ABSTRACT

Mullerian Inhibiting Substance (MIS) is a member of the TGF β family, a class of molecules that govern a myriad of cellular processes including growth, differentiation, and apoptosis. In male embryos, MIS causes regression of the Mullerian duct. We have recently demonstrated the presence of MIS receptors in mammary tissue and in breast cancer cell lines suggesting that the mammary gland is a likely target for MIS. MIS inhibited the growth of both ER positive and negative breast cancer cells by inducing cell cycle arrest and apoptosis. We have demonstrated that MIS promotes IFN- γ -induced apoptosis demonstrating a functional interaction between these two classes of signaling molecules in regulation of breast cancer cell growth. To evaluate whether MIS and IFN- γ may be useful in breast cancer therapy, we determined whether the growth inhibitory effect of MIS and IFN- γ observed *in vitro* would be recapitulated *in vivo*.

The C3(1)Tag transgenic mouse model carries the SV40 large T antigen targeted to the epithelium of the mammary and prostate glands and progression of disease in these animals correlates well with progressive stages of human breast cancer. Mammary tumors arising in the C3(1) T antigen mouse model expressed the MIS type II receptor, and MIS *in vitro* inhibited the growth of cells derived from tumors. Administration of MIS to mice was associated with a lower number of palpable mammary tumors compared with vehicle-treated mice ($p=0.048$), and the mean mammary tumor weight in the MIS-treated group was significantly lower compared with the control group ($p=0.029$). Analysis of PCNA expression and caspase-3 cleavage in tumors revealed that exposure to MIS was associated with decreased proliferation and increased apoptosis, respectively, and not due to decline in T-antigen expression. The effect of MIS on tumor growth was also evaluated on xenografted human breast cancer cell line MDA-MB-468, which is estrogen receptor (ER) and Rb-negative and expresses mutant p53, and thus complements the C3(1)Tag mouse mammary tumors which do not express ER and have functional inactivation of Rb and p53. In agreement with results observed in the transgenic mice, MIS decreased the rate of MDA-MB-468 tumor growth and the gain in mean tumor volume in SCID mice compared to vehicle treated controls ($p=0.004$). These results suggest that MIS can suppress the growth of mammary tumors *in vivo*.

We have observed that MIS improves the growth inhibitory effects of Interferon-gamma on breast cancer cell lines *in vitro* by augmenting IFN-gamma induced gene expression and apoptosis. We will now test the effect of IFN γ on the growth of mammary tumors in xenograft and C3SV40T antigen mouse model. Next, we will test whether MIS can improve the growth inhibitory effects of IFN-gamma in these mouse models. Thus, this study indicates the possibility of using MIS independently or in combination with IFN-gamma as an alternative therapy for the breast cancer cure.

REPORT CONTENT

Introduction:

Mullerian Inhibiting Substance (MIS) is a member of the TGF β family, a class of molecules that govern a myriad of cellular processes including growth, differentiation, and apoptosis. However, a postnatal role for MIS in males and females has yet to be defined. MIS inhibits breast cancer cell growth by interfering with cell cycle progression and inducing apoptosis. We recently demonstrated the presence of MIS receptors in mammary tissue and in breast cancer cell lines suggesting that the mammary gland is a likely target for MIS (1). In the rat mammary gland, expression of the MIS type II receptor is suppressed during puberty when the ductal system branches and invades the adipose stroma and during massive expansion at pregnancy and lactation, but is upregulated during involution, a time of tissue regression (2,3). The decline in MIS type II receptor expression during various stages of postnatal mammary growth suggested a growth suppressive role for MIS in the mammary gland.

Interferon regulatory factor-1 (IRF-1), a gene known for its growth inhibitory functions in breast cancer cells is induced by MIS and IFN- γ through a NF κ B and STAT pathway respectively. Treatment of breast cancer cells with MIS and interferon- γ (IFN- γ) co-stimulated the expression of IRF-1 and CEACAM1, a target gene of IRF1. A combination of IFN- γ and MIS inhibited the growth of breast cancer cells to a greater extent than either one alone as assessed by MTT assay. Both reagents significantly decreased the fraction of cells in the S-phase of the cell cycle, an effect not enhanced when they were used in combination. Thus the enhanced inhibition of breast cancer cell growth by MIS and IFN- γ could not be explained by combined changes in cell cycle progression compared to treatment with either agent alone (4).

In the present report we demonstrate that MIS promotes IFN- γ -induced apoptosis demonstrating a functional interaction between these two classes of signaling molecules in regulation of breast cancer cell growth. To evaluate whether MIS and IFN- γ may be useful in breast cancer therapy, we determined whether the growth inhibitory effect of MIS and IFN- γ observed *in vitro* would be recapitulated *in vivo*. Assaying the effect of MIS on mammary tumor models *in vivo* is critical to determine whether MIS could act as an anti-tumor agent. We have developed human breast cancer xenografts in SCID mice using MDA-MB-468 cells and demonstrated that MIS when injected intraperitoneally can inhibit the growth of these breast cancer xenografts in mice. Using a C3(1)Tag mouse model, which carries the SV40 large T antigen targeted to the epithelium of the mammary and prostate glands and develops spontaneous mammary tumors, we have observed that mean mammary tumor weight and growth of tumors in MIS treated animals to be significantly lower than the vehicle treated controls. Analysis of PCNA expression and caspase-3 cleavage in tumors revealed that exposure to MIS was associated with decreased proliferation and increased apoptosis, respectively, and not due to decline in T-antigen expression.

In the future we will be testing the effect of various doses of IFN- γ on the progression of breast cancer in these mouse models. Once optimal doses are determined, we will test if MIS can improve the anti tumor effects of IFN- γ *in vivo*.

BODY (Results and Significance)

Specific Aim I: Characterization of the molecular mechanism that integrates IFN- γ and MIS mediated signaling (12 months)

Task 1: To identify the molecular mechanism by which MIS and IFN- γ induce IRF-1 expression in breast cancer cells (Completed)

Task 2: To determine if MIS mediated activation of IRF-1 occurs via the Smad pathway (Completed)

Task 3: To test the effect of MIS and IFN- γ on the gene expression of growth regulatory genes (In Progress)

MIS and IFN- γ induce the expression of p21, Lysyl Oxidase and MHC classII

Lysyl Oxidase a target of IRF1 with an IRF1 response element in its promoter (5). IFN- γ (1ng/ml) induced the expression of lysyl oxidase in T47D cells treated for 2 and 3 hours (Fig.1a). Treatment of T47D cells with MIS upregulated mRNA expression of Lysyl oxidase with maximum induction at 24hrs (Fig.1b). We will analyse if treatment of cells with both MIS and IFN- γ will further affect the expression of lysyl oxidase.

