13. SUPPLEMENTARY NOTES					
14. ABSTRACT The goal is to combine Treg inactivation with Nau DNA vaccination to inhibit tumor growth in BALB NeuT mice without inducing excessive autoimmunity such as experimental autoimmune thyroiditis (EAT). We established a test system to access in the same animal the effect of tumor regression and mouse thyroglobulin immunization and observed a synergy between anti-neu and anti-mTg immunity. We tested the vaccination efficacy of pE2TM (encoding human Her-2 ECD and TM domains) combined with pGITRL. Mice co-activated with these two plasmid DNA showed comparable anti-neu and anti-tumor immunity as those receiving pneu TM and pGM-CSF. The co-stimulatory activity of GITRL/CITR interaction may account for this level of activity, but stimulation of GITR may not affect Treg activity as demonstrated in several recent reports. We will use the residual resources to test a new strategy to enhance anti-tumor immunity without excessive, systemic modulation of Treg, i.e. expression of foreign antigens in the tumor by intratumoral DNA electroporation. We showed the expression of luciferase in the tumor for 17 days or longer. The treatment schedule will be optimized to achieve high level, sustained expression and tumor growth will be monitored.

INTRODUCTION

The goals of this project are:

Task 1 Test the hypothesis that anti-tumor but not autoimmunity will be induced by DNA vaccine encoding pNeuTM and GITRL

- (A) Month 1-24 Construction and biochemical testing of DNA plasmids encoding GITRL or GITRL-ecd
- (B) Month 1-24 In vitro and in vivo testing of pGITRL or pGITRL-ecd in association with pNeuTM vaccination.
 - I. Establish the read-outs for NeuTM DNA vaccination, including antibody production and T cell response measured by ELISPOT.
 - II. Establish the read-outs for autoimmune response, including antibody and T cell reactivity to mouse thyroglobulin (mTg) and inflammatory infiltration in the thyroid.
 - III. Measure anti-neu and anti-mTg reactivity in mice immunized with DNA encoding NeuTM and GITRL.

BODY

Objective 1A Construction and biochemical testing of DNA plasmids encoding NeuTM/GITRL

As described in the last progress report, full length mouse GITRL and the extracellular domain of GITRL (GITRL-ecd) have been cloned into pVIVO2 as pGITRL and pGITRL-ecd. The expression of the recombinant proteins was verified by transient transfection and flow cytometry.

Objective 1B-I Establish the read-outs for NeuTM DNA vaccination, including antibody production and T cell response measured by ELISPOT.

Objective 1B-II Establish the read-outs for autoimmune response, including antibody and T cell reactivity to mouse thyroglobulin and inflammatory infiltration in the thyroid

Results from Objectives 1B-I and II have been reported in “Wei,WZ., Jacob, J.B., Zielinski, J.F., Flynn, J.C., Shim, K.D., Alsharabi, G., Giraldo, A.A., Kong, Y.M. Concurrent induction of anti-tumor immunity and autoimmune thyroiditis in CD4+CD25+ regulatory T cell depleted mice, Cancer Research, 65:8471-8478, 2005.”

In order to monitor in the same animal both anti-neu immunity which mediates tumor rejection and anti-mTg immunity which mediates experimental autoimmune thyroiditis (EAT), we established a test system for inducing, concurrently, tumor regression and EAT. BALB/c mice were inoculated s.c with neu positive TUBO cells and subjected to anti-CD25 mAb treatment on days 1 and 3 after tumor inoculation to remove regulatory T cells. We described in the last progress report that this treatment could result in TUBO tumor regression and anti-neu immunity. Starting on day 10, the same mice also received 40 µg of mTg for 4 consecutive days followed by 3 day rest. MTg

injection was repeated for 4 wks without adjuvant (Figure 1A). At 21 days following the final mTg injection, sera, splenocytes, and thyroids were collected. Antibodies and T cell responses to neu and mTg were analyzed as described in the last progress report. Inflammatory infiltration and destruction of the thyroids were assessed in histological sections and recorded as % thyroid infiltration. All mice receiving TUBO cells without Treg depletion developed tumors by wk 3. None of the tumors regressed (Figure 1B). In mice depleted of Treg, tumors started to regress when they reached $\sim 100 \text{ mm}^3$ and three of four tumors regressed completely. In all 7 mice which received anti-CD25 mAb and mTg, TUBO tumors completely regressed. Anti-neu Abs were measured at wk 10 or at time of sacrifice. Anti-neu IgG in untreated, tumor bearing mice averaged $6 \pm 2.4 \text{ } \mu\text{g/ml}$ (Fig. 1C). With Treg depletion and tumor regression, average antibody level increased to $28.7 \pm 26 \text{ } \mu\text{g/ml}$. Interestingly, concurrent exposure to mTg in mice undergoing TUBO tumor regression resulted in an average of $78.6 \pm 56 \text{ } \mu\text{g/ml}$ of anti-neu IgG, demonstrating an upregulation of anti-neu response when mice were responding to both neu and mTg ($P=0.05$).

Neu-specific T cell response was measured by ELISPOT following in vitro stimulation with the engineered antigen presenting cells 3T3/NKB which expressed neu, K^d and B7.1. Low level of IFN- γ producing T cells were detected following tumor regression. neu reactive T cells increased from $<10/10^6$ splenocytes in mice undergoing TUBO regression to $\sim 45/10^6$ in those also immunized with mTg (Figure 1D). Depletion of regulatory T cells resulted in tumor regression with anti-neu immunity which is further enhanced when anti-mTg reactivity is also triggered with this regimen.

In Treg depleted mice which received mTg immunization after TUBO cell inoculation, serum antibody to mTg was induced (appendix). To measure T cell responses, spleen cells were cultured with mTg for 3 days before they were transferred to ELISPOT plates pre-coated with anti-IFN- γ (Fig. 1E). Using this two-step ELISPOT assay, 612 ± 31 IFN- γ producing cells per 10^6 spleen cells were detected in Treg depleted mice which received TUBO and mTg. Histological analysis of the thyroid glands revealed low level of mononuclear infiltration, consisting of mostly T lymphocytes and macrophages as we previously reported, in 3 of 7 mice (43%) (Fig. 1F). Therefore, depletion of Treg enhanced autoreactivity to mTg with further elevation after tumor regression, leading to thyroid infiltration.

