

The Test and Evaluation Uses of Heterogeneous Computing: GPGPUs and Other Approaches

Dan M. Davis, Gene Wagenbreth, and Robert F. Lucas

Information Sciences Institute, USC, Marina del Rey, California

Paul C. Gregory

Lockheed Martin Company, Suffolk, Virginia

The test and evaluation community faces conflicting pressures: Provide more computing power and reduce electrical power requirements, both on the range and in the laboratory. The authors present some quantifiable benefits from the implementation of General Purpose Graphics Processing Units (GPGPUs) as heterogeneous processors. This produces power, space, cooling, and maintenance benefits that they have documented. Other efforts in the field of power reduction techniques will be outlined, e.g., the efficient low-power microprocessor approach of Prof. William Dally and IBM's well-publicized Blue Gene project. The utility of all of these techniques for the test and evaluation community is assessed. The authors will report on several aspects of their experience with GPGPUs: programmability, performance of codes implemented in several areas of computational science, and the compute power per unit of electrical consumption. An overview of code design and implementation approaches is discussed.

Key words: Code development; computing cost; computing power per watt; efficient low-power microprocessor (EM); energy conservation; IBM's Blue Gene; military experimentation; modeling; simulation fidelity; training; William Dally.

It is commonly held that test and evaluation (T&E) is one of the most critical steps in the development of virtually all defense systems (Fox et al. 2003). It is the central means of making sure that new systems will reliably perform their intended functions in their intended environment, often combat. T&E of current systems is an elaborate and time-consuming process that reflects both the intricacies of the object of the test and the range of equipment, personnel, and environments required. Many argue that this process consumes far too much of the time that it takes to put new systems into the hands of the warfighters and uses way too many resources without much obvious benefit for those in combat.

One solution to ameliorating these costs and delays is the increased use of computer simulations, ranging from agent-based models of battlespaces to Mechanical Computer Aided Engineering (MCAE) analyses of hardware to esoteric simulations using computational fluid dynamics to assess everything from new airframes to dispersion of chemical and biological agents.

Computing costs are significant as well. These costs are not only the computer purchase price, but a small workstation or time on High Performance Computers (HPC). They must include the costs of training, programming, maintaining, validating, and supporting extensive code bases (Kepner 2004). These questions are even more urgent because increasing emphasis in T&E concerns the expenditures of money and time in the development process. Efficiency is critical when cost overruns and schedule delays are deleterious and costly (Fox et al. 2004).

One potential approach to reducing costs, time-to-roll-out, and physical danger, all the while improving validity, transparency, and utility, is to adopt the strategy of heterogeneous computing. Heterogeneous computing is the use of a variety of different types of computational units to aid the central processing unit (CPU), such as accelerators like General Purpose Graphics Processing Units (GPGPUs), field programmable gate arrays, and digital signal processors. There is a growing body of evidence on the use of these devices, some of it created by the authors in their work on large-scale battlespace simulations at the U.S. Joint

Forces Command (JFCOM) and its Joint Concept Development and Experimentation Directorate (J9).

Joint SemiAutomated Forces (JSAF)

One program in use at JFCOM is JSAF code. JSAF is loaded onto a network of processors in either workstations or Linux clusters. They communicate via a local or wide area network. Communication is implemented with high level architecture and a custom version of runtime infrastructure software, called RTIs. A run is implemented as a federation of simulators or clients, and multiple clients, in addition to JSAF, are typically included in a simulation.

As is common in the T&E community, operational imperatives drive experimental designs that require even further expansion of simulation code capabilities. These needs include some of the following:

- more background entities,
- more complex behaviors,
- larger geographic area,
- multiple resolution terrain, and
- more complex environments.

The energy efficiency issues addressed here are not new ones. The lack of energy resources and the inability to adequately conserve existing power reserves can arguably be advanced as one of the reasons for the loss of World War II by both major Axis powers.

In T&E settings, the need for power conservation is still paramount, mainly for cost, maintenance, and habitability reasons. These may vary by region, e.g., power is on the order of three times as expensive on Maui as it is in Maryland, and by installation, e.g., size and temperature constraints differ between a high performance computing center and a test aircraft cockpit. Nevertheless, all of the previously mentioned parameters are important, critical, or vital, as the case may be.

