14. ABSTRACT We have successfully identified a set of breast tissue gene expression changes that distinguish parous from nulliparous rats and mice. This is a critical step in our development of a chemoprevention approach to mimic the protective effect of pregnancy in women. These differences are now being studied in women. We have also shown that breast epithelium is overwhelmingly concentrated in mammographically dense areas. This provides a deep insight into the increased risk associated with densities and, since densities are reduced by pregnancy, insight into another mechanism by which pregnancy reduces risk. Fresh breast tissue sample collection from normal women is now well underway and the first chemoprevention-associated study has begun recruiting women.

INTRODUCTION: This Innovator Award is designed to provide insight into the ways in which a chemoprevention regimen can mimic the protective effect of a full-term pregnancy (a birth) against breast cancer. In addition, we are aiming to understand the mechanisms underlying the risk associated with increased mammographic density, the strongest known risk factor for breast cancer after the highly penetrant genetic risk factors of BRCA1 and BRCA2 mutations. Mammographic densities are permanently reduced by births; and this relationship is being explored in depth in order to determine if this is an important part of the mechanism by which births provide protection against breast cancer. This work is being conducted both in humans and rodents.

BODY: The Innovator Award consists of four projects (Projects 1 and 2 are being completed through a subcontract to our colleague Dr. Lewis Chodosh at the University of Pennsylvania, and Projects 3 and 4 are being completed by the team at USC).

Projects 1 and 2 involve both rat and human components and consists of 10 tasks.

Task 1: Months 1-12: Treat rats with different hormonal chemoprevention regimens, harvest mammary tissue, and isolate RNA.

This task has been completed on schedule. Groups of Lewis rats have been treated with pellets containing either estradiol, progesterone, estradiol and progesterone, β -hCG, or perphenazine. Animals were treated for 21 days. Pellets were then removed and the animals sacrificed 28 days later. Control groups consisted of parous animals allowed to undergo a single round of pregnancy, lactation, and 28 days of involution, as well as age-matched nulliparous controls. For all groups, total RNA was prepared from mammary glands by ultracentrifugation through a CsCl/guanidinium isothiocyanate cushion.

The effects of each of these hormonal treatments on the susceptibility to MNU-induced mammary tumorigenesis was tested using standard protocols either with MNU administered before hormonal treatments or after. Results confirmed that treatment with estradiol, estradiol and progesterone, or β -hCG is protective against mammary tumorigenesis, whereas treatment with progesterone alone is not. Additionally, we found that treatment with perphenazine was partially protective against MNU-induced tumorigenesis.

Task 2: Months 6-24: Analyze morphological changes and determine global gene expression profiles for rat mammary gland samples from rats treated with different hormonal chemoprevention regimens.

Per the SOW, considerable progress has been made on this aim. Analysis of mammary gland morphology by carmine stained whole mounts as well as by hematoxylin and eosin-stained sections indicates that, after 21 days of treatment with estradiol, estradiol and progesterone, β -hCG, and perphenazine all give rise to mammary epithelial differentiation comparable to that of mid-pregnancy animals. In contrast, treatment with progesterone alone had no effect on mammary epithelial morphology.

Mammary gland morphology was also examined 28 days following treatment termination. This analysis revealed that mammary gland morphology was extremely similar among all groups and that there were no obvious differences in the amount of epithelium present.

RNA prepared from each of these experimental groups has been used to prepare biotinylated cRNA suitable for hybridization to Affymetrix oligonucleotide microarrays and many of these samples have been hybridized to arrays. In the coming study period, these hybridizations will be completed and the analysis of data performed to identify differentially expressed genes.

Task 3: Months 6-36: Identify genes that are expressed in a parity-specific manner in the rat.

This task has been completed ahead of schedule and has recently been published in *Cancer Research* (Blakely *et al.*, 66:6421-6431, 2006).

A major challenge posed by global gene expression surveys is the large number of differentially expressed genes that are typically identified, only a few of which may contribute causally to the phenomenon under study. Consequently, we considered approaches to identifying parity-induced changes in the rat mammary gland that would permit the resulting list of expressed genes to be narrowed to those most robustly associated with parity-induced protection against mammary tumorigenesis. Given the marked genetic and biological heterogeneity between different inbred rat strains, we reasoned that identifying expression changes that are conserved across multiple strains exhibiting hormone-induced protection against mammary tumorigenesis would facilitate the identification of a core set of genes associated with parity-induced protection against breast cancer.

To achieve this goal, we focused on gene expression changes that are conserved among different strains of rats that exhibit hormone-induced protection against mammary tumorigenesis. Four inbred rat strains that exhibit marked differences in their intrinsic susceptibilities to carcinogen-induced mammary tumorigenesis were each demonstrated to display significant protection against MNU-induced mammary tumorigenesis following treatment with estradiol and progesterone. Microarray expression profiling of parous and nulliparous mammary tissue from these four strains yielded a common 70-gene signature. Examination of the genes constituting this signature implicated differences in TGF- β signaling, the extracellular matrix, amphiregulin expression, and the growth hormone-Igf1 axis between parous and nulliparous rats. Notably, related changes have been associated with extent of mammographic density, which itself is strongly associated with breast cancer risk. Our findings demonstrate that hormone-induced protection against mammary tumorigenesis is widely conserved among divergent rat strains and define a gene expression signature that is tightly correlated with reduced mammary tumor susceptibility as a consequence of a normal developmental event.

Given the conservation of this signature, these pathways may contribute to pregnancy-induced protection against breast cancer.

Task 4: Months 6-36: Identify genes whose expression in rats correlates with protection against breast cancer.

This task has been completed ahead of schedule and has recently been published in *Cancer Research* (Blakely *et al.*, 66:6421-6431, 2006). Please see the description under Task 3 above.

Task 5: Months 1-48: Isolate RNA from human mammary gland samples and control epithelial and stromal samples.

Significant progress has been made on this aim. RNA has been isolated from a large number of the available human specimens. In addition, we have prepared RNA from control samples consisting of: intact adipose tissue, intact fibrous (e.g. stromal and epithelial) breast tissue, epithelial organoids isolated by collagenase digestion, cultured epithelial organoids, and cultured fibroblasts from reduction mammoplasty specimens.

Task 6: Months 3-52: Determine global gene expression profiles for human mammary gland samples using oligonucleotide microarrays.

Work on this aim has been initiated and progress has been made. Biotinylated cRNA has been prepared from a subset of the RNA samples isolated in Task 5 and proof-of-principle experiments have been performed to demonstrate that these samples can be run on Affymetrix microarrays and meet established quality control standards.

Task 7: Months 12-60: Identify genes whose expression in the mammary gland in women reflects aspects of reproductive history that impact on breast cancer susceptibility. This task will be initiated in the next study period.

Task 8: Months 1-36: Determine the effect of short-term, low-dose estradiol and progesterone treatment on MNU-induced mammary tumor susceptibility. Per the SOW, we are currently initiating work on this aim.

Task 9: Months 12-60: Determine the effect of hormone treatment on MNU-induced mammary epithelial proliferation. Per the SOW, this task will be initiated in the next study period.

Task 10: Months 12-60: Determine whether p53 loss abrogates pregnancy-induced protection against carcinogen-induced mammary tumorigenesis. Per the SOW, this task will be initiated in the next study period.

Project 3 was designed to recruit 48 nulliparous patients undergoing a biopsy for a suspicious (for cancer) lesion to be treated with a short-term low-dose estrogen/high-dose progesterone (EP) regimen with a second biopsy following the treatment. A number of

hormonal, genetic and cellular analyses will be carried out on the biopsy specimens obtained before and after the treatment regimen.

