The Accuracy of Remapping Irregularly Spaced Velocity Data onto a Regular Grid and the Computation of Vorticity

R.K. Cohn and M.M. Koochesfahani

Abstract. The velocity data obtained from Molecular Tagging Velocimetry (MTV) are typically located on an irregularly spaced measurement grid. To take advantage of many standard data processing techniques, the MTV data need to be remapped onto a grid with a uniform spacing. In this work, accuracy and noise issues related to the use of a least-squares-fit to various low order polynomials for the remapping of these data onto a uniformly spaced grid and the subsequent computation of vorticity from these data are examined. This information has relevance to PIV data processing as well. As noted by Spedding and Rignot (1993), the best estimate of the velocity vector acquired through the use of tracer techniques such as PIV, is at the midpoint of the displacement vector. Thus, unless special care is taken, PIV data are also initially obtained on an irregular grid.

As in the results of Fouras and Soria (1998), the error in the re-mapped velocity and the calculated vorticity field is divided into a mean bias error and a random error. In the majority of cases, the mean bias error is a more significant source of error than the more often quoted random error. Results of the simulation show that the best choice for remapping is the use of a least-squares fit to a 2nd order polynomial and the best choice for vorticity calculation is to use a 4th order accurate, central, finite difference applied to uniformly sampled data. The actual value of the error depends upon the data density and the radius used for the selection of velocity measurements to be included in the remapping process. Increasing the data density and reducing the fit radius improve the accuracy.

1 Introduction

In recent years, many researchers have made use of full-field, two-component optical velocity measurement techniques, such as Particle Image Velocimetry (PIV), to derive flow quantities such as the out-of-plane vorticity from velocity data. The velocity field acquired from PIV is normally thought to be gathered on a uniformly spaced grid which allows for a variety of standard post-processing methods to be utilized. The development of Molecular Tagging Velocimetry (MTV) has placed an additional complication on the calculation of flow variables in that the data are not normally collected on a uniformly spaced grid. This paper deals with the questions related to remapping MTV data onto a regularly spaced grid and the

methods used to compute the out-of-plane vorticity component from these remapped data sets.

Molecular Tagging Velocimetry is a full-field optical diagnostic which allows for the non-intrusive measurement of a fluid velocity field. This technique takes advantage of molecules which have long-lived excited states when tagged by a photon source. This technique can be thought of as the molecular equivalent of Particle Image Velocimetry. Rather than tracking particles placed in the flowing medium, the luminescence of regions of the flow containing the tracer molecules is tracked. A more complete description of the implementation of the molecular tagging technique, its applications, and the parameters necessary for an optimal experiment can be found in Gendrich and Koochesfahani (1996) and Gendrich et al. (1997), and Koochesfahani (1999). The accuracy of velocity measurements made using Molecular Tagging Velocimetry is comparable to the digital version of PIV (DPIV).

In the implementation of MTV, a series of laser-lines is used to generate a two-dimensional spatial distribution in the intensity field within the flowing medium. Velocity vectors are calculated at the intersection of these laser-lines. Generally, the measurement locations are not uniformly spaced. Thus, it is necessary to place the velocity data onto a regular grid before flow variables, such as vorticity, can be computed via standard finite difference techniques. It should be noted that even though it is possible to generate a series of regularly spaced laser-lines in the flow, it is still necessary to remap the data. Both an unpublished study conducted at Michigan State University and Spedding and Rignot (1993) have reported that the best estimate of the location of the velocity vector determined by a measurement technique which tracks a tracer in a flow is located at the midpoint of the displacement vector. Thus, unless special care is taken in the selection of the measurement windows, data collected from PIV measurements is not on a uniformly spaced grid.

Few studies have examined the effect of remapping randomly spaced velocity data onto a regular grid. Agui and Jimenez (1987) reported that low order polynomial fits and "kriging" techniques produced the most accurate representation of the actual velocity field. However, the advantage was small with respect to other methods and no quantitative information on the performance of the polynomial and kriging methods was given. Spedding and Rignot (1993) compared an inverse distance approach with the use of a "global basis function" and found that the global basis function produced generally more accurate results; however, the results were highly dependent upon the measurement density.