Fig. 1 IFN- γ and MIS stimulate the expression of Lysyl oxidase, p21 and MHC classII in T47D cells

Fig. 1a

Fig.1a T47D cells were treated with IFN γ (1ng/ml) for 0-6 hrs. Total RNA was tested for the expression of Lysyl oxidase.

Fig. 1b

Fig.1b T47D cells were treated with MIS(5ug/ml) for 0-24 hrs. Total RNA was tested for the expression of Lysyl oxidase.

IRF1 can inhibit tumor growth through the induction of p21, a growth inhibitory gene (6). We observed that both MIS and IFN- γ induce p21 expression in T47D cells as observed by Western blot analysis but the expression was not further affected when cells were treated with a combination of MIS and IFN- γ for 4hrs (Fig. 1c).

MHC classII, another gene downstream of IRF1 was upregulated by IFN- γ (7). T47D cells when treated for 48hrs with MIS and IFN- γ demonstrated a synergistic induction of MHCII mRNA (Fig. 1d).

Thus, we have observed that MIS and IFN- γ costimulate the expression of IRF1 with a synergistic induction of the downstream genes CEACAM1 and MHCII in breast cancer cells.

Fig. 1c

Fig.1c. Expression of p21 in T47D cells treated with IFN-g (5ng/ml) and MIS (5ug/ml) for 2 and 4 hrs as assessed by Western blot analysis

Fig. 1d

Fig.1d. Expression of MHCII in T47D cells treated with IFN-g (5ng/ml) and MIS (5ug/ml) for 48 hrs as assessed by Northern blot analysis

Specific Aim II: Test the effect of MIS, IFN- γ , or both on breast cancer cell growth using *in vitro* and *in vivo* model systems (24 months)

Task 4: To characterize the mechanism by which MIS and IFN- γ inhibit breast cancer cell growth (completed)

Effect of MIS and IFN- γ on activated caspase-3

Both MIS and IFN- γ increased the cleaved caspase3, an apoptosis marker in MDA-MB-468 cells with an increase in the activated/ cleaved caspase3 when cells were treated in combination with MIS and IFN- γ for 3 days as demonstrated by Western blot analysis in fig 2a.

Effect of MIS and IFN- γ on breast cancer cell growth

Translocation of annexinV from the inner surface of the plasma membrane to the outside occurs after initiation of apoptosis and thus serves as a marker of apoptosis. MDA-MB-468 cells were treated with MIS, IFN- γ or MIS+IFN- γ for 96 hours and cell surface expression of annexinV was analyzed by staining cells with a FITC-annexinV antibody. Quantification of annexinV positive cells demonstrated that IFN- γ is a strong inducer of apoptosis in breast cancer cells (figure 2b). MIS consistently increased apoptosis in several experiments but its effect was much less potent than that of IFN- γ at the concentration tested. However, treatment of cells with a combination of MIS+IFN- γ together resulted in a synergistic increase in the fraction of cells in early and late stages of apoptosis. Thus growth inhibition of MDA-MB-468 cells following co-treatment with MIS and IFN- γ results from enhanced apoptosis.

Fig. 2a

Fig. 2a MDAMB468 cells were treated with MIS(5ug/ml) and IFN- γ (5ng/ml) for 3 days. Activated caspase3 was assessed using Western blot analysis.

Fig. 2b

Early+ Late Stage apoptosis (Zones B+ C)

Fig. 2b MDA-MB-468 cells were treated with 5ng/ml IFNg or 5ug/ml MIS or both for 96 hrs. Cells were stained with annexinV-FITC and DAPI and analysed by FACS. Percentage of cells undergoing apoptosis is shown. Statistical analysis was done using ANOVA.

Thus, we have observed that a combination of MIS and IFN- γ led to a greater degree of growth inhibition compared with either agent alone due to enhanced apoptosis rather than a combinatorial effect on cell cycle progression.

Task 5: To test the growth inhibitory effect of MIS and IFN- γ *in vivo*, breast cancer cells will be injected under the mammary fat pad of SCID, RAG-2 knock out and irradiated nude mice. The mouse model in which tumor growth is most robust will be selected for further studies (*completed*).

Establish xenografts in nude mice

In order to consider the use of rhMIS for the treatment of human breast cancer, it will be necessary to assess the responsiveness of tumor growth *in vivo* to IFN- γ and MIS. OVCAR-8 human ovarian cancer cell line grows best in both nude mice and in RAG-2 knockout mice, while IGROV-1 cells grew well only in SCID mice (Drs. Patricia Donahoe and David McLaughlin; personal communication).

We used ER negative breast cancer cell line MDA-MB-468 cells to establish human xenografts in the irradiated nude mice. The MDA-MB-468 cells are ER negative, Rb negative, harbor a mutant p53 and are highly responsive to MIS and rhuIFN- γ treatment *in vitro*. For this, MDA-MB-468 (4 million cells/ site) were injected subcutaneously in the mammary fat pad of nude mice. Palpable tumors appeared but had severe necrosis and thus were not suitable for further treatment. Next, the xenografts established in these animals were divided into smaller fragments and tumor fragments of equal sizes were placed in the 4 week old SCID mice. But the xenografts established had extensive necrosis and thus this animal model was not used further.

Establish xenografts in SCID mice

Next, MDA-MB-468 xenografts were established by bilaterally injecting 4×10^6 cells/site in 50 μ l of DMEM subcutaneously into the dorsal flanks of ten, 6-week old female SCID mice. Tumors appeared within one week of injections and did not demonstrate central necrosis. Palpable tumors were observed in 8 of 10 animals. Mice were ear-tagged to monitor the kinetics of tumor growth at each site. Four weeks after the injection of cells, animals with tumors $> 250 \text{ mm}^3$ were randomly divided into treatment groups. Thus, the SCID animals with MDA-MB-468 xenografts established on the dorsal flanks were used for further studies.

Spontaneously arising mammary tumors in mice

In addition to the human breast cancer xenograft model described above, we have also obtained a novel transgenic mouse model for spontaneous mammary carcinoma from Dr. Jeffrey Green at NIH, in which targeted expression of the early region of the SV40 large tumor Ag was achieved using the promoter of the rat prostatic steroid binding protein. Mammary tumors in this model occur in 100% of mice with very early onset. Atypia of the mammary gland develops at ~8 weeks progressing to intraepithelial neoplasia resembling human DCIS at ~12 weeks with development of invasive carcinomas at about ~16-24 weeks. It has also been utilized in several studies to test novel therapeutic strategies on various

stages of tumor progression (9). These tumors are ER negative and have functionally inactive p53 and Rb and thus complement MDA-MB-468 xenografts in SCID mice (10).