Task 1. The first task for Project 3 was to develop an appropriate protocol and hormonal treatment regimen that would mimic the protective effect of pregnancy. For this purpose we organized a group at USC with expertise in endocrinology, gynecology, breast cancer pathology, oncology, radiology and epidemiology to discuss the issues involved and how we might approach them. There are profound differences between rodents and women in the relative levels of estrogen in the estrus/menstrual cycle and during pregnancy. Peak pregnancy estrogen levels in women are 100-fold higher than estrogen levels in the menstrual cycle; in contrast, pregnancy levels of estrogen in rodents are no more than 3-4 times higher than the levels during the estrus cycle. In contrast to rodents, treatment of women with pregnancy levels of estrogen is completely out of the question. Pregnancy levels of progesterone can however be attained and it is possible that, as long as low levels of estrogen are maintained, that such levels of progesterone will be protective. After weighing the different options open to us, it was decided that as a first step we would take advantage of the fact that premenopausal women with excessive bleeding are treated in our Department of Obstetrics and Gynecology with a 90-day high dose progestin treatment regimen. Together with Dr. Karine Chung of the Obstetrics and Gynecology Department, a protocol has been developed to perform pre-treatment and post-treatment breast biopsies on premenopausal women taking high-dose Megace as standard treatment for endometrial hyperplasia. Data from these women should allow us to determine if a high-dose progestin regimen can be developed to achieve the protective effects we are looking for. We will be comparing not only gene expression changes (with the emphasis on the changes seen by Chodosh's group - see above), but changes in progesterone receptor status (to check whether the progestin has a receptor to interact with through the 90 days of treatment), and changes in breast composition suggested by our work on the biological basis of the risk associated with mammographic densities. This protocol has been submitted to the USC IRB and includes the study of 10 women. We expect to complete the evaluation of the treatment regimen within 6 months. If this approach does not appear encouraging, we will evaluate additional regimens, including the use of human chorionic gonadotrophin (hCG). We have also re-thought our initial plan to test any potential breast cancer chemoprevention regimen on women with suspicious (for cancer) breast lesions. We now believe it will be better to recruit women attending the USC benign breast disease clinic for this purpose. The recruitment goal of 48 nulliparous women will be easier to meet with this patient population because they are typically younger than the women being evaluated for a suspicious lesion.

We believe that we will still be on target to complete the other tasks of this project within the specified time frame. Therefore we expect tasks 2-5 to be conducted over the next four project periods as planned.

Project 4. The second project being conducted at USC (Project 4) calls for the recruitment of 150 elective reduction mammoplasty patients. We will collect breast tissue from these women and conduct the same types of hormonal, genetic, and cellular

analyses as will be done in Project 3. In addition, cellular analyses on 100 tissue slides from previous reduction mammoplasties will be conducted.

Task 1 for Project 4 indicated that we would recruit 150 elective reduction mammoplasty patients. In the first year of the project, we developed and finalized the protocol and began recruitment. Thus far, we have recruited 11 subjects; all the eligible subjects we have approached. The slow recruitment is due primarily to delays caused by our co-investigator surgeon, Dr. Susan Downey, moving to another institution (Pacific Surgery Center, Santa Monica, CA) in December 2006. We have been working since December to obtain the necessary IRB approvals to recruit subjects at her new institution. Although we received the necessary local IRB approvals very quickly, the U.S. Army Medical Research and Materiel Command Office of Research Protection (ORP) felt that additional steps needed to be taken. This has resulted in many months of delay. However, we have now had a meeting with the ORP, believe that all remaining issues have been resolved and submitted the required documentation to fulfill all of the requirements put forth by the ORP. We are optimistic that final approval will be achieved by mid-August. In addition to Dr. Downey, we will be working with other surgeons, including Dr. Ruth Carr, a colleague of Dr. Downey, and Dr. Randy Sherman at USC, and should be able to recruit the 150 reduction mammoplasty patients by the end of year 4.

Task 1a for this project refers to conducting cellular (immunohistochemical) assays on 100 tissue samples from previous reduction mammoplasties. This work is well underway and has already resulted in a seminal publication (Hawes *et al.*, *Breast Cancer Res* 8:R24-29, 2006). The results of this publication will not be discussed here as the paper is included in the Appendix. In addition to the work described in the publication, we have expanded to 35 subjects and are including additional markers. We are currently evaluating the apoptotic pathway (caspase-3 and bax), estrogen receptor (ER)- α , progesterone receptor (PR)-A, PR-B, BCL2, transforming growth factor- β , TIMP3, vascular endothelial growth factor, and ECAD. The analysis of each of these markers is ongoing. In addition, we have performed Masson's Trichrome staining to evaluate the collagen content of the slide. Dense and non-dense areas are being compared and analysis is ongoing. Trichrome provides an overall collagen content measure, however we are also interested in determining individual collagen levels since the composition of collagen may be influenced by age, parity, and other breast cancer risk factors. Staining for collagen I, II and IV has been completed and staining of collagen V (suggested by results from Chodosh's group) will be conducted in the next few weeks.

The time involved in studying these markers has been much greater than we had envisaged. Although we have utilized the Clariant Automated Cellular Imaging System II (San Juan Capistrano, CA) which was purchased through a cost-share with this grant, a very significant amount of review is still required by our study pathologist, Dr. Debra Hawes, to identify particular cell components on the slides.

This set of 35 subjects should be extremely informative because we have obtained reproductive and hormone use histories on these women and can conduct more detailed

analyses on these samples by considering age, parity, oral contraceptive use, and menopausal hormone therapy in the analysis. We are continuing to contact additional subjects for permission to include their samples and to complete the reproductive and hormonal questionnaire and will add their specimens as the data are gathered.

Task 2. Dr. Stanczyk in the reproductive endocrinology lab has begun preparatory work on refining the assays to measure tissue hormone levels in fat and non-fat breast tissues. Their previous experience was limited to measuring hormones in breast fat while an important element of this grant is to compare hormone levels in dense and less dense tissue, since the breast epithelium is markedly differently distributed in these tissues, and thus it is critical to ensure that the methods developed for measurements in breast fat can be used for stromal (dense) tissue as well. We have now completed a number of experiments and demonstrated that the protocol is working well. A few additional experiments will be completed in the next month to collect additional data on reproducibility and to compare the use of buffer and 70% methanol in conducting the tissue hormone extraction in both the fat (non-dense) and stromal tissue (dense). Once the protocol for tissue hormone measurement is finalized, we plan to begin testing of specimens collected from our prospective reduction mammoplasty study.

Task 3. We have not yet assayed the blood samples for hormone levels as this will be done in batches and in parallel with our measurement of the tissue hormone levels. Therefore, we expect to conduct our first batch analysis at the beginning of September.

Task 4. Although our initial statement of work included a plan to conduct gene expression studies in months 37-48 we have decided to test our first 15 specimens. In order to conduct gene expression studies comparing dense and non-dense tissue it is critical to microdissect the tissue into epithelial, stromal and fat compartments and then to extract the RNA. We have identified a pathology fellow to perform this microdissection and this work is expected to begin in mid-August. Microdissection is extremely labor intensive. We estimate that microdissection of 15 specimens will be completed by the end of September; these specimens will represent the first group of specimens that will be used for our microarray gene expression studies.

Task 5. This task calls for analysis and manuscript preparation in months 13-60. We have already published one paper (see Hawes *et al.*, Appendix) and expect to prepare a manuscript on other histochemistry markers in the next several months. We will continue to write up our results as appropriate.

KEY RESEARCH ACCOMPLISHMENTS:

- Treatment of rats with hormonal chemoprevention regimens and determination of effective regimens.
- Evaluation of rat mammary gland morphology.
- Identification of genes expressed in a parity-specific manner in multiple rat strains resulting in a key publication in *Cancer Research* (Blakely *et al.*, 2006, see Appendix).

- Development of a novel research protocol to allow us to evaluate the appropriateness of a progestin-based breast cancer chemopreventive approach.
- Development and initiation of a research protocol to collect interview data, tissue specimens, and mammograms on women having elective reduction mammoplasties.
- Evaluation of tissue samples from previous reduction mammoplasties resulting in a seminal publication in *Breast Cancer Research* (Hawes *et al.*, 2006, see Appendix).
- Contact and interview 35 previous reduction mammoplasty subjects to obtain demographic, reproductive, and hormone use data.
- Staining and evaluation of previous reduction mammoplasty samples for a number of potentially critical cellular markers.
- Development of methods for assaying hormone levels in dense (stromal) tissue.
- A further key accomplishment is the development of a network of collaborators at USC and across the United States to further the work being funded by this grant.
 - At USC we have formed a working group of investigators with expertise in endocrinology, gynecology, breast cancer pathology, oncology, radiology, epidemiology and molecular biology/embryology who meet at least twice a month to review progress of the various projects and specific related tasks and to discuss any data generated from the studies and any new questions that may arise from our studies or published literature. An important new research protocol to obtain breast tissue biopsies from women who were very recently pregnant has been approved by the USC IRB and is underway. The sample set obtained through this protocol will represent the largest collection of tissue samples from the pregnant breast (or recently pregnant). Although this work is funded through other mechanisms it is a direct off-shoot of the meetings held to further the goals of this research grant.
 - We have also sought out a number of investigators with similar interests in breast cancer across the United States. We are now collaborating with Dr. Sue Bartow and Dr. Dorothy Pathak to perform cellular marker analysis on breast specimens from autopsies performed in New Mexico. These are the same specimens utilized by Dr. Norman Boyd's group (Li *et al.*, *Cancer Epidemiol Biomarkers Prev* 14:343-349, 2005) and we are collaborating with Dr. Boyd to further our understanding of the biology of mammographic densities. Although this work is not currently funded through this grant it also came about as a direct result of planning to meet the goals of this grant.
 - As part of this grant, we have had meetings with Dr. Dan Medina and his colleagues at Baylor, and with Dr. Satyabrata Nandi and his colleagues at UC Berkley to ensure that we were aware of their current thinking regarding chemoprevention in rodents. Two of us also attended the Gordon Research Conference "Mammary Gland Biology", where a number of important contacts were made, including one with Dr. Charlotte Kuperwasser of Tufts University and Dr. Pepper Schedin of the University

of Colorado, both of whom are scheduled to visit and discuss possible collaborations relevant to this grant.