Several authors have examined the accuracy of various means to compute vorticity from velocity data already on a regular grid. Spedding and Rignot (1993) used a 1st order finite difference technique for the inverse distance method and directly differentiated the global basis function to compute vorticity. It was found that direct differentiation of the global basis function produced generally superior results. However, as with the velocity results, the accuracy was highly dependent upon the ratio of a characteristic length scale of the flow, L, to the mean spacing between measurements, δ. Abrahamson and Lonnes (1995) found that calculating vorticity by computing the local circulation around a point resulted in slightly more accurate vorticity

results than differentiating a least-squares fit to a model velocity field. Luff et al. (1999) compared the 1st and 2nd order finite difference methods and an 8-point circulation method in the calculation of vorticity in the presence of both noise and missing data points. In terms of only the computed vorticity RMS, the 1st order finite difference technique produced the best results.

One shortcoming of the above mentioned studies is that only the random component of the error field is examined. Fouras and Soria (1998) found that the error in the vorticity field could be better represented if it is divided into two portions: a mean bias error due to spatial filtering, and a random error resulting from the propagation of error in the velocity measurements into the vorticity calculation. In some cases, the mean bias error can be significantly larger than the random error. This study recommends differentiating a 2nd order polynomial least-squares fit to the velocity data for the calculation of vorticity based on the 21 closest points. However, at low data densities, this produces larger bias errors then the use of a finite difference method. The results based on differentiating the fit were sensitive to the number of points used in the fit. This work is based entirely on regularly sampled velocity data; issues connected to remapping an irregular data set were not considered.

The aforementioned investigations suggest different optimum methods for vorticity computation depending upon the criterion used to assess the error. In our work, we directly compare several of the different vorticity calculation methods which were determined in the previous studies to produce the best results. In addition, we include the effect of the remapping of the velocity field on the estimation of the vorticity is also considered.

2 Comparison Method

The present study makes use of a simulation of an Oseen vortex in order to study the effect of remapping an irregularly sampled velocity field onto a regular grid and the calculation of the out-of-plane vorticity component. This flowfield has also been used in the works of Spedding and Rignot (1993), Fouras and Soria (1998), and Luff et al. (1999). The azimuthal velocity, u_θ, and out-of-plane vorticity, ω_z of this flow field are described by:

$$u_\theta = \frac{\omega_{\max} r_{core}^2}{2r}(1 - e^{-(r^2/r_{core}^2)})$$

$$\omega_z = \omega_{\max} e^{-(r^2/r_{core}^2)}. \tag{1}$$

In order to simulate the irregular sampling found in the original velocity field measurements, the simulation data are irregularly spaced. The irregular spacing is generated by sub-dividing the measurement field into $\delta \times \delta$ sized regions, where δ is the mean spacing between velocity measurement points. A random number generator is then used to determine a location for the simulated velocity within each $\delta \times \delta$ sized region. Equation (1) is then used to establish the velocity at this location. In this manner, the mean spacing between measurement points remains equal to δ; however the actual location of the measurement varies.

The random error inherent in MTV and PIV measurements is simulated by the addition of noise to the velocity field. The method used is similar to that in Luff, et al. (1999). A random number generator is used to add a random percentage of noise, with a maximum value of $n\%$ to each component of the cartesian components, i.e. u and v, of the velocity field. Using this formulation, the velocity at each point in the simulation has a value of:

$$u = u_{act}(1 + n_{random})$$

$$v = v_{act}(1 + n_{random}) \tag{2}$$

where n_{random} is a random number with a value $-n < n_{random} < +n$.

The quantities u_{act} and v_{act} represent the actual cartesian velocities determined from u_θ in equation (1). Although error values ranging from $0\% < n < 10\%$ were examined in the simulations, only 0% and 6% values are presented as they are representative of the other noise values.

The velocity data in the present study are remapped onto a regular grid by means of a local least-squares fit to a two-dimensional 2nd, 3rd, or 4th order polynomial. The u and v velocity fields are fit separately. Only the velocity measurements located within the fit radius, R, from the regular grid point are used in the fitting procedure. In this study, this radius is normalized by the mean spacing between velocity measurements, δ. For all cases, the number of points used in the fit is such that the least-squares fit is over-determined. After the fits for the two velocity components are generated, each of the local fits is evaluated at the coordinate of the regular grid point in order to determine the velocity at that location. Clearly choosing a value of R that is too large will result in a large amount of spatial filtering of the data, while a small value of R will limit the ability of the fit to reduce the random noise present in the original data. Note that the order of the polynomial places a limit on the minimum size of R that can be used. For all of the studies conducted, the density of the remapped, uniformly spaced grid remains the same as the initial irregularly spaced measurement grid.