Objective 1B-III Measure anti-neu and anti-mTg reactivity in mice immunized with DNA encoding NeuTM and GITRL

To determine whether co-vaccination with pGITRL or pGITRL-ecd increases immune response to Her-2/neu, normal mice were electro-vaccinated twice, 2 wks apart, with pE2TM encoding the extracellular and transmembrane domains of human Her-2 and either pGITRL or pGITRL-ecd. Following the second immunization, antibody and T cell responses were analyzed. Mice vaccinated with pE2TM and either pGITRL or pGITRL-ecd produced high levels of anti-Her-2 antibodies at 174 ± 33 and $168 \pm 65 \text{ } \mu\text{g/ml}$, respectively, (Figure 2A). In T cell response, mice vaccinated with pE2TM and pGITRL showed 89 ± 32 IFN- γ -producing T cells/ 10^6 spleen cells when stimulated in vitro with Her-2 expressing antigen presenting cells (Figure 2B). When compared with mice vaccinated with pE2TM and pGM-CSF, the anti-Her-2 antibody and T cell responses were comparable whether mice received pGM-CSF or pGITRL (Figure 3A/B). The effect on tumor growth was tested in human Her-2 transgenic mice produced in our lab, tumor growth was comparable whether mice received pE2TM/pGM-CSF or pE2TM/pGITRL (Figure 3C).

Therefore, increase in anti-neu or anti-tumor immunity is comparable whether pGM-CSF or pGITRL was co-injected. These results are consistent with recent reports showing that stimulation of GTR triggers co-stimulatory signals in both effector and regulatory T cells, but the activity of Treg may not be reduced (1-4). Alternative measures may be required to amplify anti-tumor immunity without systemic Treg depletion which would trigger autoimmunity.

Figure 1. Effect of Treg depletion and mTg immunization on anti-neu and anti-mTg immunity in TUBO cell inoculated mice. (A) BALB/c mice were inoculated with TUBO cells on day 0 and treated with anti-CD25 mAb on days 1 and 3. Starting on day 10 and continuing for 4 wk, mice were injected with 40 μg of mTg daily for 4 days followed by a 3 day rest before the next cycle of injections. (B) Tumor growth in Treg depleted mice, with (▲) or without (●) mTg treatment. Mice in the control group received PBS (□). (C) Anti-neu antibody was measured by flow cytometry, and (D) Anti-neu IFN-γ producing cells were analyzed by ELISPOT assay. There were four mice in each group except 7 mice in the group receiving TUBO cells, anti-CD25 and mTg. (E) Anti-mTg IFN-g producing cells were analyzed by ELISPOT assay. (F) thyroid infiltration was monitored with histological sections.

Figure 2. Anti-Her-2 response induced by pE2TM and either pGITRL or pGITRL-ecd. Normal mice were electrovaccinated 2 times with pE2TM and either pGITRL or pGITRL-ecd, as adjuvant. (A) Anti-Her-2 antibody response was measured by flow cytometry. (B) Her-2-reactive IFN- γ -secreting cells were analyzed 2 wk following the final immunization by ELISPOT. * $p < 0.005$ when compared with mice Recevubg oGITRL or pGITRLecd, using student's t test.

Figure 3. Anti-Her-2 response induced by pE2TM and either pGM-CSF or pGITRL. (A) Normal mice were electrovaccinated 2 times with pE2TM and either pGM-CSF or pGITRL. Anti-Her-2 antibody response was measured by flow cytometry. (B) Her-2-reactive IFN- γ -secreting cells were analyzed 2 wk following the final immunization by ELISPOT. (C) Her-2 transgenic mice were electrovaccinated with pE2TM and either pGM-CSF or pGITRL three times before they were challenged s.c. with 2×10^5 EL4-E2 cells. The results are recorded as % tumor free mice.

Although very limited resources are left for this project, we will endeavor to test a new strategy to amplify anti-tumor immunity with minimal systemic, non-specific immune modulation by expressing exogenous antigens in the tumor itself. Our rationale is based on the following observation: after a single cycle of Treg depletion in BALB/c mice, TUBO tumors grew to ~ 10 mm in diameter, then regressed, indicating that a growing tumor of significant size and expressing a foreign Ag, neu, was fully capable of inducing a strong primary immune response to the tumor associated neu to destroy a bulky tumor. Following this line of reasoning, it will be logical to express a foreign antigen on tumor cells *in situ* to trigger immune response to the foreign antigen and amplify immune priming to the tumor associated antigens (TAA) expressed by the tumor cells. Although only a portion of the tumor cells will be transfected *in situ*, they may be sufficient to amplify the immune reactivity to TAA, when combined with systemic vaccination to bring about a robust tumor immunity. This may be particularly important when attempting to control tumor metastasis because the primary tumor can be surgically removed after it serves the function of immune priming and the immunity induced by the foreignized primary tumor may inhibit metastasis.

To this end, we have initiated the testing of expressing exogenous genes by intratumoral DNA electroporation. BALB/c mice bearing s.c. mammary tumors were injected intra-tumorally with 100 μ g of pGL3 (Promega), encoding luciferase, followed by electroporation using a 2-needle electrode. The treatment was repeated two days later and expression of luciferase was monitored on days 10 and 17 by injecting the substrate D-luciferin and imaging the luminescence with the Kodak In Vivo imaging station (Figure 4). Luciferase activity was detected on both day 10 and 17. Therefore, it is feasible to express an exogenous gene in the tumor by DNA electroporation for 17 days or longer. We will optimize the treatment schedule for expressing luciferase gene, monitor tumor growth and measure anti-neu immunity.

Figure 4 Intratumoral expression of luciferase gene. BALB/c mice bearing s.c. implanted mammary tumor received intratumoral injection of 100 μ g luciferase DNA (pGL3, Promega) in 50 μ l of PBS, followed immediately by square wave electroporation at the injection site using a BTX830 (BTX Harvard Apparatus, Holliston, MA). A 2-needle electrode was used to deliver 8 pulses at 100V for 20 msec. Intratumoral DNA injection was repeated on d.3. On days 10 and 17, mice were anesthetized with ketamine/xylazine and 100 μ l of 4 mg/ml luciferase substrate, D-luciferin (BD Biosciences), was injected intratumorally. Luminescence was detected by Kodak In Vivo Imaging Station with 10 min exposure.

KEY RESEARCH ACCOMPLISHMENTS

1. Establish the test system and read-outs for the concurrent induction of tumor regression and EAT
2. Determine the immune response to the co-vaccination with pE2TM and pGITRL or pGITRL-ecd.

REPORTABLE OUTCOMES

Wei, WZ., Jacob, J.B., Zielinski, J.F., Flynn, J.C., Shim, K.D., Alsharabi, G., Giraldo, A.A., Kong, Y.M. Concurrent induction of anti-tumor immunity and autoimmune thyroiditis in CD4⁺CD25⁺ regulatory T cell depleted mice, *Cancer Research*, 65:8471-8478, 2005.