Task 6: Determining the dose of MIS and IFN- γ required for tumor regression studies (completed).

In order to investigate the pharmacokinetics of rhuIFN- γ , two female SCID mice were injected intraperitoneally with a single dose of 1 μ g rhuIFN- γ and blood samples were drawn from the orbital plexus under anesthesia at 30 min, 1h, 3h, 6 h and 24 hours. Each animal was sampled three times (one animal at 0, 3h and 24h and the other at 1h, 6h and 24 h). Serum was prepared and analyzed by ELISA. Another 2 SCID mice were simultaneously injected once with 10 μ g of rhuIFN- γ and blood was drawn at the times indicated above. Serum rhuIFN- γ concentrations, estimated based on a standard concentration curve, increased in proportion to the dose, peaked at ~1-3 hours and was undetectable at 24 hours (Table 1). Serum of animals injected with 10 and 100 ng rhuIFN- γ once intraperitoneally had undetectable levels of rhuIFN- γ 6-24 hrs after injection. Although, rhuIFN- γ as high as 10 μ g injected once intraperitoneally did not cause any harmful effects to the animals but because of the known toxic effects of IFN- γ , 10-100ng rhuIFN- γ will be injected intraperitoneally to these animals 5 days a week for 4 weeks.

Table 1

Inteferon-gamma time (h)	1 μ g Conc in serum (ng/ml)	10 μ g Conc in serum (ng/ml)
0	0	0
0.5	8.68	59
1	16.38	51.75
3	0.28	137.7
6	0.34	5 1.24
24	undetectable	undetectable

Human and mouse interferon- γ proteins share 41% sequence homology and are species specific (13, 14). Thus mouse IFN- γ (mIFN- γ ; R & D systems) will be used to inject C3SV40 Tantigen mouse.

Previously, we have observed that 10 μ g rhMIS/ animal inhibits the growth of human ovarian cancer cell xenografts grown in nude mice (Drs. Patricia Donahoe and David McLaughlin; personal communication). Since, this dose had no harmful effects on animals and in order to further improve its anti-tumor effects we have injected 20 μ g rhMIS/ animal intraperitoneally for 5 days a week with two treatment free days/ for 4 weeks.

Task 7: Once optimal dosages are estimated, animals with established tumors will be divided into four groups to administer (1) vehicle, (2) MIS, (3) IFN- γ and (4) MIS + IFN- γ . Serum MIS and IFN- γ concentration will be measured by ELISA. The tumor size will be measured by using calipers (*In progress*).

A) Effect of MIS on MDA-MD-468 tumor growth in SCID mice

MBA-MD-468 xenografts were grown subcutaneously and bilaterally in the dorsal flanks of 6-week old female SCID mice. After ~4 weeks, the 8 animals with palpable tumors were randomized into two groups with 4 animals in the PBS control group and 4 mice in the MIS-treatment group. Both groups were treated at the same time with either PBS or 20 μ g MIS/animal for 5 days a week with a treatment free interval of two days for 4 weeks. Volume was calculated as $L \times W^2$ [length=L and width=W] at regular intervals. The rate of mean volume gain of tumors belonging to the PBS- and MIS-treated groups was calculated to be 455 mm³/day and 269 mm³/day respectively. The gain in tumor volume over the course of treatment calculated as volume at the end of treatment-volume at the beginning of treatment, was higher in the PBS group than in the MIS group (figure 3; $p=0.004$ by two-tailed student's t-test).

Fig.3 Effect of MIS on MDA-MB-468 tumor growth in SCID mice

Fig. 3. MDA-MB-468 tumor xenografts were established in SCID mice and animals with palpable tumors were treated with PBS or MIS and tumor volumes were measured using calipers

B) MIS inhibits the growth of spontaneously arising mammary tumors in C3(1) Tag mice *in vivo*

Two groups of 10-week old mice were injected with either PBS or 20 μ g of MIS daily for 5 days with 2 days of treatment free interval for 6 cycles. The PBS and the MIS injected group consisted of 13 and 12 mice respectively. Externally palpable tumors were not observed in any of the animals at the commencement of treatment.

During the course of treatment, 10 animals in the PBS treated group and 6 animals in the MIS injected group developed externally palpable tumors. Of the 10 animals that developed palpable tumors in the PBS injected group, 7 presented with tumors on day 28, one on day 32, one on day 37 and another on day 42 of treatment. Upon sacrifice, an additional two animals in this group were found to have measurable tumors in their mammary gland. In the MIS treated group, 2 animals presented with externally palpable tumors on day 28 of treatment, 1 on day 32 and an additional 3 animals presented with tumors on day 42. Interestingly the animals in this group, which did not present with

externally palpable tumors, did not have any large tumor masses upon sacrifice. These results indicate that by 42 days of treatment, MIS exposure is associated with animals having fewer palpable tumors (figure 4a; $p < 0.048$ by one sided Fisher's Exact test).

At the end of the experiment, animals were sacrificed and tumors were excised and weighed. The tumor weights in the PBS-treated control animals ranged from 0.08-4.63 mg with a mean tumor weight of 0.71 mg and a median of 0.38 mg. The tumor weights in the MIS treated animals ranged from 0.07-0.64 mg with a mean weight of 0.16 mg and a median of 0.10 mg. The lowest tumor (0.07 mg) in this group represents the total weight of micronodules of tumor that could not be excised free of normal tissue. The mean tumor weight in animals was significantly lower in the MIS-treated group compared to controls (figure 4b; $p = 0.029$ by Kruskal-Wallis test). To ensure that the decrease in tumor growth in the MIS-treated animals was not due to suppression of SV40 T antigen in tumors, tumor samples from PBS and MIS treated mice were analyzed by western blot. As demonstrated in figure 4c, MIS treatment did not alter the expression of SV40 T antigen in tumors.

Fig. 4 Effect of MIS on the growth of spontaneously arising mammary tumors in C3(1) Tag mice *in vivo*

Fig. 4a. Ten week old C3(1)Tag mice were injected with either PBS or MIS and animals were monitored for palpable tumor. The graph shows the percentage of animals with measurable tumors in each group vs the days of treatment.

Fig. 4b. At the end of experiment, animals were sacrificed, tumors excised and weighed. The graph gives mean tumor weight per animal.

Fig. 4c Proteins extracted from tumors in PBS and MIS treated animals were immunoblotted with an anti SV40Tag antibody

C) Effect of IFN- γ on the growth of mammary tumors in C3SV40T antigen animals and xenografts established in SCID animals (In progress).

D) To test if MIS and IFN- γ can inhibit the breast tumor growth better than MIS or IFN- γ alone *in vivo* (In progress)

Task 8: The tumors will be tested histopathologically to evaluate the histology of grafts (In progress).