REPORTABLE OUTCOMES:

1. Blakely CM, Stoddard AJ, Belka GK, Dugan KD, Notarfrancesco KL, Moody SE, D'Cruz CM, and Chodosh LA. Hormone-induced protection against mammary tumorigenesis is conserved in multiple rat strains and identifies a core gene expression signature induced by pregnancy. *Cancer Research*, 66:6421-6431, 2006.
2. Hawes D, Downey S, Pearce CL, Bartow S, Wan P, Pike MC, Wu AH. Dense breast stromal tissue shows greatly increased concentration of breast epithelium but no increase in its proliferative activity. *Breast Cancer Res*, 8:R24-29, 2006.

CONCLUSION:

The successful identification of a set of breast tissue gene expression differences (changes) that distinguish parous from nulliparous rats of multiple strains (and confirmed in a strain of mice) is a critical step in our development of a chemoprevention approach to mimic the protective effect of pregnancy. If we can confirm these genetic expression changes in rodents treated with a variety of hormonal chemoprevention regimens (part of our current work) and also confirm them in women (part of our current work), they should provide a critical biomarker of effect for chemoprevention approaches in women that attempt to mimic the protective effect of pregnancy.

Our finding that breast epithelial tissue in women is overwhelmingly concentrated in mammographically dense areas of the breast (areas of high collagen concentration not seen in rodent breast) provides a deep insight into the reason for increased mammographic density being so closely associated with increased risk of breast cancer - women with increased mammographic density have more breast epithelium. The reason(s) for this relationship is at present unclear and is a focus of our current research. Breast densities are reduced in parous compared to nulliparous women, so that this endeavor ties in closely with our development of a chemoprevention regimen to mimic the protective effect of pregnancy. It may be that the genetic expression changes brought about by pregnancy (discussed above) are themselves responsible for the reduction in densities - how to study this is not completely clear at the moment but we are actively trying to identify an animal species with mammographic densities where this could be directly studied. In addition, our embryologist colleague, Dr. Randy Wideltz, at our behest has identified a KO mouse with breast densities and this may prove to be a model that could be useful in this regard. Our forthcoming discussions with Drs. Kuperwasser and Schedin may also identify experimental systems that will help in this regard.

Finally, with IRB issues behind us we are now in a position to collect a sufficient number of fresh breast samples to allow for detailed genetic expression and other work to proceed as planned.

Abstract

Women who have their first child early in life have a substantially lower lifetime risk of breast cancer. The mechanism for this is unknown. Similar to humans, rats exhibit parity-induced protection against mammary tumorigenesis. To explore the basis for this phenomenon, we identified persistent pregnancy-induced changes in mammary gene expression that are tightly associated with protection against tumorigenesis in multiple inbred rat strains. Four inbred rat strains that exhibit marked differences in their intrinsic susceptibilities to carcinogen-induced mammary tumorigenesis were each shown to display significant protection against methylnitrosourea-induced mammary tumorigenesis following treatment with pregnancy levels of estradiol and progesterone. Microarray expression profiling of parous and nulliparous mammary tissue from these four strains yielded a common 70-gene signature. Examination of the genes constituting this signature implicated alterations in transforming growth factor- β signaling, the extracellular matrix, amphiregulin expression, and the growth hormone/insulin-like growth factor I axis in pregnancy-induced alterations in breast cancer risk. Notably, related molecular changes have been associated with decreased mammographic density, which itself is strongly associated with decreased breast cancer risk. Our findings show that hormone-induced protection against mammary tumorigenesis is widely conserved among divergent rat strains and define a gene expression signature that is tightly correlated with reduced mammary tumor susceptibility as a consequence of a normal developmental event. Given the conservation of this signature, these pathways may contribute to pregnancy-induced protection against breast cancer. (Cancer Res 2006; 66(12): 6421-31)

Introduction

Epidemiologic studies clearly show that a woman's risk of developing breast cancer is influenced by reproductive endocrine events (1). For example, early age at first full-term pregnancy, as well as increasing parity and duration of lactation, have each been shown to reduce breast cancer risk (2, 3). In particular, women who have their first child before the age of 20 have up to a

50% reduction in lifetime breast cancer risk compared with their nulliparous counterparts (2). Notably, the protective effects of an early full-term pregnancy have been observed in multiple ethnic groups and geographic locations, suggesting that parity-induced protection results from intrinsic biological changes in the breast rather than specific socioeconomic or environmental factors. At present, however, the biological mechanisms underlying this phenomenon are unknown.

Several models to explain the protective effects of parity have been proposed. For instance, parity has been hypothesized to induce the terminal differentiation of a subpopulation of mammary epithelial cells, thereby decreasing their susceptibility to oncogenesis (4). Related to this, parity has been suggested to induce changes in cell fate within the mammary gland, resulting in a population of mammary epithelial cells that are more resistant to oncogenic stimuli by virtue of decreased local growth factor expression and/or increased transforming growth factor (Tgf)- β 3 and p53 activity (5, 6). Others have suggested that the process of involution that follows pregnancy and lactation acts to eliminate premalignant cells or cells that are particularly susceptible to oncogenic transformation (5). Conversely, parity-induced decreases in breast cancer susceptibility could also be due to persistent changes in circulating hormones or growth factors rather than local effects on the mammary gland (7). At present, however, only limited cellular or molecular evidence exists to support any of these models.

Similar to humans, both rats and mice exhibit parity-induced protection against mammary tumorigenesis. Administration of the chemical carcinogens, 7,12-dimethylbenzanthracene or methylnitrosourea, to nulliparous rats results in the development of hormone-dependent mammary adenocarcinomas that are histologically similar to human breast cancers (8). In outbred Sprague-Dawley, and inbred Lewis and Wistar-Furth rats, a full-term pregnancy either shortly before or after carcinogen exposure results in a high degree of protection against mammary carcinogenesis (7, 9, 10). Similarly, treatment of rats with pregnancy-related hormones, such as 17- β -estradiol (E) and progesterone (P), can mimic the protective effects of pregnancy in rat mammary carcinogenesis models (11, 12). This suggests that the mechanisms of parity-induced protection and estradiol and progesterone-induced protection may be similar. Using analogous approaches, Medina and colleagues have shown parity-induced as well as hormone-induced protection against 7,12-dimethylbenzanthracene-initiated carcinogenesis in mice (13, 14). As such, rodent models recapitulate the ability of reproductive endocrine events to modulate breast cancer risk as observed in humans. This, in turn, permits the mechanisms of parity-induced protection to be studied within defined genetic and reproductive contexts.

Previously, analyses of gene expression changes that occur in rodent models in response to parity, or hormonal treatments that mimic parity, have been used to suggest potential cellular and molecular mechanisms for pregnancy-induced protection against breast cancer (6, 15). Rosen and colleagues used subtractive hybridization analysis to identify genes in the mammary glands of Wistar-Furth rats that were persistently up-regulated 4 weeks posttreatment with estradiol and progesterone (15). Estradiol and progesterone treatment was found to increase the mRNA expression of a wide range of genes, including those involved in differentiation, cell growth, and chromatin remodeling. Similarly, we used microarray expression profiling to assess global gene expression changes induced by parity in the mammary glands of FVB mice (6). This analysis revealed parity-induced increases in epithelial differentiation markers, *Tgfb3* and its downstream targets, and cellular markers reflecting the influx of macrophages and lymphocytes into the parous gland. We also found that parity resulted in persistent decreases in the expression of a number of growth factor-encoding genes, including amphiregulin (*Areg*) and insulin-like growth factor (*Igf-I*). Together, these studies provided initial insights into cellular and molecular mechanisms that could contribute to parity-induced protection.

Notably, early first full-term pregnancy in humans primarily decreases the incidence of estrogen receptor (ER)-positive breast cancers (16). Because rats are more similar to humans than are mice with respect to the incidence of ER-positive mammary tumors (17), in the present study we used microarray expression profiling to identify persistent gene expression changes in the mammary glands of this rodent species to explore potential mechanisms of parity-induced protection. To date, a comprehensive analysis of parity-induced up-regulated and down-regulated gene expression changes in the rat has not been performed.

