gallon per minute (gal/min)	0.06309	liter per second
gallon per day (gal/d)	0.003785	cubic meter per day

Temperature in degrees Celsius (°C) may be converted to degrees Fahrenheit (°F) as follows:

$$^{\circ}\text{F}=(1.8^{\circ}\text{C})+32$$

Vertical coordinate information is referenced to the National Geodetic Vertical Datum of 1929 (NGVD 29)—a geodetic datum derived from a general adjustment of the first-order level nets of both the United States and Canada, formerly called Sea Level Datum of 1929; horizontal coordinate information is referenced to the North American Datum of 1927 (NAD 27). **Altitude**, as used in this report, refers to distance above or below NGVD 29.

ABBREVIATED WATER-QUALITY UNITS

Chemical concentration and water temperature are given only in metric units. Chemical concentration in water is given in milligrams per liter (mg/L) or micrograms per liter ($\mu\text{g/L}$). Milligrams per liter is a unit expressing the solute mass (milligrams) per unit volume (liter) of water. One thousand micrograms per liter is equivalent to 1 milligram per liter. For concentrations lower than 7,000 milligrams per liter, the numerical value is about the same as for concentrations in parts per million. Specific conductance is given in microsiemens per centimeter at 25 degrees Celsius ($\mu\text{S/cm}$ at 25°C).

Ground-Water, Surface-Water, and Water-Chemistry Data, Black Mesa Area, Northeastern Arizona—2001–02

By Blakemore E. Thomas

Abstract

The N aquifer is the major source of water in the 5,400-square-mile area of Black Mesa in northeastern Arizona. Availability of water is an important issue in this area because of continued industrial and municipal use, a growing population, and precipitation of about 6 to 14 inches per year.

The monitoring program in the Black Mesa area has been operating since 1971 and is designed to determine the long-term effects of ground-water withdrawals from the N aquifer for industrial and municipal uses. The monitoring program includes measurements of (1) ground-water pumping, (2) ground-water levels, (3) spring discharge, (4) surface-water discharge, and (5) ground-water chemistry.

In 2001, total ground-water withdrawals were 7,680 acre-feet, industrial use was 4,530 acre-feet, and municipal use was 3,150 acre-feet. From 2000 to 2001, total withdrawals decreased by 1 percent, industrial use increased by 1 percent, and municipal use decreased by 3 percent.

From 2001 to 2002, water levels declined in 5 of 14 wells in the unconfined part of the aquifer, and the median change was +0.2 foot. Water levels declined in 12 of 17 wells in the confined part of the aquifer, and the median change was -1.4 feet.

From the prestress period (prior to 1965) to 2002, the median water-level change for 32 wells was -15.8 feet. Median water-level changes were -1.3 feet for 15 wells in the unconfined part of the aquifer and -31.7 feet for 17 wells in the confined part.

Discharges were measured once in 2001 and once in 2002 at four springs. Discharges decreased by 26 percent and 66 percent at two springs, increased by 100 percent at one spring, and did not change at one spring. For the past 10 years, discharges from the four springs have fluctuated; however, an increasing or decreasing trend is not apparent.

Continuous records of surface-water discharge have been collected from 1976 to 2001 at Moenkopi Wash, 1996 to 2001 at Laguna Creek, 1993 to 2001 at Dinnebito Wash, and 1994 to 2001 at Polacca Wash. Median flows for November, December, January, and February of each water year were used as an index of ground-water discharge to those streams. Since 1995, the median winter flows have decreased for Moenkopi Wash, Dinnebito Wash, and Polacca Wash. Since 1997, there is no consistent trend in the median winter flow for Laguna Creek.

In 2002, water samples were collected from 12 wells and 4 springs and analyzed for selected chemical constituents. Dissolved-solids concentrations ranged from 96 to 636 milligrams per liter. Water samples from 8 of the wells and from 3 of the springs had less than 300 milligrams per liter of dissolved solids. There are no appreciable time trends in the chemistry of water samples from 9 wells and 4 springs; the 9 wells had more than 7 years of data, and the 4 springs had more than 9 years of data.

INTRODUCTION

The Black Mesa area includes about 5,400 mi² in northeastern Arizona ([fig. 1](#)) and has a diverse topography that includes flat plains, mesas, and incised drainages. Black Mesa is about 2,000 mi², is bounded by 2,000-foot cliffs on the north and northeast sides, and slopes gradually downward to the south and southwest. Availability of water is an important issue in the study area because of continued ground-water withdrawals, a growing population, and precipitation that averages about 6 to 14 in. per year (U.S. Department of Agriculture, 1999).

