatially collocated equal power dipoles, a magnetic and electric dipole moment pair oriented along the x-axis, with the dipole pairs driven /2 out of phase to support circular polarization. For this source the analytically predicted radiation Q is zero independently of the relative electrical size ka of the antenna, where a is the radius of the smallest virtual sphere that circumscribes the antenna and k is the wave-number of radiation.

Final Report: No. F49620-96-1-0353
Entitled: Efficient Radiation from an Electrically Small Antenna
By: Dr. Craig A. Grimes, The University of Kentucky

Under the scope of program auspices the following milestones were achieved.

1. The first and only published analytic technique that correctly calculates the radiation Q of a general radiation field was developed [1,2].

2. Applying the analytic technique, two antenna designs were found for which the radiation Q was below the limit determined by Chu for electrically small antennas.

The simplest design is a turnstile antenna comprised of two perpendicularly oriented collocated electric dipoles that are phased to support circular polarization, for which the radiation Q is slightly less than a single electric dipole.

The most intriguing antenna design consists of four spatially collocated equal power dipoles; a magnetic and electric dipole moment pair oriented along the x -axis, and a magnetic-electric dipole moment pair oriented along the y -axis, with the dipole-pairs driven $\pi/2$ out of phase to support circular polarization. For this source the analytically predicted radiation Q is zero independently of the relative electrical size ka of the antenna, where a is the radius of the smallest virtual sphere that circumscribes the antenna and k is the wave-number of radiation equal to $2\pi/\lambda$.

3. Numerical [3-5] and experimental [4,5] works have shown that the radiation Q s of the two different, multi-element antenna designs are a function of the relative phasing between the radiating elements.

4. The 'zero- Q ' antenna has been experimentally and numerically characterized [5]. Experimentally, for the 'zero- Q ' antenna of relative electrical size $ka = 0.39$, the measured Q is a factor of approximately three below the so-called Chu limit. Numerical simulations, with which we were able to characterize the antenna over a broader frequency range than possible with our experimental measurements, indicate that at $ka = 0.23$ the antenna Q is a factor of 20 below the Chu limit, and demonstrates wide-band operation indicative of self-tuning as discussed in [A]. Furthermore, while the energy field phasing required for low Q emission can be readily obtained in transmission, for reception the phasing for low Q operation is unlikely to be met by an incident wave, hence the antenna should operate as a non-reciprocal device [A].