A major challenge posed by global gene expression surveys is the large number of differentially expressed genes that are typically identified, only a few of which may contribute causally to the phenomenon under study. Consequently, we considered approaches to identifying parity-induced changes in the rat mammary gland that would permit the resulting list of expressed genes to be narrowed to those most robustly associated with parity-induced protection against mammary tumorigenesis. Given the marked genetic and biological heterogeneity between different inbred rat strains, we reasoned that identifying expression changes that are conserved across multiple strains exhibiting hormone-induced protection against mammary tumorigenesis would facilitate the identification of a core set of genes associated with parity-induced protection against breast cancer.

To achieve this goal, we focused on gene expression changes that are conserved among different strains of rats that exhibit hormone-induced protection against mammary tumorigenesis. We first identified four genetically distinct inbred rat strains that exhibit hormone-induced protection against methylnitrosourea-induced mammary tumorigenesis independent of their inherent susceptibility to this carcinogen. We then used oligonucleotide microarrays to identify a core 70-gene expression signature that closely reflects parity-induced changes in the mammary gland that were conserved among each of these strains. The results of this analysis extend prior observations with respect to parity-induced changes in the growth hormone/*Igf-I* axis, identify novel parity-induced changes associated with the extracellular matrix (ECM), and implicate a core set of pathways in pregnancy-induced protection against breast cancer.

Materials and Methods

Animals and tissues. Lewis, Wistar-Furth, Fischer 344, and Copenhagen rats (Harlan, Indianapolis, IN) were housed under 12-hour light/12-hour dark cycles with access to food and water ad libitum. Animal care was performed according to institutional guidelines. To generate parous (G1P1) rats, 9-week-old females were mated and allowed to lactate for 21 days after parturition. After 28 days of postlactational involution, rats were sacrificed by carbon dioxide asphyxiation and the abdominal mammary glands were harvested and snap-frozen following lymph node removal, or whole-mounted and fixed in 4% paraformaldehyde. Whole-mounted glands were stained with carmine alum as previously described (6). For histologic analysis of whole mammary glands and tumors, paraffin-embedded tissues were sectioned and stained with H&E or Mason's trichrome as previously described (6). Tissues were harvested from age-matched nulliparous (G0P0) animals in an identical manner.

Carcinogen and hormone treatments. Twenty-five to 30 nulliparous female Lewis, Fischer 344, Wistar-Furth, and Copenhagen rats were weighed and treated at 7 weeks of age with methylnitrosourea (Sigma-Aldrich, St. Louis, MO) at a dose of 50 mg/kg by a single i.p. injection. At 9 weeks of age, animals from each strain were assigned to one of two groups and treated with hormone pellets (Innovative Research, Sarasota, FL) by s.c. implantation. Group 1 received pellets containing 35 mg of 17- β -estradiol + 35 mg of progesterone, whereas group 2 received pellets containing placebo. Pellets were removed after 21 days of treatment. No signs of toxicity were observed. The development of mammary tumors was assessed by weekly palpation. Animals were sacrificed at a predetermined tumor burden, or at 60 weeks postmethylnitrosourea. At sacrifice, all mammary glands were assessed for tumors, which were fixed in 4% paraformaldehyde and embedded in paraffin. Tumor samples from each strain were confirmed as carcinomas by histologic evaluation. Statistical differences in tumor-free survival between experimental groups were determined by log rank tests and by the generation of hazard ratios (HR) based on the slope of the survival curves using GraphPad Prism 4.0 software.

Microarray analysis. RNA was isolated from snap-frozen abdominal mammary glands by the guanidine thiocyanate/cesium chloride method as previously described (6). Ten micrograms of total RNA from individual Wistar-Furth (six G0P0 and five G1P1), Fischer 344 (eight G0P0 and six G1P1), and Copenhagen (six G0P0 and five G1P1) rats was used to generate cDNA and biotinylated cRNA as previously described (6). For Lewis rats, three G0P0 and three G1P1 samples were analyzed, each of which was comprised of 10 μ g of pooled RNA from three animals. To permit the identification of epithelial as well as stromal gene expression changes, intact mammary glands (with lymph nodes removed) were used. Samples were hybridized to high-density oligonucleotide microarrays (RGU34A) containing ~8,800 probe sets representing ~4,700 genes and expressed sequence tags. Affymetrix comparative algorithms (MAS 5.0) and Chipstat were used to identify genes that were differentially expressed between nulliparous and parous samples (18). Robust Multichip Average signal values were generated using Bioconductor (19).

Genes were selected for further analysis whose expression changed significantly by the above analysis in three out of four strains. Significance was assessed by randomly generating eight lists equal in size to the up-regulated and down-regulated lists for each strain from the population of nonredundant genes called present on the chip in at least one sample (2,428 genes). One million random draw trials were performed to calculate a nominal *P* value for combined list length and to estimate the false discovery rate (FDR) using the median list size occurring by chance.

Hierarchical clustering was done using R statistical software¹ and as described (20). Mouse genes were identified using the Homologene database (National Center for Biotechnology Information).

Quantitative real-time PCR. Five micrograms of DNase-treated RNA were used to generate cDNA by standard methods. *Csn2*, *Mmp12*, *Tgfb3*,

¹ <http://www.R-project.org>.

Igfbp5, *Areg*, *Igf-I*, *Ghr*, *Serpinh1*, and *Sparc* were selected for confirmation by quantitative real-time PCR (QRT-PCR) using TaqMan assays (Applied Biosystems, Foster City, CA). *B2m* was used as a control (21, 22). Reactions were performed in duplicate in 384-well microtiter plates in an ABI Prism Sequence Detection System according to standard methods (Applied Biosystems). One-tailed *t* tests were performed to determine statistical significance using Prism 4.0 software.

Results

Hormone-induced protection in inbred rat strains. To determine whether hormone-induced protection against mammary tumorigenesis is a feature unique to carcinogen-sensitive strains, we compared the extent of protection induced by hormones in four different rat strains: Lewis, Wistar-Furth, Fischer 344, and Copenhagen. Two of these strains (Lewis and Wistar-Furth) have been reported to exhibit hormone-induced protection (9, 12). However, it has not been determined whether carcinogen-resistant strains of rats, such as Copenhagen (23), also exhibit protection. Female rats from each strain were treated with a single dose of methylnitrosourea at 7 weeks of age, followed by s.c. implantation of either placebo or hormone pellets (35 mg of estradiol + 35 mg of progesterone) at 9 weeks of age. Among the placebo-treated groups, Lewis rats exhibited the highest susceptibility to methylnitrosourea-induced mammary tumorigenesis with 100% penetrance and a median tumor latency of 13 weeks (Fig. 1A). Fischer 344 and Wistar-Furth rats displayed intermediate carcinogen sensitivity with latencies of 24 and 36 weeks, respectively. In contrast, Copenhagen rats exhibited a high degree of resistance to methylnitrosourea-induced mammary tumorigenesis with only 5 of 12 animals developing mammary tumors, with an average latency of 51 weeks.

Surprisingly, despite the wide variance in carcinogen sensitivity of nulliparous rats from these four strains, estradiol and progesterone treatment induced a significant ($P < 0.05$) degree of protection against mammary tumorigenesis in each strain (Fig. 1B). For example, whereas Lewis and Copenhagen strains differed markedly in their sensitivity to methylnitrosourea, they exhibited strikingly similar degrees of hormone-induced protection with HRs of 0.19 [95% confidence interval (CI), 0.05-0.40] and 0.16 (95% CI, 0.02-0.63), respectively. The Wistar-Furth (HR, 0.31; 95% CI, 0.09-0.90) and Fischer 344 (HR, 0.38; 95% CI, 0.10-0.71) strains exhibited lesser, but significant degrees of protection. These experiments show that hormone treatments that mimic pregnancy confer protection against mammary tumorigenesis in each strain irrespective of the intrinsic carcinogen susceptibility of nulliparous animals from that strain.

Morphologic changes induced by parity in the rat mammary gland. Parity-induced changes in breast cancer susceptibility have been reported to be accompanied by persistent changes in the structure of the mammary gland in humans, as well as in rats and mice (4, 6). Consistent with this, carmine-stained whole-mount analysis of nulliparous and parous mammary glands from each of the four rat strains revealed that the architecture of the parous mammary epithelial tree was more complex than that of age-matched nulliparous animals, with a higher degree of ductal side-branching (Fig. 1C). These effects were observed in each of the four strains analyzed, suggesting that changes in the structural and cellular composition of the mammary gland may occur as a consequence of parity.