The N aquifer is the major source of water for industrial and municipal uses in the Black Mesa area. The N aquifer consists of three formations—the Navajo Sandstone, the Kayenta Formation, and the Lukachukai Member¹ of the Wingate Sandstone that are hydraulically connected and function as a single aquifer ([fig. 2](#)). Within the Black Mesa area, Peabody Western Coal Company is the principal industrial user of water, and the Navajo Nation and Hopi Tribe are the principal domestic and municipal users.

Withdrawals from the N aquifer in the Black Mesa area have been increasing during the last 30 years ([table 1](#)). Peabody Western Coal Company began operating a strip mine in the northern part of the mesa in 1968. The quantity of water pumped by the company increased from about 100 acre-ft in 1968 to a maximum of 4,740 acre-ft in 1982. About 4,530 acre-ft of water was pumped in 2001. Withdrawals for municipal use from the N aquifer have increased steadily from an estimated 250 acre-ft in 1968 to 3,150 acre-ft in 2001.

The Navajo Nation and the Hopi Tribe have been concerned about the long-term effects of withdrawals from the N aquifer on available water supplies, on stream and spring discharge, and on ground-water chemistry. In 1971, these concerns led to the establishment of a monitoring program of the water resources in Black Mesa by the U.S. Geological Survey (USGS) in cooperation with the Arizona Department of Water Resources (ADWR). In 1983, the Bureau of Indian Affairs (BIA) joined the cooperative effort. Since 1983, the Navajo Tribal Utility Authority

(NTUA); Peabody Western Coal Company; the Hopi Tribe; and the Western Navajo Agency, Chinle Agency, and Hopi Agency of the BIA have assisted in the collection of hydrologic data.

Purpose and Scope

This report presents results of ground-water, surface-water, and water-chemistry monitoring in the Black Mesa area from January 2001 to June 2002. The monitoring is designed to determine the effects of industrial and municipal pumpage from the N aquifer on ground-water levels, stream and spring discharge, and ground-water chemistry. Continuous and periodic data are collected for ground water and surface water. Ground-water data include pumpage, water levels, spring discharges, and water chemistry. Surface-water data include discharges at four continuous-record streamflow-gaging stations.

Previous Investigations

Nineteen progress reports on the monitoring program for the Black Mesa area have been prepared by the USGS (U.S. Geological Survey, 1978; G.W. Hill, hydrologist, written commun., 1982, 1983; Hill, 1985; Hill and Whetten, 1986; Hill and Sottolare, 1987; Hart and Sottolare, 1988, 1989; Sottolare, 1992; Littin, 1992, 1993; Littin and Monroe, 1995a, 1995b, 1996, 1997; Littin and others, 1999; Truini and others, 2000; Thomas and Truini, 2000; and Thomas, 2002). Most of the data from the monitoring program are contained in these reports. Stream-discharge and periodic water-quality data from Moenkopi Wash collected before the 1982 water year were published by the U.S. Geological Survey (1963–64a, b; 1965–74a, b; and 1976–83). Stream-discharge data from water years 1983 to 2001 for Moenkopi Wash and other streams in the Black Mesa area are published in White and Garrett (1984, 1986, 1987, and 1988), Wilson and Garrett (1988, 1989), Boner and others (1989, 1990, 1991, 1992), Smith and others (1993, 1994, 1995, 1996, 1997), Tadayon and others (1998, 1999, 2000, 2001), and McCormack and others (2002). Before the monitoring program, a large data-collection effort in the 1950s resulted in a compilation of well and spring data for the Navajo and Hopi Indian Reservations (Davis and others, 1963).

¹ The name Lukachukai Member was formerly abandoned by Dubiel (1989) and is used herein for report continuity in the monitoring program as it relates to that part of the Wingate Sandstone included in the N aquifer.

¹Metered pumpage from the confined part of the aquifer by Peabody Western Coal Company.

²Does not include withdrawals from the wells equipped with windmills.