Both PBS and MIS-treated animals with grossly palpable tumors had well developed invasive adenocarcinomas (Fig. 5A). Histological evaluation of tissues demonstrated that the mammary glands of MIS-treated animals that did not have externally palpable tumors had nodular atypical hyperplasia and mammary intraepithelial neoplasia, in which neoplastic cells filled the lumens of the duct, but did not present with invasive carcinomas (Fig. 5b).

Fig. 5. MIS decreases proliferation and increases apoptosis in mammary tumors

Fig. 5a Histological analysis of the mammary tumors excised from the MIS and PBS treated animals

Fig. 5b Histological analysis of the mammary gland of MIS treated mice, which did not present with palpable tumors

MIS suppresses proliferation in mammary tumors *in vivo*

In order to determine whether suppression/delay in mammary tumors observed in MIS-treated mice was due to decreased proliferation and/or increased apoptosis compared with that observed in PBS-treated controls, tumors were stained with antibodies against PCNA, a marker of proliferation, and cleaved caspase-3, a marker of early stage apoptosis. The extent of PCNA staining in the mammary adenocarcinomas resected from PBS-treated animals was uniform through out the tumors while the MIS-treated adenocarcinomas demonstrated PCNA positive regions interspersed with PCNA negative patches (figure 5c). The nodular atypical hyperplasia and mammary intraepithelial neoplasia in the mammary glands of MIS-treated mice also demonstrated patchy PCNA staining. These results indicate that mammary tumors exposed to MIS undergo less proliferation compared to those in PBS-treated controls.

MIS induces apoptosis in mammary tumors *in vivo*

Staining the tumors for activated caspase-3, revealed a marked increase in the number of apoptotic cells in the MIS treated tumors compared to PBS injected controls (figure 5d) suggesting that exposure to MIS induces apoptosis in the mammary tumors *in vivo*. The growth inhibitory effects of MIS could be beneficial in the treatment/prevention of these hormone refractory mammary tumors, especially since high levels of MIS have not shown any harmful effects in humans (11), and the serum levels used here are well below those sustained in normal healthy postnatal to prepubertal boys (12).

Fig.5c

Fig.5d

Fig. 5c. Immunohistochemical expression of PCNA (anti PCNA antibody from Zymed lab.) in tumors resected from PBS and MIS treated mice. A representative tumor from each group is shown

Fig. 5d. Caspase3 cleavage in PBS and MIS treated tumors as assessed immunohistochemically in tumors from PBS and MIS treated mice using anti caspase3 antibody from Cell Signalling. A representative tumor from each group is shown

We have already established that MIS can inhibit the growth inhibitory effects of IFN- γ *in vitro*. To recapitulate the *in vitro* findings to *in vivo* conditions, we have already demonstrated that MIS can suppress the growth of spontaneously arising mouse mammary tumors and established human breast cancer xenografts in immune competent and immune compromised mice, respectively. I am now working on the effect of IFN- γ on breast cancer growth in these mouse models, for which I am using different doses of IFN- γ and testing the mammary tumors growth. The experiments are being carried out, following which these mouse models will be used to test the combined effect of MIS and IFN- γ on the tumor regression.

Key Accomplishments:

MIS and IFN- γ induce the expression of p21, Lysyl Oxidase and MHCII. MIS and IFN- γ costimulate the expression of IRF1 with a synergistic induction of the downstream genes CEACAM1 and MHCII in breast cancer cells.

MIS and IFN- γ co-stimulate the expression of activated caspase3, an apoptosis marker in MDA-MB-468 cells.

MIS and IFN- γ together resulted in a synergistic increase in the fraction of cells in early and late stages of apoptosis as observed by enhanced translocation of annexinV from the inner surface of the plasma membrane to the outside, which occurs after initiation of apoptosis.

To test the growth inhibitory effect of MIS and IFN- γ *in vivo*, MDA-MB-468 xenografts were established by bilaterally injecting 4×10^6 cells/site in $50 \mu\text{l}$ of DMEM subcutaneously onto the dorsal flanks of SCID mice.

For *in vivo* experiments, IFN- γ and MIS doses are determined. Although, rhuIFN- γ as

high as 10 μ g did not cause any harmful effects to the animals but because of the known toxic effects of IFN- γ , 10- 100ng rhuIFN- γ will be injected intraperitoneally to the SCID animals and mIFN- γ to C3SV40Tantigen mice, 5 days a week with two treatment free days/ for 4 weeks.

MIS treatment (20 ug/ animal for 5 days a week with two treatment free days/ for 4 weeks) decreased the rate of mean volume gain of tumors established as xenografts in SCID mice as compared to vehicle treated group

Administration of MIS to C(3)SV40Tantigen mice with spontaneous mammary tumors was associated with a lower number of palpable mammary tumors compared with vehicle-treated mice, and the mean mammary tumor weight in the MIS-treated group was significantly lower compared with the control group.

Analysis of PCNA expression and caspase-3 cleavage in tumors revealed that exposure to MIS was associated with decreased proliferation and increased apoptosis, respectively, and not due to decline in T-antigen expression.

Currently, I am working on the effect of IFN- γ on breast cancer growth in the C(3)SV40 Tantigen mouse and in SCID mouse with MDA-MB-468 xenografts. I am testing the effect of different doses of IFN- γ on the mammary tumor growth. The experiments are being carried out, following which these mouse models will be used to test the combined effect of MIS and IFN- γ on the tumor regression.

Presentations:

Gupta V, Carey JL, Kawakubo H, Muzikansky A, Green JE, Donahoe PK, Maclaughlin DT, Maheswaran S. Mullerian inhibiting substance suppresses tumor growth in the C3(1)T antigen transgenic mouse mammary carcinoma model. Era of Hope, June 8- 11, 2005, Philadelphia Convention Center, Philadelphia.

Conclusions:

1. MIS and IFN- γ induce the expression of p21, Lysyl Oxidase and MHC classII with a synergistic increase in MHC class II mRNA expression.
2. MIS and IFN- γ together resulted in a synergistic increase in the fraction of cells undergoing apoptosis.
3. MDA-MB-468 cells grow robustly as xenografts in SCID mice when injected as 4x10⁶ cells/site in 50 μ l of DMEM subcutaneously onto the dorsal flanks.
4. MIS treatment decreased the rate of mean volume gain of tumors established as xenografts in SCID mice as compared to vehicle treated group.

5. Administration of MIS to C(3)SV40Tantigen mice with spontaneous mammary tumors was associated with a lower number of palpable mammary tumors and the mean mammary tumor weight as compared with the control group.
6. Analysis of PCNA expression and caspase-3 cleavage in tumors revealed that exposure to MIS was associated with decreased proliferation and increased apoptosis, respectively, and not due to decline in T-antigen expression.