Microarray analysis of parity-induced changes in the rat mammary gland. The similar morphologic changes induced by parity suggested that the hormone-induced protection against

mammary tumorigenesis that we observed in different rat strains might be accompanied by common molecular alterations. To identify these changes, we first performed oligonucleotide microarray expression profiling on pooled samples from nulliparous and parous Lewis rats. Genes whose expression changes were considered to be statistically significant using established algorithms, and whose expression changed by at least 1.2-fold as a result of parity, were selected for further analysis (18). This combined analytic approach has previously been shown to be capable of identifying differentially expressed genes with high sensitivity and specificity (18). Gene expression analysis performed in this manner identified 75 up-regulated and 148 down-regulated genes in parous compared with nulliparous mammary glands. Examination of this list of differentially expressed genes confirmed our previous findings in mice that parity results in the persistent up-regulation of *Tgfb3*, as well as differentiation and immune markers, as well as the persistent down-regulation of growth factor encoding genes, such as *Areg* and *Igf-I* (ref. 6; data not shown).

To narrow the list of candidate genes whose regulation might contribute to the protected state associated with parity, we attempted to identify parity-induced gene expression changes that were conserved across multiple rat strains. To this end, total RNA was isolated from the mammary glands of nulliparous and parous Wistar-Furth, Fischer 344, and Copenhagen rats, and analyzed on RGU34A arrays in a manner analogous to that employed for Lewis rats. This led to the identification of 68, 64, and 92 parity up-regulated genes and 132, 209, and 149 parity down-regulated genes in Wistar-Furth, Fischer 344, and Copenhagen rats, respectively.

Unsupervised hierarchical clustering performed using the expression profiles of 1,954 globally varying genes across the nulliparous and parous data sets representing the four rat strains revealed that samples clustered primarily based on strain without regard to parity status (Fig. 2A). This suggested that the principal source of global variation in gene expression across these data sets was due to genetic differences between strains rather than reproductive history. This observation suggested that determining which parity-induced gene expression changes were conserved among these highly divergent rat strains could represent a powerful approach to defining a parity-related gene expression signature correlated with hormone-induced protection against mammary tumorigenesis.

To identify parity-induced gene expression changes that were conserved across strains, we selected genes that exhibited ≥ 1.2 -fold change in at least three of the four strains analyzed. This led to the identification of 24 up-regulated (Table 1) and 46 down-regulated genes (Table 2). Based on the number of parity-induced gene expression changes observed for each strain, an overlap of this size is highly unlikely by chance (up-regulated: $P < 1 \times 10^{-6}$, FDR < 1%; down-regulated: $P < 1 \times 10^{-6}$, FDR = 4%). As such, this approach led to the identification of 70 genes whose expression is persistently altered by parity across multiple strains of rats that exhibit hormone-induced protection against mammary tumorigenesis.

A gene expression signature distinguishes parous and nulliparous rats and mice. To confirm the validity of the 70-gene parity-related expression signature derived from the above studies, we performed oligonucleotide microarray analysis on samples from nulliparous and parous Lewis rats that were generated independently from those used to derive this signature. Hierarchical clustering analysis of these independent samples using the 70-gene signature revealed that the expression profiles of these genes were sufficient to accurately distinguish parous from nulliparous Lewis rat samples in a blinded manner (Fig. 2B).

To determine whether this parity-related signature could distinguish between nulliparous and parous mammary glands from multiple strains of rats, Lewis, Wistar-Furth, Fischer 344, and Copenhagen microarray data sets were clustered in an unsupervised manner based solely on the expression of the 70 genes comprising the parity signature (Fig. 2C). In each of the four rat strains examined, the 70-gene signature was sufficient

to distinguish parous from nulliparous rats (Fig. 2C). Thus, this signature reflects parity-induced gene expression changes that are highly conserved among four genetically divergent rat strains.

Early full-term pregnancy has been reported to result in protection against mammary tumorigenesis in mice, as it does in humans and rats (13). Accordingly, we mapped the 70 genes

Figure 1. Hormone-induced protection against mammary tumorigenesis is conserved among multiple rat strains. **A**, Kaplan-Meier curves plotting the time to the formation of a first mammary tumor in placebo-treated groups for Lewis ($n = 15$), Wistar-Furth ($n = 12$), Fischer 344 ($n = 13$), and Copenhagen ($n = 12$) rats treated with methylnitrosourea (MNU) at 7 weeks of age. Significant differences in tumor incidence were identified between Lewis and Wistar-Furth ($P = 0.0003$), Lewis and Fischer 344 ($P = 0.0005$), Lewis and Copenhagen ($P = 0.0001$), Wistar-Furth and Copenhagen ($P = 0.024$), and Fischer 344 and Copenhagen ($P = 0.0001$) as determined by a log rank test. Wistar-Furth and Fischer 344 were not significantly different ($P = 0.14$). **B**, mammary tumor incidence for placebo and estradiol and progesterone-treated rats is plotted for each strain. Cohort sizes for estradiol and progesterone-treated animals were: Lewis ($n = 16$), Wistar-Furth ($n = 12$), Fischer 344 ($n = 12$), and Copenhagen ($n = 12$). Each strain exhibited significantly decreased tumor incidence in estradiol and progesterone-treated compared with placebo-treated cohorts. **C**, carmine-stained whole mounts of abdominal mammary glands from nulliparous (G0P0) and parous (G1P1) rats from each strain (original magnification, $\times 50$). Samples are representative of three animals per group.

Figure 2. A parity-related gene expression signature distinguishes between nulliparous and parous rats and mice. Unsupervised hierarchical clustering analysis. Nulliparous (N), parous (P), Lewis (LEW), Fischer 344 (F344), Wistar-Furth (WF), and Copenhagen (COP). A, nulliparous and parous samples from each strain were clustered based on the median expression values of ~1,900 genes exhibiting global variation in gene expression across the data sets. B, six independent Lewis samples (three nulliparous (N1-N3) and three parous (P1-P3)) were clustered based solely on the expression of genes in the 70-gene parity signature. C, clustering analysis based solely on the expression of the 70-gene parity signature was performed on nulliparous and parous samples from Lewis, Wistar-Furth, Fischer, and Copenhagen rats. D, the 70-gene rat parity signature was mapped to the mouse genome using Homologene, yielding 47 mouse genes. Six FVB mouse samples [three nulliparous (N1-N3) and three parous (P1-P3)] were clustered based on the expression profiles of these 47 genes.

constituting the rat parity signature to the mouse genome, and assessed their expression profiles in nulliparous and parous FVB mouse mammary samples. Of the 70 genes that were mapped, 47 were represented on Affymetrix MGU74Av2 microarrays. These 47 genes were sufficient to distinguish nulliparous from parous samples in a blinded manner (Fig. 2D). Thus, a parity-related gene

expression signature generated in the rat is able to predict reproductive history in the mouse, suggesting that the persistent molecular alterations that occur in response to parity are conserved across rodent species.

Among the 70 genes that we identified as being consistently regulated by parity, at least five categories were evident.

Table 1. Genes up-regulated in parous rats

NOTE: Genes identified as up-regulated by at least 1.2-fold in three out of four rat strains as a result of parity are reported from the highest to lowest median fold change. Gene names and symbols are reported based on the Rat Genome Database, and Gene ID according to Entrez Gene. Gene functions and categories are based on Gene Ontology.

Abbreviations: WF, Wistar-Furth; F344, Fischer 344; Cop, Copenhagen.

These included the previously identified differentiation, immune, Tgf- β , and growth factor categories (6), as well as an additional category of genes that are involved in ECM structure and function (Tables 1 and 2). We previously showed that clustering based on genes in each of the first four categories was sufficient to distinguish between nulliparous and parous rats (6). In an analogous manner, we tested whether unsupervised clustering based solely on ECM-related genes would be sufficient to differentiate between nulliparous and parous rat or mouse samples. In each case, ECM-related gene expression patterns alone were sufficient to distinguish between nulliparous and parous mammary samples from the four different rat strains (Fig. 3A), from independent mammary samples derived

from nulliparous and parous Lewis rats (Fig. 3B), and from mammary samples derived from FVB mice (Fig. 3C). This indicates that differential expression of a subset of genes involved in ECM structure and function represents a conserved feature of parity-induced changes in the rodent mammary gland.

Parity up-regulates *Tgfb3* and expression of differentiation and immune markers. Our previous analysis of parity-induced gene expression changes in FVB mice was consistent with the parity-induced up-regulation of Tgf- β 3 activity. Similarly, in the current study, we found that *Tgfb3* expression was up-regulated by parity in each of the four rat strains examined (Table 1). This finding was confirmed by QRT-PCR

NOTE: Genes identified as down-regulated by at least 1.2-fold in three out of four rat strains as a result of parity are reported from the highest to lowest median fold change. Gene names and symbols are reported based on the Rat Genome Database, and Gene ID according to Entrez Gene. Gene functions and categories are based on Gene Ontology.