³Includes estimated pumpage, 1965–73, and metered pumpage, 1974–79, at Tuba City; metered pumpage at Kayenta and estimated pumpage at Chilchinbito, Rough Rock, Piñon, Keams Canyon, and Kykotsmobi before 1980; metered and estimated pumpage furnished by the Navajo Tribal Utility Authority and the Bureau of Indian Affairs and collected by the U.S. Geological Survey, 1980–85; and metered pumpage furnished by the Navajo Tribal Utility Authority, the Bureau of Indian Affairs, various Hopi Village Administrations, and the U.S. Geological Survey, 1986–2000.

Many interpretive studies have been done in the Black Mesa area. Cooley and others (1969) made the first comprehensive evaluation of the regional hydrogeology of the Black Mesa area. Eychaner (1983) developed a two-dimensional numerical model of ground-water flow in the N aquifer. Brown and Eychaner (1988) recalibrated the model using a finer grid and revised estimates of selected aquifer characteristics. GeoTrans, Inc. (1987) also developed a two-dimensional model of the N aquifer in the 1980s. In the late 1990s, HSI GeoTrans, Inc. and Waterstone Environmental Hydrology and Engineering, Inc. (1999) developed a detailed three-dimensional numerical model of the D and N aquifers.

Kister and Hatchett (1963) made the first comprehensive evaluation of the chemistry of water from wells and springs in the Black Mesa area. HSI GeoTrans, Inc. (1993) evaluated the major-ion and isotopic chemistry of the D and N aquifers. Lopes and Hoffmann (1997) analyzed ground-water ages, recharge, and hydraulic conductivity of the N aquifer using geochemical techniques. Zhu and others (1998) estimated ground-water recharge using isotopic data and flow estimates from the model developed by GeoTrans, Inc. (1987). Zhu (2000) estimated recharge again using the same isotopic data, but added numerical flow and transport modeling to the method.

HYDROLOGIC DATA

In 2001–02, the Black Mesa monitoring program included metering and estimating ground-water withdrawals, measuring depth to ground water, measuring discharge in streams and springs, and collecting and analyzing water samples from wells and springs. Continuous monitoring was done on ground-water withdrawals from 34 well systems, water levels at 6 observation wells, and surface-water discharge at

4 sites. Annual measurements were made of discharge at 4 springs and ground-water levels at 27 wells. Spring discharges and ground-water levels were measured between April and June 2002. Ground-water samples were collected from 12 wells and 4 springs in April–June 2002 and analyzed for chemical constituents. Identification information for the 49 wells used for water-level measurements and water-quality sampling is shown in table 2.

Withdrawals from the N Aquifer

Withdrawals from the N aquifer are separated into three categories—(1) industrial use from the confined part of the aquifer, (2) municipal use from the confined part of the aquifer, and (3) municipal use from the unconfined part of the aquifer (table 1, fig. 3). The industrial category includes eight wells at the well field of Peabody Western Coal Company in northern Black Mesa (fig. 4). The BIA, NTUA, and Hopi Tribe operate about 70 municipal wells (fig. 4). Withdrawals from the N aquifer were compiled primarily on the basis of metered data (tables 1 and 3).

Withdrawals from wells equipped with windmills are not measured in this monitoring program. About 270 windmills in the Black Mesa area withdraw water from the D and N aquifers, and estimated total withdrawals by the windmills are about 65 acre-ft/yr (HSIGeoTrans, Inc., and Waterstone Environmental Hydrology and Engineering, Inc., 1999). This amount is less than 1 percent of the total annual withdrawal from the N aquifer.

In 2001, the total ground-water withdrawal from the N aquifer was about 7,680 acre-ft (table 1), which is a 1 percent decrease from the total withdrawal in 2000. Withdrawals for municipal use from the confined part of the aquifer totaled 1,490 acre-ft, which is a 7 percent decrease from 2000. Withdrawals for municipal use from the unconfined part of the aquifer totaled 1,660 acre-ft, which is a 1 percent increase. Withdrawals for industrial use totaled 4,530 acre-ft, which is a 1 percent increase.

Withdrawals from the N aquifer have been increasing since the 1970s (table 1, fig. 3). Total withdrawals increased from 1,170 acre-ft in 1970 to 4,300 acre-ft in 1972 when industrial use increased from 740 to 3,680 acre-ft. Since 1973, industrial use has fluctuated between 2,520 and 4,740 acre-ft/yr. Municipal use increased by about 20 percent per year during the 1970s, slowed to an increase of about 4 percent per year in the 1980s, and slowed further to an increase of about 3 percent per year in the 1990s.