CONCLUSIONS

We have established a test system to induce, concurrently, tumor regression and EAT after Treg depletion. A synergy between anti-neu and anti-mTg immunity was observed in BALB/c mice experiencing tumor regression and mouse thyroglobulin immunization at the same time. Co-vaccination with pE2TM and pGITRL induced comparable anti-neu immunity as did pneuTM and pGM-CSF. These results are consistent with the co-stimulatory activity of GITRL, but there may not be a direct effect on Treg activity as described in several recent reports. To enhance anti-tumor immunity without excessive systemic modulation of Treg, we are testing the expression of foreign antigens in the tumor by intratumoral DNA electroporation.

Abstract

When CD4⁺CD25⁺ regulatory T cells are depleted or inactivated for the purpose of enhancing antitumor immunity, the risk of autoimmune disease may be significantly elevated because these regulatory T cells control both antitumor immunity and autoimmunity. To evaluate the relative benefit and risk of modulating CD4⁺CD25⁺ regulatory T cells, we established a new test system to measure simultaneously the immune reactivity to a tumor-associated antigen, neu, and an unrelated self-antigen, thyroglobulin. BALB/c mice were inoculated with TUBO cells expressing an activated rat neu and treated with anti-CD25 monoclonal antibody to deplete CD25⁺ cells. The tumors grew, then regressed, and neu-specific antibodies and IFN- γ -secreting T cells were induced. The same mice were also exposed to mouse thyroglobulin by chronic i.v. injections. These mice produced thyroglobulin-specific antibody and IFN- γ -secreting T cells with inflammatory infiltration in the thyroids of some mice. The immune responses to neu or thyroglobulin were greater in mice undergoing TUBO tumor rejection and thyroglobulin injection than in those experiencing either alone. To the best of our knowledge, this is the first experimental system to assess the concurrent induction and possible synergy of immune reactivity to defined tumor and self-antigens following reduction of regulatory T cells. These results illustrate the importance of monitoring immune reactivity to self-antigens during cancer immunotherapy that involves immunomodulating agents, and the pressing need for novel strategies to induce antitumor immunity while minimizing autoimmunity. (Cancer Res 2005; 65(18): 8471-8)

Introduction

CD4⁺CD25⁺ regulatory T (Treg)–like cells have been described in patients with different types of cancers (1–3). We and others have shown that removal of CD4⁺CD25⁺ cells from tumor-bearing mice resulted in the regression of certain mouse tumors (4, 5), suggesting that Treg may negatively regulate antitumor immunity and depletion of Treg may be a powerful way to control tumor growth. In addition to CD4 and CD25, Treg express CTLA-4 (6), a glucocorticoid-induced tumor necrosis factor receptor family member (TNFRSF18; ref. 7), CD80 (8), CD62L, membrane-bound

transforming growth factor β (9), as well as the transcription factor scurf, encoded by *foxp3* (10). They do not proliferate when stimulated *in vitro* via CD3. Treg suppressive activity is triggered through the T-cell receptor by specific antigen and can inhibit T-cell activation in an antigen-specific (11) or nonspecific (12, 13) manner through a contact-dependent mechanism.

In this study, rat neu is used as the model tumor-associated antigen. Overexpression of erbB-2 or Her-2/neu in a number of common cancers, such as breast, ovarian, colorectal, prostate, and pancreatic adenocarcinoma (14–17), is correlated with a more aggressive course of disease (18, 19), rendering Her-2 an important target of cancer therapy. The therapeutic effect of anti-Her-2 monoclonal antibody (mAb), Herceptin, in stage IV breast cancer patients further distinguishes this molecule as an exceptional target of immunotherapy and vaccination. Because of self-tolerance, it is difficult to elicit strong immune responses to Her-2, as we showed in Her-2 transgenic mice (20), and Treg depletion may be a plausible strategy to amplify anti-Her-2/neu immunity.

Depletion of CD4⁺CD25⁺ cells combined with CTLA-4 blockade has been shown to enhance the efficacy of B16 melanoma cell vaccine with an increase in autoimmune skin depigmentation, demonstrating the concurrent induction of antitumor immunity and autoimmunity directed at common antigens (21). Autoimmunity induced through modulation of regulatory T cells is, however, not restricted to such common antigens. Autoimmune thyroiditis and a spectrum of other autoimmune diseases have been observed in cancer patients receiving melanoma gp100 or Her-2 peptide vaccines with immunomodulating agents (22, 23). In this study, we examined the induction of autoimmunity in the thyroid which does not share common antigens with Her-2.

We have shown that depletion of Treg in CBA/J mice increased their susceptibility to experimental autoimmune thyroiditis (24), the murine model of Hashimoto's thyroiditis. Hashimoto's thyroiditis, the leading cause of hypothyroidism, is characterized by mononuclear cell infiltration and destruction of the thyroid, elevation of thyroid-stimulating hormone, and decrease of thyroid hormones (T3 and T4). The production of autoantibodies (25) and T-cell proliferation to thyroid antigens (26) are indicators of autoreactivity. Susceptibility to thyroiditis is strongly influenced by the haplotype of class II MHC. For example, human *HLA-DRB1*0301* (DR3) transgene (27) and murine *H2^k* (CBA/J) confer susceptibility to autoimmune thyroiditis, whereas murine *H2^d* (BALB/c) is associated with resistance (28).

In genetically susceptible mice, experimental autoimmune thyroiditis is induced by injection of mouse thyroglobulin (mTg), usually in the presence of a strong adjuvant (e.g., complete Freund's Adjuvant or lipopolysaccharide; ref. 29), or by repeated injections of mTg for 4 weeks (30). Like Hashimoto's thyroiditis, experimental

autoimmune thyroiditis is also characterized by mononuclear cell infiltration, autoantibody production, and T-cell proliferation. Susceptible mice can be tolerized to mTg by short-term elevation of circulating mTg (31). This induced tolerance is abrogated by depletion of CD25⁺ cells and mice again become susceptible to experimental autoimmune thyroiditis (24).

In this study, we assessed the risk of experimental autoimmune thyroiditis in genetically resistant BALB/c mice undergoing Treg depletion to induce tumor regression. Our results show that in a Treg-deprived environment, tumor cells effectively prime the immune system, resulting in tumor regression and persistent immunologic memory. The same depletion enhanced autoimmunity to mTg in resistant BALB/c mice. Concurrent tumor regression and mTg immunization resulted in further elevation of both antitumor and anti-mTg immunity. This report describes the first test system to analyze simultaneous antitumor and anti-self immunity while reducing immune regulatory mechanisms as a form of cancer therapy.