Abbreviations: WF, Wistar-Furth; F344, Fischer 344; Cop, Copenhagen.

analysis of independent parous and nulliparous Lewis rat samples (Fig. 4A).

Also consistent with our prior observations, parity resulted in a persistent increase in the expression of genes involved in mammary differentiation, including the milk proteins β -casein and γ -casein, and the metal ion transporters ceruloplasmin and transferrin (ref. 6; Table 1; Fig. 4A).

As we have previously shown in the mouse, the 70-gene rat parity-related gene expression signature reflected the increased presence of immune cells in the parous mammary gland. In particular, increased expression of multiple immunoglobulin heavy and light chain genes in the parous gland suggested an increase in the population of plasma cells, whereas up-regulation of *Mmp12* and *Tnfrsf21* was consistent with increased numbers of macrophages and T cells (Table 1; Fig. 4A). Similarly, increased antibacterial and antiviral activity was suggested by the up-regulation of *Lbp*, *Lcn2*, and *Ccl5* (refs. 24–26; Table 1).

Parity results in down-regulation of amphiregulin and the growth hormone/Igf-I axis. Previous gene expression profiling of mouse mammary development revealed that parity results in a persistent decrease in the expression of several growth factor-encoding genes, including *Areg* and *Igf-I* (6). The present study confirmed that decreased expression of *Areg* and *Igf-I* are consistent features of the parous state in rats (Table 2; Fig. 4B). Additional evidence supporting parity-induced down-regulation of the growth hormone/Igf-I axis in the mammary glands of multiple rat strains was suggested by a decrease in growth hormone receptor (*Ghr*) expression (Table 2; Fig. 4B) as well as an increase in

Igfbp5 expression (Table 1; Fig. 4A), which functions to sequester local Igf-I in the ECM (27).

Parity regulates ECM gene expression. Mammary epithelial-ECM interactions play an important role in both normal mammary gland development and tumorigenesis (28). Moreover, persistent changes in the structure and function of the ECM have been shown in the mammary glands of parous rats (29). In the present study, microarray expression profiling suggested that a principal effect of parity in the rodent mammary gland is alteration of ECM gene expression. Thirteen of the 70 genes constituting the parity signature encode ECM structural components or proteins that regulate ECM formation or signaling (Tables 1 and 2). Notably, the majority of ECM-related gene expression changes induced by parity represented decreases in expression, including the ECM structural components, fibronectin 1, lumican, and collagen type I and collagen type V (Table 2). Parity-induced decreases in the expression of genes that regulate ECM formation or cellular interactions were also observed, including, *Sparc*, *Lgals1*, *Lgals7*, *Serpinh1*, *Cyr61*, and *Mcpt1* (Table 2; Fig. 4B).

To determine whether these parity-induced ECM-related gene expression changes were accompanied by differences in ECM structure, we stained histologic sections with Mason's trichrome to evaluate total collagen content. Although proximal epithelial structures seemed similar with respect to periductal trichrome staining (data not shown), a significant decrease in the extent of trichrome staining surrounding distal ducts was observed in the parous gland (Fig. 4C). These results provide further evidence that parity results in structural changes in the ECM.

Discussion

Women who have their first child early in life have a substantially reduced lifetime risk of breast cancer, an effect that is largely restricted to ER-positive tumors. Similar to humans, rats frequently develop ER-positive breast cancers and exhibit parity-induced protection against mammary tumorigenesis. In the current study, we set out to identify persistent parity-induced changes in gene expression that are conserved among multiple rat strains that exhibit hormone-induced protection against mammary tumorigenesis. We found that four genetically diverse inbred rat strains exhibit hormone-induced protection against mammary tumorigenesis and share a 70-gene pregnancy-induced expression signature. Our findings constitute the first global survey of parity-induced changes in gene expression in the rat—which represents the principal model for studying this phenomenon—as well as the first study to show conservation of parity-induced gene expression changes in multiple inbred rat strains that exhibit hormone-induced protection. Beyond suggesting that parity-induced protection is as robust and widely conserved a phenomenon in rats as it is in humans, our findings provide new insights into potential mechanisms by which early first-full term pregnancy decreases breast cancer risk.

These current studies extend our previous observations that parity results in persistently increased mammary expression of *Tgfb3* to include multiple additional strains of rats. Notably, loss of Tgf- β signaling in stromal fibroblasts promotes the growth and invasion of mammary carcinomas (30). Tgf- β may also have direct effects on mammary epithelial cells, resulting in the inhibition of mammary tumorigenesis (31). The sum of these effects is predicted to decrease the susceptibility of the parous gland to oncogenic transformation.

One of the most consistent and robust parity-induced changes in gene expression that we have observed in the rodent mammary gland is down-regulation of the epidermal growth factor receptor ligand, *Areg*. AREG is overexpressed in a high proportion of human breast cancers and correlates with large tumor size and nodal involvement (32). Studies in genetically engineered mice and mammary epithelial cell lines suggest an important role

for AREG in driving mammary epithelial proliferation, whereas recent evidence indicates that this growth factor may alter the ECM by the regulation of protease expression and secretion, including matrix metalloproteinase-2, matrix metalloproteinase-9, urokinase-type plasminogen activator, and plasminogen activator inhibitor-1 (33). Thus, parity-mediated down-regulation of *Areg* may not only inhibit epithelial proliferation, but may also hinder the invasive abilities of transformed cells in the mammary gland.

In addition to the down-regulation of *Areg*, we have confirmed that parity also results in the persistent down-regulation of *Igf-I*. Notably, a strong positive correlation exists between serum IGF-I levels and breast cancer risk in premenopausal women (34). Local and serum levels of IGF-I are regulated by growth hormone through its interaction with growth hormone receptor (35). Additional findings indicate that parity results in a persistent decrease in circulating growth hormone levels in rats (7); moreover, treatment of parous rats with Igf-I results in an increase in carcinogen-induced mammary tumorigenesis to levels similar to those observed in nulliparous controls (36). Consistent with this, spontaneous dwarf rats, which lack functional growth hormone, are highly resistant to carcinogen-induced mammary tumorigenesis (37).

Additional evidence for down-regulation of the growth hormone/Igf-I axis within the parous mammary gland was suggested in the present study by increases in *Igfbp5* expression and decreases in *Ghr* expression. As such, our findings suggest that—in addition to reducing circulating levels of growth hormone—parity may modulate local expression and activity of Igf-I within the mammary gland. Whereas Igf-I acts directly on mammary epithelial cells to promote proliferation and inhibit apoptosis (38), Igf-I in the mammary gland is likely produced in the stromal compartment in response to Ghr signaling (39). Local regulation of Igf-I activity also occurs through interactions with Igf-I binding proteins, such as *Igfbp5*, which binds and sequesters Igf-I in the ECM (40). As such, parity-induced down-regulation of Ghr and Igf-I expression in the mammary gland, coupled with up-regulation of *Igfbp5* expression, would be predicted to result in decreased Igf-I activity. This represents a

Figure 3. ECM gene expression distinguishes between nulliparous and parous rats and mice. Unsupervised hierarchical clustering analysis. A, a subset of parity-regulated genes involved in ECM structure and regulation was used to cluster nulliparous and parous mammary samples from Lewis (LEW), Wistar-Furth (WF), Fischer (F344), and Copenhagen (COP) rats. B, six independent Lewis samples [three nulliparous (N1-N3) and three parous (P1-P3) samples] were clustered based on the expression of ECM-related genes. C, six FVB mouse samples [three nulliparous (N1-N3) and three parous (P1-P3)] were clustered based on the expression of ECM-related genes identified in the rat parity signature that were mapped to the mouse genome.

Figure 4. Confirmation of gene expression changes. *A* and *B*, TaqMan QRT-PCR was performed on cDNAs generated from 21 nulliparous and 21 parous Lewis rat mammary samples. Each reaction was performed in duplicate. Expression values for each gene were normalized to *B2m*. *A*, relative expression of parity up-regulated genes. White columns, mean expression in nulliparous samples normalized to 1.0 for each gene; gray columns, mean expression of each gene in parous relative to nulliparous samples; bars, $\pm$ SE. *B*, relative expression of parity down-regulated genes. White columns, mean expression of each gene in nulliparous relative to parous samples; gray columns, mean expression in parous samples normalized to 1.0 for each gene; bars, $\pm$ SE. *P* values were generated using a one-tailed, unpaired Student's *t* test. *C*, Mason's trichrome staining. Abdominal mammary glands from nulliparous and parous Lewis rats were stained with Mason's trichrome to assess total collagen present in the ECM surrounding epithelial structures. Images are representative of distal structures in the mammary glands of three nulliparous and three parous Lewis rats (original magnification, $\times 200$).

plausible mechanism by which parity may confer protection against breast cancer.