In the 1970s, industrial use was about 75 percent of the total withdrawal. With the increase in municipal use over the last 30 years, industrial use, as a percentage of total withdrawals, has declined to about 60 percent in the late 1990s and in 2001.

In an effort to improve and ensure the accuracy of ground-water withdrawal data, a quality-assurance program was begun in 1985 for withdrawal data from industrial and municipal wells completed in the N aquifer. Nearly all industrial and municipal wells in the study area are equipped with totalizing flowmeters to measure ground-water withdrawals. The flowmeters on the wells are tested about once every 5 years by measuring pumpage with a calibrated mechanical flowmeter and comparing the measured pumpage to the metered pumpage. For the purpose of this study, the allowable difference between the discharge measured by the permanent totalizing flowmeter and the test meter is 10 percent. No testing of flowmeters was done this past year.

¹ Well taken out of service.

² Industrial pumpage.

³ Estimated. Well PM4 not metered. Annual pumpage from PM4 was estimated as 37.0 acre-feet on the basis of previous metered data and an estimated 33,000 gallons per day. Pumping from the remaining wells (PM5 and PM6) may include some water from the D aquifer.

Ground-Water Levels in the N Aquifer

Ground water in the N aquifer is under confined conditions in the central part of the study area and under unconfined or water-table conditions around the periphery (fig. 5). The ground water generally flows radially outward from recharge areas near Shonto to the southwest, south, southeast, and east (Thomas, 2002).

Ground-water levels are measured each year and compared with levels from previous years to determine changes over time. In April–June 2002, water levels were measured in 32 wells that are used for observation, municipal supply, or stock supply (table 4). Six of the 32 wells are observation wells that were operated on a continuous basis; water levels were recorded daily. Water levels were measured manually four times between April 2001 and April 2002 in the six continuous-observation wells.

The wells used for water-level measurements are spread throughout the study area (fig. 5). Although all the wells are completed in the N aquifer, characteristics of the wells vary considerably. Construction dates range from 1934 to 1993, depths range from 107 to 3,535 ft, and depths to the top of the N aquifer range from 0 to 2,400 ft (table 5).

From 2001 to 2002, water levels declined in 17 of 31 wells. The median water-level change in the 31 wells was -0.2 ft. Changes ranged from -22.7 ft in the Keams Canyon PM2 well to +7.7 ft in well 2T-502 (table 4).

From 2001 to 2002, water levels declined in 5 of 14 wells in unconfined areas. The median change was +0.2 ft, and the changes ranged from -3.4 ft to +7.7 ft. In confined areas, water levels declined in 12 of 17 wells. The median change was -1.4 ft, and the changes ranged from -22.7 ft to +6.1 ft (table 4).

Median annual water-level changes for observation wells from 1983 to 2002 are shown in figure 6. Median annual changes before 1983 are not shown because there were insufficient water-level data to compute median values. For wells in confined areas, the average annual median water-level change was -1.8 ft, and there is no appreciable trend in the annual water-level changes from 1983 to 2002. For wells in unconfined areas, the average annual median water-level change was +0.2 ft, and there is a break in the trend of annual water-level changes. There is no appreciable trend from 1983 to 1992, and there is a decreasing trend from 1993 to 2001.

From the prestress period (prior to 1965) to 2002, the median water-level change in 32 wells was -15.8 ft. Water levels in 15 unconfined wells had a median change of -1.3 ft and ranged from -42 ft to +14.6 ft (table 4). Water levels in 17 confined wells had a median change of -31.7 ft and ranged from -191.5 ft to +15.5 ft.

The areal distribution of water-level changes from the prestress period to 2002 is shown in figure 5. Hydrographs of water levels in the annual observation-well network show the time trends of changes since the 1950s, 1960s, or 1970s (fig. 7). In most of the unconfined area, water levels have changed only slightly. In the Tuba City area, however, water levels have declined 30 to 40 ft in a few of the wells. In most of the confined area, water levels have declined; however, the magnitudes of declines are variable. Larger declines are near the municipal pumping centers (wells Piñon PM6 and Keams Canyon PM2) or near the wells for Peabody Western Coal Company. Smaller declines are away from the pumping centers (wells 8T-522 and 10R-119).