Materials and Methods

Mice and cell lines. Six- to eight-week-old female BALB/c mice (*H2^d*) were obtained from Charles River Laboratory (Frederick, MD). All animal procedures were conducted in accordance with accredited institution guidelines and the U.S. Public Health Service Policy on Humane Care and Use of Laboratory Animals (<http://grants.nih.gov/grants/olaw/olaw.htm#pol>). D2F2 is a mouse mammary tumor line derived from a spontaneous mammary tumor that arose in the BALB/c hyperplastic alveolar nodule line D2 (32). The TUBO cell line, kindly provided by Dr. Guido Forni (Department of Clinical and Biological Sciences, University of Turin, Orbassano, Italy), was derived from a spontaneous mammary tumor which arose in a BALB NeuT transgenic mouse expressing a transforming rat neu (33, 34). TUBO cells grow progressively in normal BALB/c mice and give rise to tumors which are histologically similar to those in BALB NeuT mice. All tissue culture reagents were purchased from Invitrogen (Carlsbad, CA) unless otherwise specified. Cell lines were maintained *in vitro* in DMEM supplemented with 5% heat-inactivated cosmic calf serum (Hyclone, Logan, UT), 5% heat-inactivated fetal bovine serum (Sigma, St. Louis, MO), 10% NCTC 109 medium, 2 mmol/L L-glutamine, 0.1 mmol/L MEM nonessential amino acids, 100 units/mL penicillin, and 100 µg/mL streptomycin. D2F2 cells were cotransfected with pRSV2/neo and pCMV/neu, which encodes wild-type rat neu. Stable clones of D2F2/neu were selected and the expression of neu protein on the cell surface was verified by flow cytometry. Transfected cell lines were maintained in medium containing 0.8 mg/mL G418 (Geneticin, Sigma).

Depletion of CD25⁺ T cells with anti-CD25 monoclonal antibody, PC61. The hybridoma line PC61 which produces rat anti-mouse CD25 immunoglobulin G1 [IgG1; American Type Culture Collection (ATCC), Manassas, VA] was propagated in severe combined immunodeficient mice. BALB/c mice were injected i.p. with ~0.5 mg of PC61 or normal rat immunoglobulin (or PBS). Depletion of CD25⁺ cells was verified by flow cytometry. Lymph node cells were prepared and washed with PBS containing 0.1% sodium azide and 2% cosmic calf serum. All samples were treated with Fc receptor blocker (rat antibody to CD16/CD32; PharMingen, San Diego, CA) for 15 minutes on ice, then washed once. Cells were incubated with goat anti-GITR IgG (R&D Systems, Minneapolis, MN) for 20 minutes on ice followed by allophycocyanin-rat anti-CD4 (RM4-5), FITC-rat anti-CD25 (7D4), and phycoerythrin-donkey anti-goat IgG. Controls were stained with FITC-rat immunoglobulin M, allophycocyanin-rat IgG2b, or normal goat IgG with phycoerythrin-donkey anti-goat IgG. mAb RM4-5, 7D4, and their isotype controls were from PharMingen. Normal goat IgG and phycoerythrin-donkey anti-goat IgG were from Jackson ImmunoResearch Lab (West Grove, PA). Single- and double-stained samples were used for instrument setup. Lymph node cells from naïve animals were measured in parallel. Flow cytometric analysis was done with a FACSCalibur (Becton Dickinson, Mountain View, CA).

Tumor growth and measurement. To measure tumor growth, mice were challenged s.c. with 2×10^5 cells in the flank. Tumor growth was monitored by weekly palpation. Tumor diameters were measured in two dimensions and mice were sacrificed when any one dimension reached 15 mm. Tumor volume was calculated as $X^2Y/2$, where *X* and *Y* represent the short and long dimension, respectively, of the tumor. Comparison of tumor-free mice was analyzed with the log-rank test.

Measurement of anti-neu antibodies. Antibody response to rat neu was determined by flow cytometry as we previously described (35). BALB/c 3T3 cells (ATCC) were stably transfected with rat neu to establish 3T3/N cells. The mouse anti-rat neu mAb (IgG2a, clone 7.16.4), which recognizes an extracellular domain of rat neu protein (Oncogene Research Products, Cambridge, MA), was serially diluted and used to stain 3T3/N cells to establish a standard binding curve. FITC-goat anti-mouse IgG was the secondary antibody (Jackson ImmunoResearch). To determine antibody concentration in test sera, serially diluted test sera were used as primary antibody. Antibody concentration was calculated by regression analysis as we previously reported (35). Normal mouse immunoglobulin was used as negative control. The isotype of bound antibody was measured with FITC-goat anti-mouse IgG1 or IgG2a (Caltag, Burlingame, CA) and the results were expressed as mean channel fluorescence. Flow cytometric analysis was done with a FACSCalibur (Becton Dickinson). The results were analyzed by two-tailed Student's *t* test and are presented as mean $\pm$ SD.

Enumeration of cytokine-producing cells by ELISPOT assay. Spleen cells were suspended in RPMI 1640 supplemented with 10% FCS, 2 mmol/L L-glutamine, and 100 units/mL penicillin and 100 µg/mL streptomycin. Three to four hundred thousand cells were added to each well of the 96-well high-throughput screening immunoprecipitation plates (Millipore, Bedford, MA), which were precoated with rat anti-mouse IFN- γ (IgG1, clone R4-6A2) or rat anti-mouse interleukin 4 (IL-4; IgG1, clone 11B11), and incubated for 24 to 48 hours at 37°C in 5% CO₂. Test wells also contained the engineered antigen-presenting cells 3T3/NKB, which were 3T3 cells expressing rat neu, H2-K^d and CD80. The control 3T3/K cells were 3T3 cells expressing H2-K^d. The ratio of spleen cells to 3T3/NKB was 10:1 and 3T3/NKB were added after spleen cells had been plated. After incubation, cells were discarded and biotinylated rat anti-IFN- γ (IgG1, clone XMG 1.2) or rat anti-IL-4 (IgG1, clone BVD6-24G2) was added. All antibodies were purchased from BD PharMingen. Plates were incubated for 12 hours at 4°C, then washed to remove unbound antibody. Bound antibody was detected by incubating the plates with 0.9 µg/mL avidin-horseradish peroxidase (Sigma) for 2 hours at room temperature. Following washing, the substrate 3-amino-9-ethyl-carbazole in 0.1 mol/L acetic acid and 0.003% hydrogen peroxide was added and the plates were incubated for 5 minutes. The substrate was discarded and the plates were washed six times with water. The visualized cytokine spots were enumerated with the ImmunoSpot analyzer (CTL, Cleveland, OH) and the results expressed as the number of cytokine-producing cells per 10⁶ spleen cells. Data were analyzed by Student's *t* test.

Immunization with mouse thyroglobulin. mTg was prepared from frozen thyroids by fractionation on a Sephadex G-200 column as previously described (36, 37) and diluted in nonpyrogenic saline before use. The presence of lipopolysaccharide was measured by *Limulus* amoebocyte assay (Associates of Cape Cod, Woods Hole, MA; ref. 30). A 40 µg dose of mTg contained <0.5 ng of lipopolysaccharide.