Four methods are used to estimate the out-of-plane vorticity, i.e,

$$\omega_z = \frac{\partial v}{\partial x} - \frac{\partial u}{\partial y}. \tag{3}$$

The first two methods estimate the two derivatives in the definition of vorticity by means of a 1st or 2nd order central finite difference techniques (2nd and 4th order accurate, respectively). The third method performs a direct differentiation of the polynomial least-squares fit used in the remapping of the velocity field. This method has the advantage that it can be used to estimate the vorticity at any point within measurement region. The final vorticity calculation method computes the circulation of the 8 points in the rectangular region extending one regular grid point in each direction around the point to be examined. The calculated circulation value is then divided by the area in order to determine the vorticity. This method has been shown in Raffel et al. (1998) to be identical to a filtered version of the 1st order central finite difference technique. Figure 1 illustrates the data points used for the calculation of the vorticity in these various methods.

This study examines the effect of varying the mean data density, L/δ and the normalized fit radius, R/δ on the accuracy of the remapped velocity field and the calculated vorticity field. The characteristic flow scale, L, used in this study is the vortex core radius, r_{core} defined as the distance from the peak vorticity to the location where the vorticity has dropped by a factor of e^{-1}. Simulations are conducted for values of L/δ ranging from 2 to 10 and for R/δ ranging from 2 to 6. Note that in order for the fit to be over-determined, not all of these values can be used for all orders of the least-squares fit.

As in the results of Fouras and Soria (1998), the accuracy of both the velocity and vorticity calculations methods are assessed in terms of the mean bias error caused by spatial filtering and the random error. Both the propagation of the error in the original measurements to the remapped field and the placement of the randomly spaced points onto the regular grid generate the random error. Within each sample set, 100 independent simulations are conducted. The mean bias error will be denoted by the subscript bias and refers to difference between the mean value of these 100 velocity (or vorticity) measurements and the exact value at each point in the flowfield determined from equation (1). The random error is quantified by the rms of the velocity (or computed vorticity) data in the sample set. For example, for the x-component of velocity, these are defined as:

$$u^*_{bias} = u_{act} - \overline{u}$$

$$u^*_{rms} = \left(\frac{1}{100}\sum_{i=1}^{100}(u_i - \overline{u})^2\right)^{1/2} \qquad (4)$$

$$\overline{u} = \frac{1}{100}\sum_{i=1}^{100}u_i.$$

In these expressions, u_i is the velocity at a particular point of an individual realization. All of the velocity and vorticity error values reported here are normalized by their respective maximum values determined from equation (1). The normalized values are shown without the $(\ )^*$.

3 Remapping Results

Figure 2a displays the mean velocity bias error for the 2nd, 3rd, and 4th order polynomial fits. The results presented in this figure are for the case of 0% added noise because the addition of noise has no effect on the bias error, which is a mean quantity. For all three fits, the mean velocity data density is kept fixed at $L/\delta = 3.5$. That is, there are nominally 7 velocity vectors along the vortex core diameter. For the 2nd and 3rd order polynomial fits, three different values of R/δ are examined. However, only the two larger values are used for the 4th order polynomial fit to ensure there are enough data points available for the fit. In terms of the mean bias error, reducing this radius results in a significant decrease in the bias error. For the 2nd and 3rd order polynomial fits, reducing from $R/\delta = 4$ to $R/\delta = 2$ results in a decrease of the peak mean bias error from 8% to less than 1%. This effect is present, although less dramatic in the results for the 4th order polynomial fit.

In terms of the mean bias error, the most accurate results are obtained using the least-squares fit to a 4th order polynomial. However, the difference in the bias error between the 4th order fit using $R/\delta = 3$, and the 2nd order fit with $R/\delta = 2$ is approximately 0.4%. It is interesting to note that the results for the 2nd and 3rd order polynomial fits are nearly identical. For all three fit orders, the peak bias error occurs at approximately $0.6r_{core}$. In the region $r/r_{core} > 1.5$, the velocity values tend to be overestimated, rather than underestimated. Since the area of the region $r/r_{core} > 1.5$ is significantly larger than the region where the velocity values are underestimated, the net average of the bias error becomes very small. Thus, one should be cautious about the use of an accuracy measure which is averaged over the entire structure as this does not represent the actual error seen at any individual measurement location.