Hydrographs for the Black Mesa observation wells show continuous water-level changes since about 1972 (fig. 8). Water levels in the two wells in unconfined areas (BM1 and BM4) have had small seasonal or year-to-year variation and have had small long-term changes since 1972. Water levels in the four wells in confined areas also have had little seasonal variation (except BM3); however, the water levels have consistently declined in all the confined wells since 1972.

Spring Discharge from the N Aquifer

Ground water in the N aquifer discharges from many springs around the margins of the Black Mesa area. Discharge from selected springs is measured annually and compared to discharge from previous years to determine changes in spring discharge over time. In April–July 2002, discharge was measured at four springs (table 6). Three springs are on the west or southwest side of the Black Mesa area, and one is on the northeast side (fig. 9). The discharge measured at all four springs represents only part of the total discharge from each spring. Because of separate seeps and problematic measuring conditions, it would be difficult to measure the total discharge at those sites.

¹Water level measured during April to June 2002.²Prestress refers to the period of record before appreciable ground-water withdrawals for mining or municipal purposes—about 1965. For wells that had no water-level measurement before 1965, the earliest water-level measurement is shown.³Continuous recorder. Except for well BM3, prestress water levels were estimated from a ground-water model (Brown and Eychaner, 1988).⁴Prestress water levels for indicated wells were changed from previous Black Mesa monitoring reports to more accurately represent prestress conditions. The water level in BM3 was 77.1 feet in the 1998 report and 60 feet in the 1995–97 reports. The water levels were 217 feet in BM4 and 735.6 feet in BM6 in the 1995–98 reports.⁵Water level not measured because of obstruction in well, no access to well, or not visited.⁶Change in water level from last measurement 2 to 4 years earlier.⁷2001 water level influenced by pumping.⁸2002 water level influenced by pumping.⁹Change in water level not shown because last measurement was more than 4 years ago.**Table 5.** Well-construction characteristics, depth to top of N aquifer, and type of data collected for wells in monitoring program, Black Mesa area, Arizona, 2001–02

¹Tongue in the Kayenta Formation.²Discharge measured at water-quality sampling site and at a different point than the measurement in 1952.³Discharge measured at a different point than later measurements.⁴Discharge measured in an irrigation ditch about 0.25 mile below water-quality sampling point.⁵Discharge measured at water-quality sampling point about 20 feet below upper spring on west side of canyon.

Figure 9. Surface-water and water-chemistry data-collection sites, Black Mesa area, Arizona, 2001–02.

In 2002, measured discharges were 0.4 gal/min from Burro Spring, 9.0 gal/min from the unnamed spring near Dennehotso, 10.2 gal/min from Moenkopi School Spring, and 37.0 gal/min from Pasture Canyon Spring. Compared with spring discharges in 2001, discharges increased by 100 percent for Burro Spring, decreased by 66 percent for the unnamed spring near Dennehotso, decreased by 26 percent for Moenkopi School Spring, and did not change for Pasture Canyon Spring.

Long-term changes in spring discharge can be evaluated for the entire record at Burro Spring but can be evaluated only for parts of the records for the other three springs because discharge measuring points changed during the periods of record. Consistent measuring points are available for 1992–2002 at the unnamed spring near Dennehotso, for 1987–2002 at Moenkopi School Spring, and for 1995–2002 at Pasture Canyon Spring (table 6). For the consistent periods of record at all four springs, the discharges have fluctuated; however, increasing or decreasing trends are not apparent (fig. 10).

Surface-Water Discharge

Surface-water discharge in the study area includes ground-water discharge and direct or shallow subsurface runoff of rainfall or snowmelt. Ground water discharges to surface water at a fairly constant rate throughout the year. In contrast, the amount of rainfall or snowmelt runoff varies widely throughout the year. In the winter and spring, the amount and timing of snowmelt runoff is a result of the temporal variation in snow accumulation, air temperatures, and rate of snowmelt. Although most rainfall runoff is in the summer, rainfall can cause surface-water discharge any time of the year. The amount and timing of rainfall runoff is a result of the intensity and duration of thunderstorms in the summer and cyclonic storms in the fall, winter, and spring.

Data on surface-water discharge have been collected continuously at selected streams each year of the monitoring program. The discharge data provide useful information about ground-water discharge and about runoff from rainfall and snowmelt. In this study, the total discharge in streams is roughly separated into ground-water discharge and runoff so that the temporal trends in ground-water discharge can be monitored.