Mice were injected i.v. with 40 µg mTg, followed in 3 hours with 20 µg *Salmonella enteritidis* lipopolysaccharide. The injections were repeated in 7 days. Alternatively, 40 µg mTg was injected i.v. on 4 successive days with 3 days of rest (30). This treatment was repeated for 3 more weeks.

Measurement of anti-mouse thyroglobulin antibody. Anti-mTg antibody titers were determined by ELISA as previously described (38). Briefly, Immulon I microtiter plates (Dynatech Laboratories, Inc., Chantilly, VA) were coated with mTg at 1 µg/well and serially diluted test sera were added. After washing, bound antibody was detected with alkaline phosphatase-labeled goat anti-mouse IgG and enzyme substrate.

Measurement of anti-mouse thyroglobulin T-cell response. T-cell proliferation was measured by [³H]thymidine incorporation. Splenocytes were cultured in triplicate in RPMI + 1% normal mouse serum, 2 mmol/L L-glutamine, 5×10^{-5} mol/L β -mercaptoethanol, 100 units/mL penicillin,

and 100 $\mu\text{g/mL}$ streptomycin, in 96-well plates at 6×10^5 cells/well, either with or without 40 $\mu\text{g/mL}$ mTg for 4 days at 37°C , 6% CO_2 . The cells were pulsed with 1.2 $\mu\text{Ci/well}$ of [^3H]thymidine and incubated for 18 hours before harvest onto glass fiber filter paper (Tomtec Mach3Man Cell Harvester, LKB Wallac, Gaithersburg, MD). [^3H]Thymidine was measured with a Microbeta Plus 1450 liquid scintillation counter (LKB Wallac). Data were analyzed by two-tailed Student's *t* test.

IFN- γ - and IL-4-producing cells were enumerated by ELISPOT assay using 40 $\mu\text{g/mL}$ mTg as the antigen. In some experiments, a two-step ELISPOT assay was done to amplify mTg-specific T-cell response. Spleen cells and mTg were incubated in 96-well tissue culture plates for 3 days before the content of the wells was transferred to high-throughput screening immunoprecipitation plates. The high-throughput screening immunoprecipitation plates were incubated for 24 hours. The detection and enumeration of cytokine spots was done as described earlier.

Histologic evaluation of experimental autoimmune thyroiditis. Thyroid specimens were sectioned vertically through both lobes and 50 to 60 histologic sections were prepared from 10 to 15 step levels. The extent of mononuclear cell infiltration was scored based on the pathology index scale of 0 to 4 and presented as percent thyroid infiltration: 0, no infiltration; 0.5, >0% to 10% thyroid infiltration consisting of perivascular foci without follicular destruction; 1.0, >10% to 20% thyroid infiltration with follicular destruction; 2.0, >20% to 40% diffuse thyroid infiltration; 3.0, >40% to 80% thyroid destruction; and 4.0, >80% to 100% thyroid destruction (36). The sections were scored without knowledge of the groups. Statistical differences were analyzed by the nonparametric Mann-Whitney *U* test.

Statistical analyses. Tumor growth expressed as percent tumor-free mice was analyzed with the log-rank test. Thyroiditis expressed as percent infiltration of thyroid was analyzed using the nonparametric Mann-Whitney *U* test. The number of IFN- γ -producing cells and the antibody levels were analyzed by Student's *t* test.

Results

Duration of $\text{CD4}^+\text{CD25}^+\text{GITR}^+$ T-cell depletion by anti-CD25 monoclonal antibody treatment. To establish the time window of Treg depletion by anti-CD25 mAb, BALB/c mice were injected i.p. on 2 consecutive days with 0.5 mg of anti-CD25 mAb, PC61. $\text{CD4}^+\text{CD25}^+\text{GITR}^+$ T cells in the lymph nodes were enumerated on days 0 to 12 after the second injection. On each test day, three test mice were sacrificed and their lymph node cells analyzed individually. Control cells were prepared by pooling lymph node cells from three mice which received normal rat immunoglobulin or PBS. Cells were stained with allophycocyanin-anti-CD4, FITC-anti-CD25, and goat anti-GITR with phycoerythrin-conjugated secondary antibodies and analyzed by flow cytometry. Figure 1 shows representative T-cell profiles on days 0, 3, 5, 9, and 12. CD4^+ T cells were gated (Fig. 1A) and percentages of $\text{CD25}^+\text{GITR}^+$ cells in gated CD4^+ cells are shown in density plots (Fig. 1B). The results from all test and control mice are summarized in a table and provided in the Supplementary data. In CD4^+ T cells, the majority of CD25^+ cells were also GITR^{hi} . These triple-positive cells were reduced from $11 \pm 0.1\%$ to $6.2\% \pm 0.5\%$ on day 1, reached their nadir of $3.0 \pm 0.7\%$ by day 5, and began to reappear after day 9. Therefore, treatment with anti-CD25 mAb maximally reduced $\text{CD4}^+\text{CD25}^+\text{GITR}^+$ cells between days 5 and 7.

TUBO tumor regression in Treg-depleted mice. *In vivo* priming to tumor-associated antigens after Treg depletion was tested with TUBO tumor, which was established from a spontaneous mammary tumor in BALB NeuT mice expressing a transforming rat neu (33, 34). Consequently, TUBO cells express neu on their cell surface (Fig. 2A, inset). Anti-CD25 mAb was administered twice, either 5 and 6 days before or 1 and 3 days after

tumor cell inoculation. In naïve mice, TUBO tumors grew progressively to reach $>500 \text{ mm}^3$ (not shown) when mice were sacrificed. In anti-CD25 mAb-treated mice, all mice developed tumors which started to regress when they were 15 to 180 mm^3 in size, and regressed completely by week 11 (Fig. 2A), suggesting *in vivo* priming by a growing TUBO tumor. The course of tumor growth and regression was nearly identical whether anti-CD25 mAb was administered before or after tumor cell inoculation. This experiment was repeated at least twice with similar results.