Mullerian inhibiting substance (MIS) inhibits breast cancer cell growth *in vitro*. To extend the use of MIS to treat breast cancer, it is essential to test the responsiveness of mammary tumor growth to MIS *in vivo*. Mammary tumors arising in the C3(1)T antigen mouse model expressed the MIS type II receptor, and MIS *in vitro* inhibited the growth of cells derived from tumors. Administration of MIS to mice was associated with a lower number of palpable mammary tumors compared with vehicle-treated mice ($P = 0.048$), and the mean mammary tumor weight in the MIS-treated group was significantly lower compared with the control group ($P = 0.029$). Analysis of proliferating cell nuclear antigen (PCNA) expression and caspase-3 cleavage in tumors revealed that exposure to MIS was associated with decreased proliferation and increased apoptosis, respectively, and was not caused by a decline in T antigen expression. The effect of MIS on tumor growth was also evaluated on xenografted human breast cancer cell line MDA-MB-468, which is estrogen receptor- and retinoblastoma-negative and expresses mutant p53, and thus complements the C3(1)Tag mouse mammary tumors that do not express estrogen receptor and have functional inactivation of retinoblastoma and p53. In agreement with results observed in the transgenic mice, MIS decreased the rate of MDA-MB-468 tumor growth and the gain in mean tumor volume in severe combined immunodeficient mice compared with vehicle-treated controls ($P = 0.004$). These results suggest that MIS can suppress the growth of mammary tumors *in vivo*.

proliferation / apoptosis / simian virus 40 large T antigen

Mullerian inhibiting substance (MIS) is a member of the TGF- β family, a class of molecules that govern a myriad of cellular processes including growth, differentiation, and apoptosis. Synthesis of MIS demonstrates a sexually dimorphic pattern and is produced by Sertoli cells of the fetal and adult testis and granulosa cells of the postnatal ovary. In male embryos, MIS causes regression of the Mullerian duct, the anlagen of the Fallopian tubes, uterus, and upper vagina (1). However, a postnatal role for MIS in males and females has yet to be defined. Signaling by MIS is propagated by binding of MIS to the MIS type II receptor, a transmembrane serine, threonine kinase expressed at high levels in the Mullerian duct, Sertoli cells, and granulosa cells of the embryonic and adult gonads and in the uterus (2–4). The MIS-bound type II receptor subsequently recruits a type I receptor, Activin-like kinase 2 (ALK2), ALK3, and ALK6 have been implicated in mediating MIS signaling in cells (5–9).

We recently demonstrated the presence of MIS receptors in mammary tissue and breast cancer cell lines, suggesting that the mammary gland is a likely target for MIS (6, 10, 11). In the rat mammary gland, expression of the MIS type II receptor is suppressed during puberty when the ductal system branches and invades the adipose stroma and during massive expansion at pregnancy and lactation, but is up-regulated during involution, a time of tissue regression (11, 12). The decline in MIS type II

receptor expression during various stages of postnatal mammary growth suggested a growth-suppressive role for MIS in the mammary gland. Consistent with this concept, MIS inhibited the growth of both estrogen receptor-positive and -negative breast cancer cells by inducing cell cycle arrest and apoptosis (10). Moreover, injection of MIS into female mice induced apoptosis in the epithelium of mammary tissue compared with vehicle-injected control animals (11).

To evaluate whether MIS may be useful in breast cancer therapy, we determined whether the growth inhibitory effect of MIS observed *in vitro* would be recapitulated *in vivo*. Assaying the effect of MIS on mammary tumor models *in vivo* is critical for determining whether MIS could act as an antitumor agent in a milieu replete with several growth factors that promote tumor growth. The C3(1)Tag transgenic mouse model carries the simian virus 40 (SV40) large T antigen targeted to the epithelium of the mammary and prostate glands. The transgenic female mice spontaneously develop atypical ductal hyperplasia by 8 weeks, nodular atypical hyperplasia by 12 weeks, and invasive carcinomas by 16–20 weeks. Disease progression in this model occurs within a relatively short period and correlates well with progressive stages of human breast cancer (13), and has been used in several studies to test novel therapeutic strategies on various stages of mammary tumor progression (13, 14).

The oncogenic SV40 large T antigen-induced tumorigenesis involves functional inactivation of the tumor suppressor genes retinoblastoma (*Rb*) and p53 (15, 16), and invasive carcinomas arising in this model are estrogen-independent. Mutations in *Rb* are prevalent in 20% of human breast cancers and p53 mutations/alterations are detected in ~50% of primary human breast tumors (17, 18), suggesting that inactivation of these two tumor suppressors may be critical in human breast tumorigenesis. The estrogen receptor-negative human breast cancer cell line MDA-MB-468 is *Rb* negative, harbors mutant p53, overexpresses the EGF receptor (19), and is highly responsive to MIS treatment *in vitro* (20). Thus testing the efficacy of MIS in severe combined immunodeficient (SCID) mice bearing MDA-MB-468 tumors would validate the antitumor studies in the C3(1)Tag model for spontaneous mammary carcinoma. In this study, we evaluated whether MIS can inhibit the growth of mammary tumors in the C3(1)Tag model as well as MDA-MB-468 xenografts established in SCID mice. Our results demonstrate that MIS suppresses the growth of mammary tumors *in vivo* in both experimental systems.

Methods

Cell Lines, Reagents, and Growth Inhibition Assays. The M6 tumor cells established from C3(1)Tag mice and MDA-MB-468 cells

Abbreviations: MIS, Mullerian inhibiting substance; PCNA, proliferating cell nuclear antigen; *Rb*, retinoblastoma; SCID, severe combined immunodeficient; SV40, simian virus 40. To whom correspondence should be addressed. E-mail: maheswaran@ch.harvard.edu.

were grown in DMEM supplemented with 10% female FBS, glutamine, and penicillin/streptomycin. To measure inhibition of M6 cell proliferation by MIS, cells were plated in a 24-well plate at a density of 2,500 cells per well and treated with 1, 5, and 10 $\mu\text{g}/\text{ml}$ of MIS for 4 days. Cell numbers were quantified by using a hemocytometer. Recombinant human MIS was immunoaffinity-purified from CHO cells transfected with the human MIS gene (21) followed by desalting and concentration by centrifuge (Millipore) and quantification by the BioRad method.

Antibodies and Western Blot Analyses. The rabbit MIS type II receptor antibody has been described (22). The anti-SV40 large Tag antibody was purchased from Pharmingen, and the anti-cleaved caspase-3 antibody was from Cell Signaling Technology, Beverly, MA. Western analysis was performed as described (23).