Figure 10. Discharge from selected springs, Black Mesa area, Arizona, 1987–2002.

In 2001, continuous-record discharge data were collected at four streamflow-gaging stations (tables 7–10). Data collection began at the gaging stations on July 1976 for Moenkopi Wash, July 1996 for Laguna Creek, June 1993 for Dinnebito Wash, and April 1994 for Polacca Wash (fig. 9, table 11).

The annual average discharges for the four gaging stations vary considerably during their periods of record (fig. 11). The discharges in Moenkopi Wash appear to have become more variable during the last 12 years with no long-term trend, discharges in Laguna Creek appear to have decreased the last 5 years, and discharges in Dinnebito Wash and Polacca Wash have been variable with no trend the last 7 years.

The ground-water discharge component of total flow at the four streamflow-gaging stations was estimated by computing the median flow for four winter months—November, December, January, and February. Ground-water discharge is assumed to be constant the entire year, and the median winter flow is assumed to represent this constant annual ground-water discharge. Most flow during the winter is ground-water discharge because rainfall and snowmelt runoff are minimal. Most of the precipitation in the winter falls as snow, and the cold temperatures prevent appreciable snowmelt. Also, evapotranspiration from streams is at a minimum during the winter. During the summer, much of the flow in streams evaporates or is transpired by plants. The median flow for November, December, January, and February, rather than the average flow, is used to estimate ground-water discharge because the median is less affected by occasional winter runoff. The 120 consecutive daily mean flows for those four months were used to compute the median flow.

The median flow for November, December, January, and February is an index of ground-water discharge rather than an absolute estimate of discharge. A more rigorous and accurate estimate would include detailed evaluations of streamflow hydrographs, flows into and out of bank storage, gain and loss of streamflow as it moves down the stream channel, and interaction of ground water in the N aquifer with ground water in the shallow alluvial aquifers in the stream valleys. The median winter flow, however, is useful as a consistent index for evaluating possible time trends in ground-water discharge.

Median winter flows were calculated for the 2001 water year, thus daily mean flows for November and December 2000 (Thomas, 2002) were combined with daily mean flows for January and February 2001.

These median winter flows were 1.1 ft³/s for Moenkopi Wash, 2.3 ft³/s for Laguna Creek, 0.37 ft³/s for Dinnebito Wash, and 0.11 ft³/s for Polacca Wash. Since 1995, the median flows for Moenkopi Wash, Dinnebito Wash, and Polacca Wash have decreased (fig. 11). Median flows for Laguna Creek are only available since 1997, and there is no consistent trend in these flows. Annual precipitation at Betatakin, about 15 miles west of Kayenta, has been less than average for 5 of the 7 years since 1995 (fig. 11).

Water Chemistry

Water samples are collected from selected wells and springs each year of the Black Mesa monitoring program. Field measurements are made and water samples are analyzed for major ions, nutrients, iron, boron, and arsenic. During the past 10 years, water samples have been collected from about 30 different wells and 10 different springs. Samples are collected from about 12 wells and 4 springs in each year of the program. Samples are collected from about the same 8 wells every year and from the other 4 wells on a rotational basis. Since 1996, samples have been collected from the same 4 springs. Long-term data for specific conductance, total dissolved solids, chloride, and sulfate for the wells and springs sampled each year are shown in the report published for that year. Historical data for other constituents for all the wells and springs are available from the USGS water-quality database or can be found in the past monitoring reports that are cited in the “Previous Investigations” section of this report.

Water from Wells Completed in the N Aquifer

In 2002, water samples were collected from 12 wells completed in the N aquifer. Eleven of the wells are in confined parts of the aquifer, and one well (Shonto PM2) is in an unconfined part of the aquifer (fig. 9). The primary types of water in the N aquifer are calcium bicarbonate and sodium bicarbonate. Calcium bicarbonate water generally is in the recharge areas of the northern and northwestern parts of the Black Mesa area, and sodium bicarbonate water is in the area that is downgradient to the south and east (Thomas, 2002). In 2002, water samples from Kayenta PM2 and from Shonto PM2 in the north were calcium bicarbonate water, and samples from the other 10 wells were sodium bicarbonate water (fig. 12). Dissolved-solids concentrations in water from the 12 wells ranged from 96 mg/L at Peabody 9 to 636 mg/L at Rough Rock PM5 (table 12, fig. 12).