Figures 2b and 2c show the random error found in the velocity remapping field for cases of 0% and 6% added noise respectively. From Figures 2b and 2c it can be seen that, generally, the value of the rms error is less than 2% at all locations. This value can only be reduced by a maximum of 1.5% by the optimal choice of fit order and R/δ, whereas a reduction of 8% is seen in the bias error. It is also interesting to note that in the 0% added noise results, reducing R/δ results in a decrease in the random error. However, for the 6% added noise results, reducing R/δ results in an increase in the random error.

Unless otherwise stated, the remainder of the results presented in this paper will use the 2nd order polynomial for the remapping process. This choice is made because of this condition has a very small bias error, and it is not as computationally intensive as the 3rd and 4th order polynomials. Figure 3 shows the effect of grid density on the accuracy of the remapping for the 2nd order polynomial fit. As expected shows that increasing the grid density can significantly reduce the bias error in the remapping. In order to achieve a bias error of less than 1%, L/δ should be greater than 3. Furthermore, increasing the grid density also results in a significant decrease in the random error.

4 Vorticity Calculation Results

In this section, the error generated by the four methods for calculating the out-of-plane vorticity field will be examined. First, we will discuss the results from directly differentiating the various polynomial orders used in the remapping procedure in order to determine the vorticity value. Then, the results from this method will be compared with those from the finite difference and circulation methods applied to the remapped data using the 2nd order polynomial.

Figure 4a shows the mean bias error for differentiating the 2nd, 3rd, and 4th order polynomials for several values of R/δ. Similar to the velocity bias error results, decreasing R/δ decreases the bias error. The smallest values for the mean bias error are found using the smallest values of R/δ and the 3rd and 4th order polynomials. These selections result in a bias error of less than 4%. It is interesting to note that although the error in the remapping of the velocity field through the use of the 2nd and 3rd order polynomials are nearly identical, the vorticity estimates by differentiating these polynomials differ.

Figures 4b and 4c show the effect of the order of the polynomial fit on the random component of the error. For the case in which no noise is added to the velocity data, the random error is less than 1.5%. The addition of 6% random noise results in a small increase in the random component of the error for the majority of cases. For the 3rd order fit and $R/\delta = 2$, a large spike is seen in the error. It is believed that this spike is generated because the number of points utilized for the fit is only slightly larger than the minimum number of points required. With the exception of that case, there is generally little difference in the random error among the various polynomial fits. Since differentiating the 4th order polynomial with $R/\delta = 3$ has one of the smallest bias errors and its random error is less than that of the 3rd order fit, only the vorticity estimated from the 4th order fit will be compared with those calculated using the finite difference and circulation methods.

Figure 5a compares ω_{bias} found by the four different methods considered here. Once again, the effect of adding noise to the initial velocity field on the bias error is negligible, therefore, only the case of 0% added noise is shown. The qualitative features of the four methods are very similar. The maximum ω_{bias} occurs at $r/r_{core} = 0$ which is the location of the peak vorticity. For $r/r_{core} > 1.5$, there is a small overshoot where the vorticity value is overestimated. Note that although the numerical amount of the overshoot is small relative to that of the undershoot, the area occupied by the region of overshoot is roughly three times larger than the region of undershoot. Thus, the overall area-averaged vorticity bias error is very small. As a result, the estimate of the overall circulation of the vortex computed by integrating the vorticity field from any of these methods is accurate to better than 0.1% even though the peak bias error for these cases is nearly 20%.

In terms of the mean bias error, it is apparent that differentiating the 4th order polynomial fit, and the use of the 2nd order finite difference technique produce the most accurate vorticity field information. For comparison purposes, the results from $R/\delta = 4$ are also shown. As expected, reducing the value of R tends to improve the accuracy of the vorticity calculation as well as decreasing the difference between the accuracy of the two techniques. The circulation method and the 1st order finite difference method produce results with a significantly larger bias error than the other two methods.