While most equipment suffers from high heat, electronics are especially sensitive. The microcircuitry now employed in every phase of computing is prone to energy constraints, the principal culprit being the need to transfer heat away from the sensitive circuits that are generating their own heat. While calling attention to this concern, it is not the intent of this article to focus on heat dissipation mitigation techniques.

This article investigates innovative and effective ways to accomplish the same amount of computation while using significantly less total energy. The technique studied by the authors is to use GPGPUs to effectively handle computationally intensive activity “spikes.” The authors report on three specific aspects of their use of GPGPUs:

- code drafting and development hurdles and opportunities,
- codes modified in several areas of computational science,
- a wide range of software results in floating point operations per second (FLOPS) per watt parameters in various hardware configurations.

An introductory synopsis of algorithmic design and implementation strategies should allow the T&E users to conceptualize the applicability of this technique to their own situations. To assist in this analysis, we discuss and display an actual working code segment along with the design rationale behind it. Further, because such new techniques cannot be implemented willy-nilly, the authors feel that their experience in training other Department of Defense (DoD) users to implement the approach will assist program managers in scoping and justifying training requirements.

GPGPUs as computer accelerators ***Methodology employed in simulation***

To better analyze potential T&E use, we set forth the method implemented by this team for forces modeling and simulation. We use existing DOD simulation codes running on advanced Linux clusters operated by JFCOM. The previous J9 clusters were on Maui and at Wright Patterson Air Force Base in Ohio, but the new cluster enhanced with 64-bit CPUs and NVIDIA 8800 GPUs was in Suffolk at JFCOM (Lucas et al. 2007). In addition to the benefits derived in force-on-force modeling, the T&E community at large could benefit from the acceleration applied in other arenas, such as

- physics-based phenomenology,
- CFD plume dispersion,
- computational atmospheric chemistry,
- data analysis.

GPGPU experiments were first conducted on a more manageable code set to ease the programming burden and hasten the results. Basic Linear Algebra Subprograms routines (Dongarra 1993) were seen as appropriate candidates. An MCAE “crash code” arithmetic kernel was used as vehicle for a basic demonstration problem, based on earlier work (Diniz et al. 2004).

This preliminary characterization of GPU acceleration focused on a subset of the large space of numerical algorithms, in this case factoring large sparse symmetric indefinite matrices. Such problems often arise in MCAE applications. The Intelligent Automation, Inc. (ISI) team made use of the single precision general matrix multiply algorithm.

Figure 1. Multicore factorization time, with and without the GPU.

The GPU should also be a very attractive T&E computation accelerator to overcome hurdles, e.g., sparse matrix factorization. Previous generations of accelerators, such as those designed by Floating Point Systems (Charlesworth and Gustafson 1986), were for the relatively small market of scientific and engineering applications. Contrast this with GPUs that are designed to improve the end-user experience in mass-market arenas such as gaming.

To get meaningful speed-up in T&E settings, we need to reduce the GPU data transfer and interaction between the host and the GPU to an acceptable minimum. The T&E user should be warned that the conduct of this analysis is not trivial, and the costs of it must always be born in mind when considering the use of GPGPUs (Kepner 2004).

Implementation research results

Results for recent runs on the C1060 from NVIDIA are shown in Figure 1, which plots the time it takes to factor the matrix as a function of the number of cores employed, both with and without the GPU. ISI used a dual-socket Nehalem host, sustaining 10.3 GFLOPS when using one core, and 59.7 GFLOPS when using all eight. When the GPU is employed, it performs $6.57E + 12$ operations, 92 percent of the total, and sustains 98.1 GFLOPS in doing so. The code's overall performance with the GPU improves to 61.2 GFLOPS when one host core is used, and 79.8 GFLOPS with all eight. For perspective, reordering and symbolic factorization take 7.9 seconds, permuting the input matrix takes 2.64 seconds, and the triangular solvers take 1.51 seconds (Lucas, Wagenbreth, and Davis 2010).

The single precision general matrix multiply function used in this work was supplied by NVIDIA. In testing, it was found that it could achieve close to 100 GFLOP/s, over 50 percent of the peak performance of the NVIDIA GTS GPU. Thus, the efforts were focused on optimizing the functions for eliminating off-diagonal panels (GPU1) and factoring diagonal blocks (GPUd).