¹Estimated value.

Two wells had appreciably higher concentrations of dissolved solids and chloride than the other 10 wells; Keams Canyon PM3 had a dissolved-solids concentration of 514 mg/L and a chloride concentration of 63 mg/L, and Rough Rock PM5 had a dissolved-solids concentration of 636 mg/L and a chloride concentration of 130 mg/L. Concentrations of dissolved solids in water samples from the other 10 wells ranged from 96 to 357 mg/L, and concentrations of chloride ranged from 1.3 to 22 mg/L. The areal distribution of dissolved solids generally was similar to the distribution of water types. Lower concentrations of dissolved solids are in or near the recharge areas of the north and northwest, and higher concentrations of dissolved solids are in areas to the south and east ([fig. 12](#)).

There are no appreciable time trends in the chemistry of water samples from 9 wells having more than 7 years of data ([table 13](#), [fig. 13](#)). The time periods of the water-chemistry data from these wells range from 1961–2002 to 1990–2002. In 7 of the 9 wells, there were small year-to-year variations in concentrations of dissolved solids, chloride, and sulfate; however, increasing or decreasing trends are not apparent. For the Shonto PM2 well, there may be an increasing trend in dissolved-solids and chloride concentrations; however, another few years of data are needed to confirm this possible trend. For the Forest Lake NTUA 1 well, the chemistry of water samples has varied considerably between 1982 and 2002. This variation may be from insufficient purging of this deep well (2,674 ft) that has multiple screens throughout an interval of about 800 ft from the lowest to highest screen ([table 5](#)).

Analyzed constituents from the 12 well samples were compared to U.S. Environmental Protection Agency (USEPA) Primary and Secondary Drinking-Water Regulations (U.S. Environmental Protection Agency, 2002). Maximum Contaminant Levels (MCLs), which are the primary regulations, are legally enforceable standards that apply to public water systems. MCLs protect drinking-water quality by limiting the levels of specific contaminants that can adversely affect public health. Secondary Maximum Contaminant Levels (SMCLs) provide guidelines for the control of contaminants that may cause cosmetic effects (such as skin or tooth discoloration) or aesthetic effects (such as taste, odor, or color) in drinking water. The USEPA recommends SMCLs for public water systems; however, compliance with SMCLs is not mandatory.

The concentrations of most of the analyzed constituents from the 12 well samples were below MCLs and SMCLs. The pH level, however, exceeded the upper SMCL (8.5 units) in samples from 10 of the 12 wells. Another SMCL was exceeded twice; the dissolved-solids SMCL of 500 mg/L was exceeded in the sample from Rough Rock PM5 (636 mg/L) and in the sample from Keams Canyon PM3 (514 mg/L). Samples from three wells had arsenic concentrations that exceeded the MCL of 10 µg/L. Arsenic concentrations were 35 µg/L in the sample from Keams Canyon PM3, 51 µg/L in the sample from Rough Rock PM5, and 18 µg/L in the sample from Second Mesa PM2.

Water from Springs that Discharge from the N Aquifer

In 2002, water samples were collected from four springs in the study area. Burro Spring is on the south side of the study area, the unnamed spring near Dennehotso is on the northeast side, and Moenkopi School Spring and Pasture Canyon Spring are on the west side ([fig. 9](#)). All the springs discharge water from the unconfined part of the N aquifer.

Water samples from the springs were two water types—the unnamed spring near Dennehotso and Pasture Canyon Spring were a calcium bicarbonate type, and Burro Spring and Moenkopi School Spring were a calcium-sodium bicarbonate type ([fig. 12](#)). Samples from the unnamed spring near Dennehotso, Moenkopi School Spring, and Pasture Canyon Spring had low dissolved-solids concentrations of 104 to 191 mg/L ([table 14](#)). The sample from Burro Spring had a much higher dissolved-solids concentration of 374 mg/L. Concentrations of all the analyzed constituents in samples from the four springs were below current USEPA MCLs and SMCLs (U.S. Environmental Protection Agency, 2002).

From the mid 1980s to 2002, trends are not apparent in the concentrations of dissolved solids, chloride, and sulfate in water samples from Burro Spring, the unnamed spring near Dennehotso, and Pasture Canyon Spring ([table 15](#), [fig. 14](#)). In water samples from Moenkopi School Spring, there appear to be no trends in concentrations of dissolved solids and sulfate and an increasing trend in concentrations of chloride.