The functional unit of the mammary gland consists of a complex stroma that surrounds the epithelial compartment. Stromal-epithelial interactions play a prominent role, not only in mammary development, but also in tumorigenesis (28). Fibroblasts represent the most prominent cell type of the periductal stroma and, in addition to secreting growth factors that activate epithelial receptors, they are the primary synthesizers of ECM constituents such as fibronectin, collagen, and proteoglycans. Accumulating evidence indicates that stromal constituents, including fibroblasts and ECM structural components, could have differential effects on epithelial cells depending on the

source of the tissue from which they are isolated (41). Consistent with this, Schedin et al. have shown that the ability of mammary epithelial cells to form ductal structures in culture is markedly influenced by the developmental context of the ECM in which they are cultured (29). Further support for the role of ECM regulation in parity-induced protection against breast cancer comes from our observation that parous mammary glands exhibit decreased trichrome staining as well as persistent down-regulation of ECM structural and regulatory genes. Because cross-talk between epithelial and stroma cells occurs through local growth factors and their receptors (42), it is possible that parity-induced down-regulation of *Areg* and *Igf-I* in combination with up-regulation of *Tgfb3* may alter stromal-epithelial interactions in such a way as to decrease susceptibility to mammary carcinogenesis.

Finally, it is interesting to speculate that parity-induced changes in the ECM may be related to measures of breast cancer risk associated with mammographic breast density. Increased mammographic density has been consistently shown to correlate with high breast cancer risk (43). Mammographic density has also been reported to be negatively correlated with parity (44). Although breast density was initially believed to reflect the epithelial content of the breast, current evidence suggests that ECM composition—in particular collagen and proteoglycans such as lumican—may be the primary determinant of mammographic density (44, 45). Intriguingly, recent studies have implicated the ratio of serum IGF-I to IGFBP3 as a major determinant of mammographic density (46). Consistent with this, Guo et al. found increased IGF-I tissue staining in samples from women with increased breast density (45). Our findings support the hypothesis that parity decreases Igf-I expression and activity and diminishes the expression of selected ECM structural components. Together, these changes may lead to decreases in both mammographic breast density and breast cancer risk. Validation of this hypothesis will require confirmation that parity alters local IGF-I levels and mammographic breast density in women, and that modulation of Igf-I in rodent models will alter breast density as well as pregnancy-induced protection against breast cancer.

In summary, the results presented in this study extend previous observations that parity results in local changes in growth factor gene expression in the mammary gland. We hypothesize that the evolutionarily conserved parity-induced alterations in gene expression identified in this study result in the modification of the extracellular environment and changes in stromal-epithelial interactions. We hypothesize that the ultimate effect of these changes is to create a tumor suppressive state, thereby providing a potential mechanism to explain parity-induced protection against mammary tumorigenesis. Whether analogous parity-induced changes occur in the human breast remains an important yet unresolved question.

Introduction Increased mammographic density is a strong risk factor for breast cancer. The reasons for this are not clear; two obvious possibilities are increased epithelial cell proliferation in mammographically dense areas and increased breast epithelium in women with mammographically dense breasts. We addressed this question by studying the number of epithelial cells in terminal duct lobular units (TDLUs) and in ducts, and their proliferation rates, as they related to local breast densities defined histologically within individual women.

Method We studied deep breast tissue away from subcutaneous fat obtained from 12 healthy women undergoing reduction mammoplasty. A slide from each specimen was stained with the cell-proliferation marker MIB1. Each slide was divided into (sets of) areas of low, medium and high density of connective tissue (CT; highly correlated with mammographic densities). Within each of the areas, the numbers of epithelial cells in TDLUs and ducts, and the numbers MIB1 positive, were counted.

Results The relative concentration (RC) of epithelial cells in high compared with low CT density areas was 12.3 (95% confidence interval (CI) 10.9 to 13.8) in TDLUs and 34.1 (95% CI 26.9 to 43.2) in ducts. There was a much smaller difference between medium and low CT density areas: RC = 1.4 (95% CI 1.2 to 1.6) in TDLUs and 1.9 (95% CI 1.5 to 2.3) in ducts. The relative mitotic rate (RMR; MIB1 positive) of epithelial cells in high compared with low CT density areas was 0.59 (95% CI 0.53 to 0.66) in TDLUs and 0.65 (95% CI 0.53 to 0.79) in ducts; the figures for the comparison of medium with low CT density areas were 0.58 (95% CI 0.48 to 0.70) in TDLUs and 0.66 (95% CI 0.44 to 0.97) in ducts.

Conclusion Breast epithelial cells are overwhelmingly concentrated in high CT density areas. Their proliferation rate in areas of high and medium CT density is lower than that in low CT density areas. The increased breast cancer risk associated with increased mammographic densities may simply be a reflection of increased epithelial cell numbers. Why epithelium is concentrated in high CT density areas remains to be explained.

Introduction

On a mammogram, fat appears radiolucent or dark, whereas stromal and epithelial tissue appears radio-dense or white. The amount of mammographic density is a strong independent predictor of breast cancer risk [1,2]. The biological basis for this increased risk is poorly understood. A critical question is

whether densities are directly related to risk or are simply a marker of risk. We addressed this question recently by studying the location of small ductal carcinoma *in situ* (DCIS) lesions as revealed by microcalcifications, and showed that such DCIS occurs overwhelmingly in the mammographically dense areas of the breast [3]. Most DCIS lesions in our study

a_H , a_L , a_M = the areas of the slide classified as being of high, low and medium CT density (in μm^2); CI = confidence interval; CT = connective tissue; DAB = 3,3'-diaminobenzidine tetrahydrochloride; DCIS = ductal carcinoma *in situ*; n_H , n_L , n_M = the numbers of epithelial cells staining positive for MIB1 within high, low and medium CT density areas; RC = relative concentration; RMR = relative mitotic rate; TDLU = terminal duct lobular unit; t_H , t_L , t_M = the numbers of epithelial cells within high, low and medium CT density areas;

Table 1**Relation between relative concentration of epithelial cells and connective tissue density**

CT density	RC	95% CI	<i>p</i>
TDLUs			
Low	1.0		
Medium	1.4	1.2–1.6	<0.001
High	12.3	10.9–13.8	<0.001

Low	1.0		
Medium	1.9	1.5–2.3	<0.001
High	34.1	26.9–43.2	<0.001

CI, confidence interval; CT, connective tissue; RC, relative concentration (per unit area); TDLUs, terminal duct lobular units.

occurred in the lateral-superior quadrant, as has been found in previous studies [4], and 'correlated strongly with the average percentage density in the different mammographic quadrants' [3]. Pre-DCIS mammograms that were taken on average about two years previously showed that the areas subsequently exhibiting DCIS were clearly dense at the time of the earlier mammogram, and this suggests that this relationship was not brought about by the presence of the DCIS. The reasons for these findings are not clear; two obvious possibilities are increased epithelial cell proliferation in mammographically dense areas of the breast and increased breast epithelium in women with mammographically dense breasts. Two groups have investigated the relationship between the amount of mammographic density of a woman and the amount of her breast epithelial tissue [5,6]. Alowami and colleagues [5] used tissue obtained from biopsies investigating breast lesions that were subsequently diagnosed as benign or pre-invasive breast disease; they studied tissue 'distant from the diagnostic lesion' without reference to its location as regards mammographic density (that is, 'random' tissue). They found that the median density of duct lobular units was 28% higher in breasts whose overall mammographic density was 50% or more ($n = 27$) than in breasts whose overall mammographic density was less than 25% ($n = 35$); this result was not statistically significant and the result was described as showing 'no difference in the density of epithelial components' [5]. Li and colleagues [6] also found in their much larger study ($n = 236$) of 'random' breast tissue collected from normal women by Bartow and colleagues [7] in their autopsy study of accidental deaths in New Mexico that women with high mammographic density had greater amounts of epithelial tissue (as measured by area of epithelial nuclear staining) and the result was highly statistically significant. Breast epithelial proliferation rates as they relate to mammographic densities in healthy women have not been well studied [8]. We have addressed these questions by studying the number of epithelial cells in terminal duct lobular units (TDLUs) and in breast ducts, and their respective prolif-

eration rates as they relate to local histological breast densities within individual women.

Materials and methods

We retrospectively identified 15 consecutive healthy women who had undergone a reduction mammoplasty performed by one of us (SD) at the University of Southern California medical facilities. The study protocol was approved by the Institutional Review Board of the University of Southern California School of Medicine.