Another application that may have T&E uses is a fast and large-scale graph-based construct, e.g., route-planning algorithms found in complex urban environment simulations. JSAF currently employs a heuristic A* search algorithm to do route planning for its millions of entities—the algorithm is sequential and thus very computationally expensive. Using the GPU, the JSAF simulation can off-load the route-planning component to the GPU and remove one of its major bottlenecks (Tran et al. 2008).

Early experimentation results at JFCOM

T&E users may benefit from an awareness of the initial year of research on JFCOM's GPU-enhanced cluster, Joshua. It was marked with typical issues of stability, operating system modifications, optimization, and experience. All of the major stated goals of the cluster proposal were met or exceeded. Joshua easily met its stability and availability requirements from JFCOM.

Any potential user would be interested in the issues of getting the machine up and running. A typical problem was getting the correct operating system installed and coordinating that with the NVIDIA staff's recommendations as to varying versions and incompatibilities. Those types of issues are still relevant today.

Joshua provided $24 \times 7 \times 365$ enhanced, distributed, and scalable computational resources that did enable joint warfighters at JFCOM and international partners to develop, explore, test, and validate twenty-first century battlespace concepts. The specific goal was to enhance global-scale, computer-generated military experimentation by sustaining more than 2,000,000 entities on appropriate terrain with valid phenomenology.

This was more than achieved in a major breakthrough in which 10 million entities were simulated in a Middle Eastern urban environment complete with demographically correct civilians (Figure 2).

The tasks of overcoming implementation hurdles and stabilizing the compute environment were interesting but not daunting. Agent-based model combat simulations of this size and sophistication were previously impossible because of limitations of computational power. The earlier pair of clusters had

Figure 2. Screen capture of 10 million entity run.

enabled the development and implementation of a proven scalable code base capable of using thousands of nodes interactively. The ISI team continues to address issues of interest to the T&E community such as enhanced security for distributed autonomous processes, interactive HPC paradigms, use of advanced architectures, self-aware models, global terrain with high-resolution insets, and physics-based phenomenology, many of which have their counterparts in T&E.

There is a general consensus that there are two possible ways to improve simulation fidelity: (a) by increasing entity counts (quantitatively) and (b) by increasing realism (qualitatively) of entity behaviors and resolution of the environment. Numerous efforts have been made to increase the former, e.g., SF Express (Brunnet et al. 1998) and Noble Resolve. They included the use of the scalable parallel processors or clusters of compute nodes (Wagenbreth et al. 2005). As for the latter, JFCOM M&S teams have made great strides in improving entity behavior models (Ceranowicz et al. 2002; Ceranowicz, Torpey, and Hines 2006) by adding intelligence to the simulation entity behaviors, and with these improvements, entities behave in more realistic fashions. Because JFCOM has been required to simulate more urban operations, the density of the road and trail networks has dramatically increased. This dictates an increase in computational costs (in terms of how entities relate to the environment), which was the heart of that research effort.

Power consumption analyses

Finding a great deal of interest in GPGPU acceleration, the following work, while necessarily preliminary because of the design dynamics of the devices being offered, may prove useful to those facing power issues today. In any case, these analyses do support the proposition that the use of GPGPUs is probably indicated as a viable method for reducing power consumption per unit of computation (usually

Figure 3. Ammeter and harness used for current quantification.

quantified here as FLOPS). Let us examine the extra power requirement for a system, first at the maximum power drain specified, then the drain at high computational loads, the drain at idle, and finally the drain with the GPGPU card removed from the node.

ISI had access to three versions of the NVIDIA GPUs that were tested, the 8800, 9400, and 9800. The NVIDIA C1060s and C2050s were not available for this early test. Data on them will be presented when it is available. In each case, the host for the GPGPU was chosen to best complement the GPU itself, so different platforms were used in every instance. While this may seem to be comparing apples and oranges, this is a necessary result of the choice of the target GPUs and would be more convoluted if they were all tried on one platform with the concomitant compromises.

A Model 22-602 Radio Shack AC ammeter probe, as seen in Figure 3, was used to test current flow to the entire node.