Figure 14. Dissolved-solids concentrations in water from selected springs, Black Mesa area, Arizona, 1984–2002.

SUMMARY

The N aquifer is the major source of water for industrial and municipal users in the Black Mesa area of northeastern Arizona. Availability of water is an important issue in the Black Mesa area because of continued industrial and municipal use, a growing population, and precipitation of about 6 to 14 in/yr.

This report presents results of ground-water, surface-water, and water-chemistry monitoring in the Black Mesa area from January 2001 to June 2002. The monitoring data for 2001–02 are compared with data for 2000–2001 and with historical data from the 1950s to the present.

In 2001, total ground-water withdrawals were 7,680 acre-ft, industrial use was 4,530 acre-ft, and municipal use was 3,150 acre-ft. From 2000 to 2001, total withdrawals decreased by 1 percent, municipal use decreased by 3 percent, and industrial use increased by 1 percent. During the past 10 years, total withdrawals and municipal and industrial use increased at an average rate of about 3 percent per year.

From 2001 to 2002, ground-water levels declined in 17 of 31 wells. The median water-level change for the 31 wells was -0.2 ft, and changes ranged from -22.7 ft to +7.7 ft. In unconfined areas, water levels

declined in 5 of 14 wells, and the median change was +0.2 ft. In confined areas, water levels declined in 12 of 17 wells, and the median change was -1.4 ft.

For wells in confined areas, the average annual median water-level change was -1.8 ft, and there is no appreciable trend in the annual water-level changes from 1983 to 2002. For wells in unconfined areas, the average annual median water-level change was +0.2 ft, and there is a break in the trend of annual water-level changes. There is no appreciable trend from 1983 to 1992, and there is a decreasing trend from 1993 to 2001.

From the prestress period (prior to 1965) to 2002, water levels in 32 wells changed by a median of -15.8 ft. Water levels in the 15 wells in the unconfined part of the aquifer had a median change of -1.3 ft, and the changes ranged from -42 ft to +14.6 ft. Water levels in the 17 wells in the confined part of the aquifer had a median change of -31.7 ft, and the changes ranged from -191.5 ft to +15.5 ft.

Discharges were measured annually at four springs in 2001 and 2002. Burro Spring had a 100 percent increase in discharge, the unnamed spring near Dennehotso had an 66-percent decrease, Moenkopi School Spring had a 26-percent decrease, and Pasture Canyon Spring had no change. For about the past

10 years, discharges in the four springs have fluctuated; however, increasing or decreasing trends are not apparent.

Continuous records of surface-water discharge have been collected from 1976 to 2001 at Moenkopi Wash, 1996 to 2001 at Laguna Creek, 1993 to 2001 at Dinnebito Wash, and 1994 to 2001 at Polacca Wash. The annual average discharges at the four streamflow-gaging stations vary considerably during the periods of record. There appears to be a decreasing trend in annual average discharge for Laguna Creek and no trend for the other three gaging stations. Median flows for November, December, January, and February of each water year are used as an index of ground-water discharge to those streams. Since 1995, the median winter flows have decreased for Moenkopi Wash, Dinnebito Wash, and Polacca Wash. Since 1997, there is no consistent trend in the median winter flow for Laguna Creek.

In 2002, water samples were collected from 12 wells and analyzed for selected chemical constituents. Dissolved-solids concentrations ranged from 96 to 636 mg/L, and samples from 8 of the wells had dissolved-solids concentrations less than 300 mg/L. There are no appreciable time trends in the chemistry of water samples from 9 wells with more than 7 years of data. The time periods of these water-chemistry data from wells range from 1961–2002 to 1990–2002.

In 2002, dissolved-solids concentrations in water samples from the unnamed spring near Dennehotso, Pasture Canyon Spring, and Moenkopi School Spring ranged from 104 to 191 mg/L, and dissolved-solid concentration in the water sample from Burro Spring was 374 mg/L. From the mid 1980s to 2002, trends are not apparent in the concentrations of dissolved solids, chloride, and sulfate in water samples from Burro Spring, the unnamed spring near Dennehotso, and Pasture Canyon Spring. In water samples from Moenkopi School Spring, there appear to be no trends in concentrations of dissolved solids and sulfate and an increasing trend in concentrations of chloride.