Animal Studies. C3(1)Tag Mice. All animals were cared for and experiments were performed at The Wellman Animal Facility, Massachusetts General Hospital under American Association for Laboratory Animal Science guidelines using protocols approved by the Institutional Review Board Institutional Animal Care and Use Committee of the Massachusetts General Hospital. A pair of young homozygous male and female C3(1)Tag mice were used to build a mouse colony. Twenty-five 10-week-old female mice (consisting of seven separate litters born 2–3 days apart) were randomized into two groups to receive PBS (vehicle control, 13 animals) and 20 μg of MIS per animal per day (12 animals) by i.p. injections. Animals were injected for 5 days with 2 days of treatment-free interval for 6 weeks. Mice were monitored daily for evidence of toxicity and found to be healthy and active during the entire course of treatment. None of the animals had externally visible tumors at the commencement of treatment. Three weeks after treatment began palpable tumors emerged in some animals. At the end of the experiment, animals were killed, and tumors were excised, weighed, and snap-frozen or fixed for histologic and biochemical evaluation.

MIS ELISA (24) to determine MIS concentration in blood collected from mice at the end of the experiment was analyzed in duplicate at six serial dilutions by using a standard curve constructed with four-parameter logistical curve fitting Delta-Soft II (BioMetallics, Princeton, NJ). Assay sensitivity was 0.5 ng/ml; and the intraassay and interassay coefficients of variation were 9% and 15% respectively. The ELISA did not recognize luteinizing hormone, follicle-stimulating hormone, activin, inhibin, TGF- β , or bovine or rodent MIS.

SCID mice. MDA-MB-468 xenografts were established by bilaterally injecting 4×10^6 cells per site in 50 μl of DMEM s.c. into the dorsal flanks of 10.6-week-old female SCID mice maintained in the Edwin L. Steffe Laboratory for Tumor Biology, Boston. Mice were ear-tagged to monitor the kinetics of tumor growth at each site. After ~ 4 weeks palpable tumors were observed in 8 of 10 animals. Some developed tumors bilaterally (7/10), whereas another had just one tumor (1/10). The eight animals with palpable tumors were divided randomly into two treatment groups. The PBS-treated group had four animals, three of which had two tumors and one of which had one tumor. The MIS treatment group had four animals, each of which had two tumors.

Treatment of both groups began at the same time. The tumor volumes in the animals in the two groups were comparable. Mice were injected daily i.p. with PBS (100 μl) or 20 μg MIS per animal for 5 days a week with a treatment-free interval of 2 days. Tumors were measured by using calipers just before treatment began and at regular intervals throughout the treatment period. Volume was calculated as $L \times W^2$ (L , length; W , width). Serum MIS concentration was measured at the end of the experiment by MIS-ELISA.

Serum MIS Measurement. Blood was collected by cardiac puncture from PBS- and MIS-treated mice and placed in 1.5-ml microcentrifuge tubes to facilitate clot formation. The clots were centrifuged, and serum was removed to measure serum MIS concentrations as described (25).

Statistical Analyses. The number of measurable tumors in each group on the last day of treatment was compared by using one-sided Fisher's exact test. Differences were considered to be significant when $P < 0.05$.

The mean tumor weights at the end of the experiment in PBS- and MIS-treated C3(1)Tag mice were compared by using the Kruskal-Wallis test, and differences were considered to be significant when $P < 0.05$.

Because each mouse is an experimental unit our calculations are based on total tumor volume per animal. In MDA-MB-468 tumor-bearing SCID mice, tumor volumes were comparable between sites and were summed to obtain total tumor volume per animal. The gain in tumor volume per mouse, at the end of the experiment, was calculated as $\{\text{tumor volume}_{\text{MIS}} - \text{tumor volume}_{\text{PBS}}\} / \text{tumor volume}_{\text{PBS}}$. Statistical analysis was performed by using two-sided Student's t test. Differences were considered to be significant when $P < 0.05$.

Immunohistochemical Analyses. Tissues were fixed in formalin and embedded in paraffin. Sections of 5- μ thickness were stained with hematoxylin and eosin. To detect apoptosis, sections were immunostained with Cleaved Caspase-3 antibody (Asp-175, Cell Signaling Technology) according to the manufacturer's instructions. Briefly, sections were deparaffinized, treated with citrate buffer at subboiling temperature to retrieve antigen, and cooled, and peroxidase quench was added. The slides were washed and blocked, and primary antibody was added and incubated overnight. After washing three times, slides were incubated with secondary antibody for 30 min, and Avidin Biotin solution was added. Color was developed with substrate chromogen, and sections were counterstained with hematoxylin.

Proliferation in tumors was assessed by staining sections with the proliferating cell nuclear antigen (PCNA) staining kit (Zymed). Sections were treated with hydrogen peroxide to inhibit endogenous peroxidase, and antigen was retrieved by microwaving the samples in citrate buffer. Slides were stained with a biotinylated PCNA mAb (clone PC10) followed by streptavidin-peroxidase as a signal generator and diaminobenzidine as chromogen. Sections were counterstained with hematoxylin.

Results

MIS Inhibits the *In Vitro* Growth of Cells Established from Mammary Tumors Arising in C3(1)Tag Mice. We had demonstrated that MIS inhibits the growth of breast cancer cells *in vitro* (10). To confirm these observations *in vivo*, the effect of MIS on the growth of mammary tumors in the C3(1)Tag mice was tested. Western blot analysis of proteins isolated from mammary tumors in the C3(1)Tag mice demonstrated the expression of MIS type II receptor. Proteins extracted from vector and MIS type II receptor-transfected COS cells were used as negative and positive controls, respectively (Fig. 1A).

Before testing the effect of MIS on mammary tumor growth *in vivo*, we first determined whether MIS could inhibit the *in vitro* growth of M6 cells established from C3(1)Tag mouse tumors. M6 cells were treated with 1, 5, and 10 $\mu\text{g}/\text{ml}$ of MIS for 4 days, and cell numbers were quantified. As shown in Fig. 1B, MIS inhibited the growth of M6 cells by 51%, 74%, and 86%, respectively ($P < 0.001$ by two-sided Student's t test), suggesting that these mammary tumor cells are responsive to the growth inhibitory effects of MIS. Consistent with this observation,

Fig. 1. MIS inhibits M6 cell growth *in vitro*. (A) MIS type II receptor expression in C3H/Tag mouse mammary tumors. Total protein from tumors was analyzed by Western blot. Untransfected and MIS type II receptor-transfected COS cells were used as negative and positive controls, respectively. Position of the MIS type II receptor protein is shown. (B) Equal numbers of M6 cells were treated with increasing concentrations of MIS. The number of cells in each well after 4 days of MIS treatment and a representative view of the wells is shown.

staining the cells for PCNA demonstrated that MIS suppressed the proliferation of M6 cells in culture (data not shown).