Anti-neu immunity in mice undergoing TUBO tumor regression. To characterize the immune responses induced during TUBO tumor regression, sera were collected at 5 and 9 weeks following tumor cell inoculation and anti-neu antibody was measured by flow cytometry as we previously reported (35). As shown in Fig. 2B, in naïve mice, tumor growth did not induce detectable anti-neu antibody at week 5. The tumor volume exceeded 500 mm^3 at week 9 (not shown), at which time $11.4 \pm 3.5 \mu\text{g/mL}$ of anti-neu IgG was detected. Mice treated with anti-CD25 mAb before and after tumor cell inoculation displayed 11.7 ± 8.6 and $8.9 \pm 6.4 \mu\text{g/mL}$, respectively, of anti-neu IgG at week 5, when the tumors were $\sim 35 \text{ mm}^3$. At week 9, when the tumors were almost completely eliminated, these same mice had 16.7 ± 9 and $34 \pm 9 \mu\text{g/mL}$ of anti-neu IgG, respectively ($P = 0.01$). Thus, depletion of CD25^+ T cells either before or after TUBO cell inoculation resulted in a more prompt and elevated antibody response, with the highest level of anti-neu IgG observed at week 9 in mice receiving anti-CD25 after TUBO cell inoculation (Fig. 2B). The isotypes of antibodies were further analyzed. Figure 2C shows the representative week 5 results from mice treated with $\alpha\text{-CD25}$ before tumor inoculation. Both IgG1 and IgG2a were elevated, suggesting activation of both T-helper (Th) 1 and Th2 cells.

To measure neu-specific T-cell response, four tumor-free mice which received anti-CD25 after TUBO cell inoculation were sacrificed at week 9. Their spleen cells were isolated and incubated individually with the engineered 3T3/NKB cells. IFN- γ - and IL-4-producing cells were enumerated by ELISPOT assay after a 2-day culture and similar results were obtained from the four mice. Figure 2D shows the result from a representative animal. There were 36 ± 2

Figure 1. Depletion of Treg with anti-CD25 mAb PC61. BALB/c mice were injected i.p. with 0.5 mg of anti-CD25 mAb on 2 consecutive days. Lymph node cells were collected from treated and control mice on days 0, 1, 3, 5, 9, and 12 after antibody treatment. The cells were stained with allophycocyanin-anti-CD4, FITC-anti-CD25, and goat anti-GITR with phycoerythrin-anti-goat IgG. Positively stained CD4^+ T cells were gated (A) and CD25 and GITR profiles of gated CD4^+ cells harvested on days 0, 3, 5, 9, and 12 were depicted as dot plots (B). The number in the top right quadrant represents the percentage of $\text{CD25}^+\text{GITR}^+$ cells within the CD4^+ T-cell population.

Figure 2. Tumor regression following Treg depletion. BALB/c mice were injected i.p. with 0.5 mg anti-CD25 mAb either 5 and 6 days before or 1 and 3 days after they received 2×10^5 TUBO cells. Control mice were treated with normal rat immunoglobulin or PBS. There were eight mice in each group. Tumor growth was monitored for 11 weeks. **A**, TUBO tumor growth in mice treated with anti-CD25 before (Δ) or after ($\blacktriangle$) tumor cell inoculation or in control mice (+). The results are expressed as percentage of tumor-free mice. *Inset*, expression of neu on TUBO cells was verified by flow cytometry using mouse anti-rat neu mAb (7.16.4, filled histogram) followed by phycoerythrin-anti-mouse immunoglobulin, and compared with isotype controls (open histogram). **B**, anti-neu IgG levels in mice treated with anti-CD25 before or after TUBO cell inoculation were measured by flow cytometry and calculated by regression analysis. **C**, IgG1 and IgG2a levels in mice treated with anti-CD25 mAb after TUBO cell inoculation are reported as mean channel fluorescence (MCF). **D**, T-cell response to neu antigen. Following anti-CD25 mAb treatment and tumor regression, tumor-free mice were sacrificed at week 9 and their spleen cells isolated and cultured with 3T3/K or 3T3/NKB cells. IFN- γ -producing cells were enumerated by ELISPOT assay, and normalized to express the number of spots per 10^6 spleen cells.

neu-specific IFN- γ -producing cells per 10^6 spleen cells. Neu-specific IL-4-producing cells were not detected (not shown), suggesting a more prominent Th1 response. Stimulation with concanavalin A typically resulted in over 1,000 spots per 10^6 spleen cells (not shown). Incubation with 3T3/K cells did not induce IFN- γ or IL-4 production.

Immunologic memory to tumor-associated antigen. To assess the strength of immunologic memory to tumor-associated antigens, the group of eight mice which rejected TUBO tumors by anti-CD25 mAb treatment postinoculation were rechallenged with TUBO or D2F2/neu cells at week 14 (week 0 in Fig. 3A). TUBO tumors were rejected by all three mice receiving this cell line as the second challenge (Fig. 3A). The other five mice received D2F2/neu cells, which were generated by transfecting a prolactin-induced BALB/c mammary tumor D2F2 with the wild-type rat neu (Fig. 3B; ref. 39). D2F2/neu cells were rejected by 4 of 5 (80%) mice. Mice which rejected TUBO tumors had 34 ± 9 $\mu\text{g/mL}$ anti-neu antibody just before they received the second tumor challenge. The level of antibody cross-reactive with D2F2 was below 1 $\mu\text{g/mL}$ and remained low after these mice rejected D2F2/neu, suggesting that the second challenge of D2F2/neu cells was rejected primarily through anti-neu immunity.

In summary, depletion of Treg in mice carrying TUBO tumors resulted in anti-neu antibodies, neu-specific IFN- γ -producing T cells, eradication of the growing tumor, as well as immunologic memory to neu and possibly other tumor-associated antigens.

Experimental autoimmune thyroiditis induced in resistant BALB/c mice. We have shown that elimination of Treg in mTg-tolerized CBA/J mice resulted in their reversion to the susceptible phenotype (4, 24). To test whether depletion of Treg in BALB/c mice, an experimental autoimmune thyroiditis-resistant mouse strain, would render them susceptible, mice were treated with anti-

CD25 mAb twice, 4 days apart. On days 5 and 12 after the second mAb injection, mice received 40 μg of mTg and 20 μg of lipopolysaccharide (29), and they were sacrificed 4 weeks after the second immunization. Anti-mTg antibody was measured by ELISA. Depletion of Treg before mTg and lipopolysaccharide treatment resulted in a significant increase in anti-mTg antibodies ($P = 0.003$; Fig. 4A), including both IgG1 and IgG2a. To measure T-cell response, splenocytes were cultured with mTg for 4 days and cell proliferation was measured by [^3H]thymidine incorporation. A significant increase ($P = 0.002$) in T-cell response was detected in mice depleted of Treg (Fig. 4B). The incidence and severity of thyroiditis was significantly increased ($P = 0.01$) with Treg depletion (Fig. 4C). Compared with control mice without anti-CD25 mAb treatment,

Figure 3. Induction of memory T cells after Treg depletion and tumor regression. **A**, BALB/c mice which had been treated with anti-CD25 at 1 and 3 days following TUBO cell inoculation, and of which tumors had regressed, were rechallenged with 2×10^5 TUBO or D2F2/neu cells. Three mice were given a second challenge with TUBO (∇) and five mice with D2F2/neu tumor cells ($\blacksquare$). Control groups were naïve mice inoculated with D2F2/neu ($\diamond$) or TUBO ($\circ$) cells. **B**, flow cytometric analysis of D2F2/neu cells (filled histogram). Normal mouse immunoglobulin was used as control (open histogram).