For each participant we obtained the formalin-fixed paraffin-embedded block of tissue that had been routinely processed and saved from her surgery. A single slide was cut from each block and stained with the proliferation marker MIB1 (BioGenex Laboratories, San Ramon, CA, USA). The slides were prepared in accordance with our previously published protocol [9]; the chromogen used was 3,3'-diaminobenzidine tetrahydrochloride (DAB). On microscopic examination one of the slides contained skin and two other slides showed areas of disintegration; all three were deemed unsuitable for study.

Each of the remaining 12 slides was divided into (sets of) areas of low, medium and high density of connective tissue (CT) (highly correlated with densities as defined by mammographic criteria [10]); see Figure 1. The total size of each of the three areas (in μm^2), and within each of the three areas the numbers of epithelial cells in TDLUs and ducts and the numbers that were MIB1 positive, were counted with the help of an automated microscope system that digitized the images and permitted the outlining of relevant areas on a high-resolution computer screen (ACIS II; Clariant, Inc., San Juan Capistrano, CA, USA). The total numbers of epithelial cells in different outlined areas within the CT density-defined areas was then automatically counted by the ACIS II nuclear counting software program, which is based on color identification. Hematoxylin was used to counterstain the MIB1-negative nuclei blue, and the DAB chromogen marked the MIB1-positive nuclei brown.

Figure 1

Example of areas of low, medium (upper right) and high (lower center) CT density.

The software calculated the numbers of MIB1-negative and MIB1-positive cells on the basis of these color differences.

Statistical analysis

For each slide, and separately for TDLU and ductal cells, three sets of values were obtained: first, the areas of the slide classified as being of low, medium or high CT density (a_L , a_M and a_H in μm^2); second, the numbers of epithelial cells within these areas (t_L , t_M and t_H); and third, the numbers of these epithelial cells staining positive for MIB1 (n_L , n_M and n_H). On the null hypothesis of no association between the t 's and the a 's – that is, no association between the numbers of epithelial cells and the CT density of the local tissue – the expected value of the t 's is simply proportional to the related a 's, so that, for example, the expected value of t_H is $(t_L + t_M + t_H) \times a_H / (a_L + a_M + a_H)$. Similarly, on the null hypothesis of no association between MIB1 positivity as a proportion of epithelial cells and the CT density of the local tissue, the expected value of the n 's is simply proportional to the related t 's, so that, for example, the expected value of n_H is $(n_L + n_M + n_H) \times t_H / (t_L + t_M + t_H)$. We analyzed these data with standard statistical software as implemented in the STATA statistical software package (procedure cs; Stata Corporation, Austin, TX, USA); the ratios of epithelial concentration (cells per unit area) and the ratios of proportions of epithelial cells staining positive for MIB1 are the measures of effect. All statistical significance levels (p values) quoted are two-sided.

Results

The 12 subjects included in the analysis were aged 18 to 60 years with a median age of 33 years; only one subject was aged 50 years or older.

Areas of the slides of low CT density comprised on average 44% of the total of areas of low plus medium plus high CT density ($a_L / (a_L + a_M + a_H)$), whereas areas of high CT density comprised on average 35% of the total area ($a_H / (a_L + a_M + a_H)$).

Table 1 shows the summary relative concentrations (RCs; ratios of cells per unit area) of epithelial cells in the three areas defined by CT density separately for TDLU cells and for ductal cells. The concentration of TDLU epithelial cells is slightly greater in the areas of medium CT density than in the areas of low CT density (RC = 1.4, 95% confidence interval (CI) 1.2 to 1.6; $p < 0.001$) but is much greater in the areas of high CT density (RC = 12.3, 95% CI 10.8 to 13.8; $p < 0.001$). The TDLU results for the individual slides (women) comparing areas of high CT density with areas of low CT density are shown in Figure 2. Although the results from individual subjects do differ somewhat, the RCs were not correlated with age (the only variable available on these women) and the summary RC seems to be a fair representation of the overall results. The results for ducts were similar.

Table 2 shows the summary relative mitotic rates (RMRs) of epithelial cells staining MIB1 positive in the three areas defined by CT density separately for TDLU cells and for ductal

Table 2**Relation between relative mitotic rate (MIB1 positive) of epithelial cells and connective tissue density**

CT density	RMR	95% CI	<i>p</i>
TDLUs			
Low	1.00		
Medium	0.58	0.48–0.70	<0.001
High	0.59	0.53–0.66	<0.001
Ducts			
Low	1.00		
Medium	0.66	0.44–0.97	0.035
High	0.65	0.53–0.79	<0.001

CI, confidence interval; CT, connective tissue; RMR, relative mitotic rate; TDLUs, terminal duct lobular units.

Figure 2

RCs (with 95% CIs) of TDLU epithelial cells in high and low CT areas.

cells. The proportion of TDLU epithelial cells staining MIB1 positive is statistically significantly less ($RMR \approx 0.6$) both in the areas of medium CT density ($p < 0.001$) and in the areas of high CT density ($p < 0.001$) than in the areas of low CT density. The median MIB1-positive proportion was about 4%. Almost all the women in this study were premenopausal on the basis of their age; this figure is close to the Ki67 figure of 4.5% given for healthy premenopausal women in the study of Hargreaves and colleagues [11]. The TDLU results for the individual slides (women) comparing areas of high CT density with areas of low CT density are shown in Figure 3. Again, although the results from individual subjects do differ somewhat, the RMRs were not correlated with age (the only variable available on these women) and the summary RMR seems to be a fair representation of the overall results. The results for ducts were again similar. There was no difference in the proliferation rates of epithelial cells in TDLUs and ducts within the same CT den-

sity area of individual women ($RMR = 1.01$, 95% CI 0.98 to 1.04; $p = 0.42$).

More details of the results are provided in the Additional file.

Discussion

Mammographic density is a very strong risk factor for breast cancer. The two groups of investigators [5,6] that studied random biopsies (single slides) from women with different mammographic densities found that the extent of mammographic densities was most strongly correlated with the amount of collagen on the slide. A weaker correlation was found with the amount of epithelial tissue. The findings reported here suggest that the relation between the extent of mammographic density and the amount of epithelial tissue is directly related to the increased concentration of collagen (the main component of

'connective tissue' as shown by collagen staining; see Figure 1) in women with high mammographic densities, because breast epithelium is overwhelmingly confined to areas of high CT density. In the earlier studies of random biopsies [5,6] the weaker relationship between mammographic density and epithelium concentration than between mammographic density and collagen concentration could be simply due to the much greater statistical variability of epithelial tissue in a random slide than one would see for collagen, which occupies a much greater extent of the slide. These results suggest that the increasing breast cancer risk associated with increasing mammographic density might be simply a reflection of more breast epithelial tissue.

We found that the proliferation rate of epithelial cells in areas of high CT density was much lower than in areas of low CT density, arguing against the possibility that dense stroma has a growth factor role in the increased breast cancer risk of women with mammographically dense breasts. In the study of Stomper and colleagues [8], comparison was made between single biopsies of either fat or dense areas in different women; they found no difference in the proliferation rates in the dense and fat areas. Further work is warranted but there is clearly no evidence that areas of high CT density are associated with increased proliferation.

Our results were obtained by conducting a comprehensive count of all the cells in each slide per subject (instead of counting a selected region) and allowed the comparison of proliferation rates in areas of differing CT density within an individual. This permitted us to control completely automatically for factors such as age, menopausal status, or time in the menstrual cycle in the analysis. This gave us great statistical power so that highly statistically significant results could be obtained even with small numbers of subjects.

This study used tissue obtained at reduction mammoplasty performed on women with large breasts. We do not believe that this affects the validity of our findings because the tissue samples were taken deep in the breast away from the subcutaneous fat, but this requires confirmation in future studies. Further studies are also needed relating the CT densities to such risk factors as parity and to understand the biology of the relationship between CT densities and breast epithelium.

Conclusion

The basis of the strong relationship between mammographic density and breast cancer risk may be simply that mammographically dense breasts contain more breast epithelial tissue. Why breast epithelial tissue should be associated with CT densities is not known. Does breast epithelium induce densities? Alternatively, can breast epithelium effectively survive only in areas of densities? Understanding the nature of the interaction between dense CT stroma and epithelial tissue should be a major focus of breast cancer research.

Competing interests

The authors declare that they have no competing interests.

Authors' contributions

DH, AHW, CLP and MCP participated in the design of the study. DH supervised the preparation of the slides and analyzed the slides with the ACIS II system. SD performed all the reduction mammoplasties that provided the tissues used in this analysis and consulted on the tissue obtained from reduction mammoplasties. SB consulted on the interpretation of the results and provided insight into the relationship between mammographic densities and tissue characteristics. CLP coordinated the study. MCP supervised the statistical analysis which was carried out by PW. AHW, CLP and MCP conceived of the study. MCP, DH and AHW drafted the manuscript; all authors read and approved the final manuscript.