MIS Inhibits the Growth of Spontaneously Arising Mammary Tumors in C3H/Tag Mice *in Vivo*. Two groups of 10-week-old mice were injected with either PBS or 20 μ g of MIS daily for 5 days with 2 days of treatment-free interval for six cycles. The PBS- and the MIS-injected groups consisted of 13 and 12 mice, respectively. Externally palpable tumors were not observed in any of the animals at the commencement of treatment. One mouse in the MIS group was removed from the experiment within a week of treatment because of a large nonmammary tumor, which caused discomfort to the animal. Except for this animal, there was neither weight loss nor any other discernible adverse effects in the animals within the two groups.

During the course of treatment, 10 animals in the PBS-treated group and 6 animals in the MIS-injected group developed externally palpable tumors. Of the 10 animals that developed palpable tumors in the PBS-injected group, 7 presented with tumors on day 28, 1 on day 32, 1 on day 37, and another on day 42 of treatment. At death, an additional two animals in this group were found to have measurable tumors in their mammary gland. In the MIS-treated group, two animals presented with externally palpable tumors on day 28 of treatment, one presented on day 32, and an additional three animals presented with tumors on day 42. Interestingly the animals in this group, which did not present with externally palpable tumors, did not have any large tumor masses at death. These results indicate that by 42 days of treatment MIS exposure is associated with animals having fewer palpable tumors (Fig. 2A; $P < 0.008$ by one-sided Fisher's Exact test).

At the end of the experiment, animals were killed and tumors were excised and weighed. The tumor weights in the PBS-treated control animals ranged from 0.08 to 4.63 mg with a mean tumor weight of 0.71 mg and a median of 0.38 mg. The tumor weights in the MIS-treated animals ranged from 0.07 to 0.64 mg with a mean weight of 0.16 mg and a median of 0.10 mg. The lowest tumor (0.07 mg) in this group represents the total weight of micronodules of tumor that could not be excised free of normal tissue. The mean tumor weight in animals was significantly lower

Fig. 2. MIS treatment is associated with a decrease in the number of palpable tumors in animals. (A) Ten-week-old C3H/Tag mice were injected with either PBS ($n = 13$) or MIS ($n = 11$), and animals were monitored for palpable tumors. The graph shows the percentage of animals with measurable tumors in each group vs. the days of treatment. On the 42nd day after treatment, the total number of measurable tumors was lower in the MIS group compared with the PBS group ($P < 0.05$ by one-sided Fisher's Exact test). (B) At the end of the experiment, animals were killed, and tumors were excised and weighed. The tumor weight in each animal is given. TNM (tumor not measurable) represents animals in which tumors could not be detected by palpation. The graph shows the mean tumor weight $\pm$ standard error in the PBS- and MIS-injected groups. (C) Proteins extracted from tumors in PBS- and MIS-treated animals were immunoblotted with an anti-SV40Tag antibody. The position of the SV40 large T antigen is shown.

in the MIS-treated group compared with controls (Fig. 2B; $P = 0.029$ by Kruskal-Wallis test). The statistical analysis was repeated excluding the largest tumor (4.627 mg) present in a mouse in the PBS-treated group and indicated that the difference in tumor weights between the two groups was still significant ($P = 0.048$). To ensure that the decrease in tumor growth in the MIS-treated animals was not caused by suppression of SV40 T antigen in tumors, tumor samples from PBS- and MIS-treated

Fig. 3. MIS decreases proliferation and increases apoptosis in mammary tumors. (A) Hematoxylin and eosin staining of palpable mammary tumors excised from the MIS- and PBS-treated animals. Histology of a representative tumor is shown. (B) Histological analysis of the mammary glands of MIS-treated mice, which did not present with palpable tumors. The higher magnifications (insets) demonstrate regions of atypical hyperplasia (left) and mammary intraepithelial neoplasia (lower left). (C) PCNA expression in tumors resected from PBS- and MIS-treated mice. A representative tumor from each group is shown. (D) Caspase-3 cleavage in PBS- and MIS-treated tumors. (e and f) Tumors from two PBS-treated animals. (g and h) Higher magnifications of e and f insets are shown in g and h, respectively. Arrowheads show cells positive for caspase-3 cleavage. (i and j) Tumors from two MIS-treated animals. (k and l) Higher magnifications of i and j insets are shown in k and l, respectively. (E) Proteins extracted from PBS- and MIS-treated tumors were analyzed by Western blot using an antibody against cleaved caspase-3.

mice were analyzed by Western blot. As demonstrated in Fig. 2C, MIS treatment did not alter the expression of SV40 T antigen in tumors.

MIS Suppresses Proliferation and Induces Apoptosis in Mammary Tumors *In Vivo*. Both PBS- and MIS-treated animals with grossly palpable tumors had well developed invasive adenocarcinomas (Fig. 3A). Histological evaluation of tissues demonstrated that the mammary glands of MIS-treated animals that did not have externally palpable tumors had nodular atypical hyperplasia and mammary intraepithelial neoplasia, in which neoplastic cells filled the lumens of the duct, but did not present with invasive carcinomas (Fig. 3B). To determine whether suppression/delay in mammary tumors observed in MIS-treated mice was caused by decreased proliferation and/or increased apo-

ptosis compared with that observed in PBS-treated controls, tumors were stained with antibodies against PCNA, a marker of proliferation, and cleaved caspase-3, a marker of early-stage apoptosis. The extent of PCNA staining in the mammary adenocarcinomas resected from PBS-treated animals was uniform throughout the tumors, whereas the MIS-treated adenocarcinomas demonstrated PCNA-positive regions interspersed with PCNA-negative patches (Fig. 3C). The nodular atypical hyperplasia and mammary intraepithelial neoplasia in the mammary glands of MIS-treated mice also demonstrated patchy PCNA staining. These results indicate that mammary tumors exposed to MIS undergo less proliferation compared with those in PBS-treated controls.

Staining the tumors for activated caspase-3 revealed a marked increase in the number of apoptotic cells in the MIS-treated

Fig. 4. MIS decreases the growth of MDA-MB-468 tumor xenografts established in SCID mice. (A) MDA-MB-468 tumor xenografts were established in mice. Animals with palpable tumors were treated with PBS ($n = 4$) or MIS ($n = 4$), and tumor volumes were measured. The graphs demonstrate changes in total tumor volume in each animal during the course of treatment in the two groups. The thick line represents the mean gain in tumor volume and the hatched line represents the trend line derived from the means, assuming that tumor growth is exponential. (B) The rates of tumor growth within the two groups were calculated based on the equations derived from trend lines. (C) The mean of the gain in tumor volume in each group $\pm$ standard error is shown; the gain in the MIS-treated group was significantly different from the PBS-treated group ($P < 0.005$ by two-sided Student's t test).

tumors compared with PBS-injected controls (Fig. 3D), suggesting that exposure to MIS induces apoptosis in the mammary tumors *in vivo*. This idea was also confirmed by immunoblotting tumor proteins for cleaved caspase-3 (Fig. 3E).