Figure 4. Enhanced anti-mTg immunity following Treg depletion. BALB/c mice were injected with 0.5 mg anti-CD25 mAb 4 days apart. On days 5 and 12 after the second injection, each mouse received i.v. 40 μ g mTg and 20 μ g lipopolysaccharide. On day 40, thyroids, sera, and spleen cells were collected for evaluation. **A**, mTg antibody measured by ELISA. Serum samples were tested at 1:2,500 dilution. **B**, *in vitro* proliferative response to mTg. A total of 6×10^5 spleen cells were incubated in the presence of 40 μ g/mL mTg for 4 days and [3 H]thymidine uptake was measured. **C**, infiltration of individual thyroids by mononuclear cells in histologic sections was recorded. There were seven mice in each group.

the incidence of thyroid infiltration was 100% (7 of 7) versus 43% (3 of 7). Follicular destruction which is associated with >10% mononuclear infiltration of the thyroid was detected only in Treg-depleted mice. Therefore, removal of Treg enabled "resistant" BALB/c mice to develop moderate experimental autoimmune thyroiditis.

Concurrent induction of anti-neu and anti-mouse thyroglobulin response in Treg-depleted mice. To evaluate the risk of autoimmunity in mice undergoing Treg depletion to enhance antitumor immunity, we inoculated BALB/c mice with TUBO cells, followed on days 1 and 3 with anti-CD25 mAb (Fig. 5A). The same mice also received mTg to assess the concurrent induction of anti-mTg immunity. Rather than immunizing with mTg and lipopolysaccharide, because the latter may complicate antitumor immunity, mice received 40 μ g of mTg i.v. on 4 consecutive days each week, for 4 weeks. In our previous report, this regimen induced experimental autoimmune thyroiditis in about 50% of susceptible CBA/J mice (30). All mice inoculated with tumor cells developed solid tumors in 2 weeks (Fig. 5A and B). In naïve mice, the tumors grew progressively and mice were sacrificed by week 7. All mice receiving TUBO cells and mTg without Treg depletion developed tumors by week 3. None of the tumors regressed (Fig. 5A and B). In mice depleted of Treg, tumors started to regress when they reached ~ 100 mm³ and three of four tumors regressed completely. In all seven mice which

received anti-CD25 mAb and mTg, TUBO tumors completely regressed. A repeated experiment showed similar results. Therefore, TUBO tumors were rejected following Treg depletion regardless of the presence of mTg.

To characterize the immune response, anti-neu antibodies were measured at week 10 or at time of sacrifice. Anti-neu IgG in untreated, tumor-bearing mice averaged 6 ± 2.4 μ g/mL (Fig. 5C). With Treg depletion and tumor regression, average antibody level increased to 28.7 ± 26 μ g/mL. Although the difference did not reach statistical significance, an increase in anti-neu antibody was observed consistently after Treg depletion. Serum samples from these two groups did not react with mTg when tested by ELISA (not shown), showing the absence of cross-reactivity between neu and mTg. Interestingly, exposure to mTg in Treg-depleted mice which undergo TUBO tumor regression resulted in an average of 78.6 ± 56 μ g/mL of anti-neu IgG, demonstrating an up-regulation of anti-neu response in about 50% of the mice responding to both neu and mTg ($P = 0.05$). Neu-specific T-cell response was measured by ELISPOT following *in vitro* stimulation with the engineered antigen-presenting cells 3T3/NKB. Low, but detectable, IFN- γ -producing cells were detected following tumor regression. Figure 5D shows the result of a representative experiment from four independent analyses. Reactive T cells increased to ~ 45 per 10^6 spleen cells after the mice were also immunized with mTg. Neu-specific IL-4-producing cells were not detected (not shown). Therefore, injection of mTg in TUBO cell-bearing mice without anti-CD25 mAb treatment did not result in enhanced anti-neu immunity (Fig. 5C and D), demonstrating that exposure to mTg, a self-antigen, per se did not enhance antitumor immunity. Rather, depletion of regulatory T cells resulted in tumor regression with anti-neu immunity, which is further enhanced when anti-mTg reactivity is also triggered with this regimen.

To assess anti-mTg response in Treg-depleted mice which received mTg immunization after TUBO cell inoculation, serum antibody to mTg was measured. In three of seven mice, the antibody level was higher than that in mice which were immunized with mTg after Treg depletion, but were not inoculated with tumor cells, although the difference between these two groups was not statistically significant with this sample size (Fig. 6A). Mice inoculated with TUBO cells and treated with anti-CD25 mAb did not produce anti-mTg antibody. Anti-mTg antibody in Treg-depleted, mTg-immunized mice did not interact with neu when measured by flow cytometry (not shown), showing the absence of cross-reactivity between mTg and neu. mTg-specific T-cell proliferation or cytokine production was not detected at week 9 (not shown). To amplify possible T-cell responses, spleen cells were cultured with mTg for 3 days before they were transferred to ELISPOT plates precoated with anti-IFN- γ (Fig. 6B) or anti-IL-4 (Fig. 6C). Using this two-step ELISPOT assay, 612 ± 31 IFN- γ -producing and 79 ± 10 IL-4-producing cells per 10^6 spleen cells were detected in Treg-depleted mice which received TUBO and mTg. Mice inoculated with TUBO cells and injected with mTg did not develop T-cell response to mTg (not shown). Histologic analysis of the thyroid glands revealed low level of mononuclear cell infiltration, consisting mostly of T lymphocytes and macrophages as we previously reported (36, 40), in 3 of 7 mice (43%; Fig. 6D). Photomicrograph showing an area of thyroid with mononuclear cell infiltration is shown in Fig. 6E. There were no pathologic changes in thyroids of mice which received mTg without experiencing tumor. Therefore, depletion of Treg enhanced autoreactivity to mTg with further elevation after tumor regression, leading to thyroid infiltration.

Discussion

The observed tumor regression in Treg-depleted mice was paralleled by the induction of anti-neu immunity. The accelerated and heightened anti-neu antibody response may contribute significantly to TUBO tumor regression because BALB NeuT tumors, like TUBO, are effectively controlled by anti-neu antibody (41). This may be due to antibody-mediated down-regulation of neu protein and neu-mediated signaling, which is critical to their survival. Antibody-dependent, cell-mediated cytotoxicity may also contribute to tumor destruction. Significant anti-neu T-cell response was shown. Unlike TUBO cells, the rejection of D2F2/neu cells is controlled primarily by T cells as we previously described (42, 43). Rejection of D2F2/neu supports the presence of neu-specific memory T cells after TUBO tumor regression. Therefore, both humoral and cellular immune responses to tumor-associated antigen were significantly elevated following Treg depletion.