Figure 5b and 5c show the random error for the vorticity calculation methods for the cases of 0% and 6% added noise respectively. Generally, differentiating the 4th order polynomial produces the

smallest random error while the 2nd order finite difference method produces the largest. As with the velocity field, the improvement which can be realized through the use of the optimal method to minimize the random error is much smaller than that which can be realized by minimizing the bias error. However, the difference in the random error between these two techniques is less than *1%*.

As expected, increasing the density of the original data also dramatically reduces the mean bias error as seen in Figure 6a. This figure only shows results for the 2nd order finite difference technique and $R/\delta = 2$, however, the qualitative features of all of the methods are identical. Increasing the mean data density, L/δ, from *2.5* to *4* results in a decrease of the mean bias error from *20%* to approximately *1%*. In terms of the random error, increasing the density of the data also results in a decrease of the random error.

5 Conclusions

The effect of remapping irregularly spaced velocity measurements onto a uniformly spaced grid and the accuracy of the out-of-plane vorticity computed from this information are studied through the use of a Gaussian core vortex simulation. Remapping onto a regular grid was performed by the use of a least-squares fit to 2nd, 3rd, and 4th order polynomials. Four methods are used for the calculation of vorticity from the velocity data. The derivatives necessary for the computation of vorticity can be found by directly differentiating the polynomials determined from the least-squares fit or by performing a 1st or 2nd order finite difference calculation on the regularly spaced data. The final method computes the local circulation of the region around a point and divides this circulation by the area. The effect of varying the normalized grid density (ratio of the flow characteristic length to the mean spacing in the initial velocity measurement) and the maximum radius from which points are used in the remapping process are examined. For all of the studies conducted, the density of the remapped, uniformly spaced grid remains the same as the initial irregularly spaced measurement grid.

As in the study by Fouras and Soria (1998), the error resulting from the remapping and the calculation of the out-of-plane vorticity is divided into a mean bias error due to spatial filtering and a random error due to the remapping process itself and the propagation of the error in the original data. Generally, the errors resulting from the bias error are significantly larger than random error. The mean bias error is not affected by noise in the original measurements and can be decreased by increasing the grid density. The random error is affected by the presence of noise in the original measurements, which causes an increase in the random error. However, the filtering inherent in the least-squares fitting process tends to decrease the magnitude of the random error in the remapped data.

In terms of the mean velocity bias error, it is necessary for the grid density to be suitably high and for the fit to be local, i.e., small values of R/δ, to generate an accurate remapping. In this study, the 4th order polynomial produced the most accurate remapping; however, due to the large number of points needed for the fit to be determined, it is not possible to use the same small values of R/δ as can be used with the lower order polynomials. The difference in the bias error between the 4th order with $R/\delta = 3$ and the 2nd order with $R/\delta = 2$ is very small. Thus, it is felt that the use of a 2nd order polynomial

for the remapping is appropriate. In order to obtain results with a maximum mean velocity bias error of approximately *1%* or less for the 2nd order polynomial, the normalized data density L/δ should be greater than *3*, and R/δ should be less than or equal to *3*. The difference in the random component of the error between the various fit orders is relatively small compared to the changes seen in the bias error. The *rms* among the methods only varied by approximately *2%* of the peak value between the various methods.

The most accurate results for the vorticity calculation were obtained by differentiating the 4th order polynomial fit and by use of the 2nd order finite difference method. The vorticity results are more sensitive to the choice of R/δ and L/δ than the velocity remapping results. However, $L/\delta \geq 3.5$ and $R/\delta \leq 2.5$ yields vorticity values with both a mean bias and random error of less than approximately *2%*. It should be noted that the value quoted is the maximum error across the vortex core. The error at most points is considerably less than *2%*. As with the velocity error, little change is seen among the various methods in terms of the random error.

Although the accuracies of direct differentiation of the 4th order polynomial and the use of the 2nd order finite difference method are comparable, it is believed that the 2nd order finite difference technique is better suited for the calculation of vorticity values from the PIV or MTV data since this method is less computationally intensive. It should be noted that if the actual value of R/δ and L/δ are known in an experiment, it is possible to use the results of these simulations to extrapolate and estimate the actual vorticity value from under-resolved data.