Wattage parameters from the vendor are typically maximum current allowed, not typical current usage under various conditions. That is why the authors measured each value themselves. All values in this article were either measured or calculated.

In each case, the amperage was measured, within the accuracy of the meter, of the current to the node under test while exercising the GPU (a) to the maximum extent feasible, (b) at idle while running, (c) at a sleep or hibernate mode, and (d) then finally, with the subject card removed. Cost, time, and instrumentation constraints precluded measuring the entire power consumption of the cluster Joshua, so figures for that power consumption were derived from findings and from data available from the vendors.

Table 1. Power readings using different GPGPUs.

Status →	Whole node watts (±4%)			
	Max	Idle	Sleep	Removed
8800	264	228	228	156
9400	444	360	324	275
9800	730	586	540	460

The authors wish to issue a caveat about the amperages cited. They can reliably be used for comparative purposes, but care should be exercised if trying to calculate actual amperages to be experienced in different computational environments and using different analytic tools. The accuracy of the meter used could be reliably certain to return comparative figures, but the absolute numbers might be off by some significant fraction. Test and retest numbers were very stable, giving some assurance that the comparative values were meaningful. The question that was being posed was: “How much power does the GPGPU card consume in each of several different states and with different host environments?” (Table 1). The details of the hosts are omitted here for space considerations but are available from the authors upon request.

These data indicate that the entire node takes on the order of 50 percent more power at full load and that the GPGPU adds on the order of 15–20 percent power consumption, even at rest, assuming one GPGPU card per processor. For T&E purposes, the authors would recommend something more on the order of one GPGPU per four to eight cores of a CPU.

GPGPU Programming in CUDA

Again, looking at the overall productivity issue, programming ease may easily outweigh power consumption and new hardware costs (Kepner 2004). While we do not want to analyze CUDA programming too stringently, the authors think it advisable to show the potential user some indication of what CUDA programming entails.

First, here is some FORTRAN code:

```
do j = jl, jr
  do i = jr + 1, ld
    x = 0.0
    do k = jl, j - 1
      x = x + s(i, k) * s(k, j)
    end do
    s(i, j) = s(i, j) - x
  end do
end do
```

Now, here is the same algorithm, implemented into CUDA:

```
ip=0;
for (j = jl; j <= jr; j++) {
  if(ltid <= (j-1)-jl){
    gpulskj(ip+ltid) = s[IDX(jl+ltid,
    j)];
  }
  ip = ip + (j - 1) - jl + 1;
}
__syncthreads();
for (i = jr + 1 + tid; i <= ld;
  i+=GPUL_THREAD_COUNT){
  for (j = jl; j <= jr; j++) {
    gpuls(j-jl,ltid) = s[IDX(i,j)];
  }
  ip=0;
  for (j = jl; j <= jr; j++) {
    x = 0.0f;
    for (k = jl; k <= (j-1); k++) {
      x = x + gpuls(k-jl,ltid) *
      gpulskj(ip);
      ip = ip + 1;
    }
    gpuls(j-jl,ltid) -= x;
  }
  for (j = jl; j <= jr; j++) {
    s[IDX(i,j)] = gpuls(j-jl,ltid);
  }
}
```

A critical factor, if not the most critical one, in heterogeneous programming is the need to understand which algorithms map well enough to the GPGPU to warrant the overhead costs of porting and maintaining them. For a more disciplined treatment of the programming environment and approach that will be useful, the reader is referred to the authors' Web sites on GPGPU processing (Davis 2009). NVIDIA also offers course materials online, and the authors willingly acknowledge the assistance that NVIDIA has given to them. Like all tasks, there seems to be a critical experience level required for reliable programming in this mode.

Other approaches to better computation/watt ratios

ELM moves data more efficiently

Many in the T&E community may be familiar with computing pioneer Bill Dally. He has been advancing a different approach to saving power during computation. Analyzing the power used on microcircuits, his team observed that most of the power was being used moving data around the chip. Because many of these movements were the nonoptimal artifacts of earlier VLSI designs, he and his Stanford team set out to make the data flows more power efficient (Dally et al. 2008).