MIS Suppresses MDA-MB-468 Tumor Growth in SCID Mice. The human breast cancer cell line MDA-MB-468 is estrogen receptor-negative and *Rb*-negative and harbors mutant *p53*. MIS inhibits the growth of MDA-MB-468 cells *in vitro*. To validate and confirm the relevance of the results obtained in transgenic mice, we tested the growth-inhibitory effects of MIS on MDA-MB-468 xenografts established in SCID mice. This experimental system closely complements the C3(1)Tag mouse mammary tumor model in which the tumors are estrogen-independent (13) and arise because of functional inactivation of *Rb* and *p53* by the oncogenic T antigen (15, 16).

MDA-MB-468 xenografts were grown s.c. and bilaterally in the dorsal flanks of 6-week-old female SCID mice. After ~ 4 weeks, the eight animals with palpable tumors were randomized into two groups with four animals in the PBS control group and four mice in the MIS treatment group. Both groups were treated at the same time with either PBS or 20 μ g MIS per animal for 5 days a week with a treatment-free interval of 2 days for 4 weeks. Volume was calculated as $L \times W^2$ (L , length; W , width) at regular intervals (Fig. 4A). Analysis of the rate of mean growth during the treatment demonstrated that tumors in the PBS group were growing more rapidly compared with tumors in the MIS-treated group (Fig. 4B). The gain in tumor volume over the course of treatment was calculated as volume at the end of treatment – volume at the beginning of treatment/volume at the beginning of treatment. The PBS group had a higher gain in tumor volume

than the MIS group (Fig. 4C; $P = 0.005$ by two-tailed Student's t test).

Discussion

The presence of MIS in the serum well after regression and differentiation of the Mullerian duct in males and females, respectively, (24, 26) suggests that MIS may have a postnatal role in adults. Moreover, the expression of MIS receptors in non-gonadal tissues such as the mammary and prostate glands (10–12, 27) suggests additional functions for this hormone besides the induction of apoptotic regression of the Mullerian duct. We had demonstrated that MIS inhibits breast cancer cell growth *in vitro* by preventing cell cycle progression and inducing apoptosis (10). In this article, using two *in vivo* model systems, we demonstrate that administration of MIS suppresses mammary tumor growth in mice. We had previously injected a single dose of 100 μ g of MIS into female mice and tested the induction of *TEX-1*, a MIS-inducible gene, in the mammary glands of mice. These results demonstrated that MIS at this high dose could induce the expression of *TEX-1* (11). Subsequently, Stephen *et al.* (28), tested the efficacy of MIS against ovarian cancer cell lines *in vivo* and reported that daily injections of 10 μ g of purified exogenous recombinant human MIS suppressed tumor growth in immunosuppressed mice. Based on these results a comparable dose of MIS (20 μ g per animal per day) was used in these experiments.

In the C3(1)Tag model, fewer animals in the MIS-treated group developed palpable tumors compared with PBS-injected controls. Although the measurable tumors in both groups progressed to adenocarcinomas, histological analyses of tumors indicated that tumors in the MIS-treated group were less dense compared with those in the PBS-treated group. This observation is consistent with the remarkable increase in apoptosis and curtailed proliferation in MIS-treated tumors compared with the PBS-injected controls. The presence of nodular atypical hyperplasia and mammary intraepithelial neoplasia in the MIS-treated mice that did not present with palpable tumors suggests that MIS may not block neoplastic transformation by the SV40 large tumor antigen but suppresses or delays tumor progression, resulting in the overall delay in the appearance of palpable tumors in the MIS-treated group.

This concept is further supported by the results observed in the MDA-MB-468 xenograft model, in which administering MIS to animals with established tumors decreased the rate of tumor growth compared with vehicle-treated controls. Although the mean tumor weight at the end of the experiment was higher in the PBS group than in the MIS group (0.51 vs. 0.33 mg), this difference was not statistically significant ($P = 0.13$ by two-sided Student's t test). This finding was surprising given that the gain in mean tumor volume during the course of the experiment was significantly higher in the PBS-treated animals ($P < 0.005$) than in the MIS-treated mice. However, this result could reflect variations in initial tumor weights, which could not be measured.

The ability of MIS to inhibit MDA-MB-468 tumor growth in SCID mice is likely to occur directly at the cellular level because SCIDs harbor a mutation that severely impairs the development of T and B lymphocytes and MIS can inhibit MDA-MB-468 cell growth *in vitro*. Although MIS has no known immune modulatory effects, whether its inhibitory effect on mammary tumors arising in the immune-competent transgenic mouse model involves enhancement of host immune function remains to be determined. We recently demonstrated that MIS signaling intersects with the IFN- γ pathway and enhances IFN- γ -induced expression of downstream target genes such as *IRF-1* and *CEACAM1*. Furthermore, a combination of MIS and IFN- γ led to a greater degree of growth inhibition of breast cancer cells compared with either agent alone because of enhanced apoptosis rather than a combinatorial effect on cell cycle progression (20). The C3(1)Tag mice would provide an excellent experimen-

tal system to confirm these observations *in vivo* because regression of mammary tumors in response to cytokine treatment in this model has been reported to correlate with an increase in serum concentration of IFN- γ (14). Our preliminary results demonstrate that IFN- γ administration to mice can suppress mammary tumor growth in both experimental systems (data not shown). Although the antitumor effect of IFN- γ *in vivo* has been well documented, toxicity associated with exposure to IFN- γ has diminished its utility in treatment (29). Whether MIS may prove to be beneficial in harnessing the antitumor effects of this cytokine remains to be determined.

Our results demonstrate that MIS can suppress the growth of spontaneously arising mouse mammary tumors and established human breast cancer xenografts in immune-competent and immune-compromised mice, respectively. These tumors are estrogen-independent and lack functional p53 and Rb mutations, alterations of which have been detected in human breast cancers

(17, 18). The growth inhibitory effects of MIS could be beneficial in the treatment/prevention of these hormone refractory mammary tumors, especially because high levels of MIS have not shown any harmful effects in humans (30), and the serum levels used here are well below those sustained in normal healthy postnatal to prepubertal boys (26). These data support expansion to larger studies to validate these findings before progressing to studies in humans.