Anti-neu and anti-mTg IgG1 and IgG2a were detected in Treg-depleted mice, suggesting the activation of both Th1 and Th2 cells. When T-cell response was tested, neu-specific IFN- γ -producing cells, but not IL-4-producing cells, were detected. mTg-specific IFN- γ - and IL-4-producing T cells were detected in the amplified two-step ELISPOT assay with greater number in IFN- γ -producing cells. These results show that depletion of Treg enhanced both Th1 and Th2 immunity.

T-cell response to mTg is usually evaluated by [3 H]thymidine incorporation because, unlike anti-mTg antibody response, *in vitro* proliferation generally correlates with thyroid infiltration (36). Compared with T-cell proliferation, ELISPOT assay for IFN- γ -producing cells is more sensitive in detecting T-cell response. It is possible to further amplify the sensitivity of ELISPOT assay by the two-step incubation. Immune cells were expanded by preculturing

with the antigen for 3 days before they were subjected to ELISPOT assay. If we estimate that effector cells divide every 12 to 16 hours on antigen stimulation, the cell number would increase between 16- and 64-fold in 3 days. Every 16 to 64 spots detected in the amplified ELISPOT assay would represent one responding cell in the starting population. The sensitivity of ELISPOT is increased significantly by preincubation, yet the difference between the control and test groups is unequivocal.

Induction of experimental autoimmune thyroiditis in Treg-depleted BALB/c mice indicated that resistance to experimental autoimmune thyroiditis determined by MHC class II was influenced in part by Treg because mononuclear cell infiltration was much less pronounced in resistant BALB/c mice carrying intact Treg (Fig. 4C). After depletion, greater humoral and cellular immunity to mTg was induced by the conventional immunization with mTg and lipopolysaccharide (Fig. 4A and B). When immunized by repeated mTg injection without lipopolysaccharide as adjuvant, a mild response to mTg was induced, but the response was significantly elevated in mice undergoing tumor regression such that more mice developed inflammatory infiltration in their thyroids (Fig. 6D). The mononuclear cell infiltration of $\sim 10\%$ in this experiment was insufficient to cause thyroid hormonal changes. Nevertheless, this synergy between anti-neu and anti-mTg responses was both intriguing and alarming. Although the specific mechanisms remain to be delineated, it is possible that repeated injections of the self-antigen mTg in Treg-depleted mice not only stimulated mTg-specific T cells, but that the attendant inflammatory cytokines released systemically may also enhance antitumor response. From the tumor standpoint, in Treg-depleted mice, TUBO tumors grew to palpable size before sufficient immune effectors were generated to commence tumor regression. At the tumor site, tumor cell destruction can be envisioned following immunologic attack.

Figure 5. Effect of Treg depletion and mTg immunization on anti-neu immunity in TUBO cell-inoculated mice. BALB/c mice were inoculated with TUBO cells on day 0 and treated with anti-CD25 mAb on days 1 and 3. Starting on day 10 and continuing for 4 weeks, mice were injected with 40 μ g of mTg daily for 4 days followed by a 3-day rest before the next cycle of injections. There were three other groups of mice which received TUBO cells and anti-CD25 mAb or mTg immunization or untreated. A, tumor growth in Treg-depleted mice with (▲) or without (●) mTg treatment. Mice in the control group received PBS (□) or mTg (×). B, tumor volume of individual mice in A. C, at week 10, anti-neu antibody was measured by flow cytometry; D, IFN- γ -producing cells were analyzed by ELISPOT assay. There were four mice in each group except seven mice in the group receiving TUBO cells, anti-CD25, and mTg.

Figure 6. Effect of Treg depletion and TUBO tumor regression on anti-mTg immunity. There were four groups of mice; two groups were the same mice as described in Fig. 5 (i.e., mice injected with TUBO cells, treated with anti-CD25, and immunized with mTg, and the control mice). There were two additional groups of mice receiving mTg with or without anti-CD25, but not inoculated with TUBO cells. A, serum samples were diluted 1:2,500 and anti-mTg IgG measured by ELISA. IFN- γ -producing (B) and IL-4-producing (C) T cells were determined by the two-step ELISPOT assay. D, infiltration of individual thyroids by mononuclear cells was recorded. E, photomicrographs showing a normal thyroid section from an untreated mouse (right) and mononuclear cell infiltration with thyroid follicular destruction involving >10% of the thyroid from a Treg-depleted mouse which experienced TUBO tumor regression and mTg immunization (left); original magnification, $\times 200$.

A cascade of immunologic events may lead to elevated reactivity to both mTg and tumor-associated antigens.

In cancer patients, more strenuous effort than one-time depletion may be required to overcome immune regulatory mechanisms before effective antitumor immunity can be induced, with increasing risk of autoimmunity from each new regimen. Our results showed that even genetically resistant BALB/c mice became more susceptible to experimental autoimmune thyroiditis once Treg were removed, particularly during tumor regression. Patients expressing high-risk *HLA* haplotypes will require close monitoring of their autoreactivity to self-antigens when their immune regulatory mechanisms are modulated. In a pilot study to test Her-2 peptide vaccine with Flt3 ligand administered systemically as an adjuvant, 2 of 15 subjects developed elevated thyroid stimulating hormone with symptoms of grade 2 hypothyroidism, indicating thyroid destruction. Thyroid hormone replacement therapy was required at the conclusion of the study (22). Significantly elevated levels of antibody to thyroglobulin and thyroid peroxidase were detected in one patient, demonstrating autoimmunity to thyroid antigens. In another study, 14 patients with metastatic melanoma received gp100 peptide vaccines along with mAb to CTLA-4, which is expressed on regulatory and activated T cells (23). In six patients,

grade III/IV autoimmune manifestations were observed, including dermatitis, enterocolitis, hepatitis, and hypophysitis. The three patients with objective cancer regression all developed severe autoimmune symptoms requiring treatment. Because of the grade III/IV autoimmune toxicity in ≥ 3 patients, accrual intended for 21 patients ceased after 14 patients were enrolled. Therefore, immunomodulating reagents which can amplify antitumor immunity in a profound manner can trigger significant autoimmunity to self-antigens. For patients with genetic predisposition, the risk of autoimmunity may be overwhelming. With the sensitive *in vitro* assays to monitor immune reactivity to self-antigens, it may be possible to detect the onset of autoimmunity during cancer immunotherapy before clinical symptoms and counter measures may be taken in a timely fashion.