Professor Dally's (ELM) project has sought high performance in the creation of a low-power and programmable embedded system. He has sought to reduce the very inefficient memory transfers by designing a chip composed of many efficient tiles and providing a full software stack. It is his intention that ELM will be able to reduce or eliminate the need of fixed function logic blocks in passively cooled systems.

The ELM team maintains that energy consumption in modern processors is dominated by supplying instructions and data to functional units. If interconnects benefit less than logic from advances in semiconductor technologies, driving the interconnects has accounted for an increasing fraction of the energy consumed. This may account for more than 70 percent of the energy consumed by the computing unit.

Providing a platform that can execute real-time computationally intensive tasks and still reduce the power used is the goal of the ELM architecture. This is being done in reaction to the fact that embedded systems, e.g., cell phones, are composed of microprocessors and fixed-function circuitry. Programmability for the system is provided by the microprocessor, but it is too inefficient to meet the computation, timing, and power constraints of many communication and multimedia protocols. This, in turn, requires fixed function logic to be added to embedded systems to provide the necessary performance. Unfortunately, this cannot be changed once the system has been fabricated.

ELM implementations are designed so that software replaces the fixed function hardware. This removes the inefficiencies associated with this programmability conundrum. Clearly, this is a good thing because software applications are more cost-effective to create and update than silicon and the concomitant power savings are still realized.

Ensembles, which are simple tiles, are made up of software managed memory (EM) and several Ensemble Processors (EPs). Prof. Dally maintains that these small tiles are much more energy efficient than large cores and offer more computation contexts for each die area. The

team is developing the tiled architecture using software to take advantage of the available computation resources. The rationale here is that a larger software up-front cost will be amortized over a program's lifetime.

Each EP can issue both an arithmetic and memory operation using a two-wide instruction. Load latencies are managed easily. Prefetching into the instruction registers prior to execution eliminates stalling on jumps. Some old parallelization techniques are used, e.g., the ELM architecture supports single-instruction multiple data execution within an ensemble. All EPs execute in lock step with instructions coming from a single instruction register file. This has effectively quadrupled the amount of instructions that can be stored.

These is a 64-entry, software-managed instruction register file that is available to the EPs. The register files are adequate to hold the inner loops of programs with little performance degradation. Reduced energy requirements are realized by having only one instruction fetch per cycle per EP.

The Stanford team reports that there can be power reductions of two orders of magnitude for individual operations on the silicon. In *Table 2*, Dally's team presents their data on power reductions (Balfour et al. 2008).

This approach shows much promise but may not be immediately applicable to the T&E community and may be encumbered by the, as yet demonstrable, capability of journeymen programmers to master the analytical techniques required for optimization. Further, the authors were not able to find any data that supported an analysis of overall power savings. In an analogous way, there is a temptation for GPGPU advocates to claim huge processing speedups for some restricted subroutine, but they are less inclined to say what the impact was on the total functioning code base that is actually needed by the user.

IBM's Blue Gene

IBM is also contributing to power reduction technologies in the form of the "big-iron" Blue Gene series of high performance computers. For its Blue Gene initiative, IBM integrated all of the putatively essential subsystems on a single chip, with each of the computational or communications nodes dissipating low power (about 17 W, including DRAMs). Low power dissipation enables the installation of as many as 1,024 compute nodes and the necessary communications nodes in the standard computer rack. This can be done in accordance with standard limits on electrical power supply and air cooling. As discussed earlier, the important performance metrics in terms of power (FLOPS per watt), space (FLOPS per square meter of floor space), and cost (FLOPS per dollar) have allowed

Table 2. Power savings using ELM.

Ensemble Processor			
Technology	TSMC CL013G	(V _{DD} = 1.2 V)

IBM to scale up to very high performance (Chiu, Gupta, and Royyuru 2005). The issue may be, “Was this done at the expense of general purpose accessibility?”

This is not a classical “general purpose” computer because it requires significant esoteric skills to make optimal use of its power. The compute nodes are attached to three parallel communications networks: peer-to-peer communications use a three-dimensional toroidal network, collective communications use a collective network, fast barriers use a global interrupt network, and external communications are provided by an Ethernet network. File system operations are handled by the I/O nodes on behalf of the compute nodes. Finally, there is a management net to provide access to the nodes for configuration, booting, and diagnostics.

The compute nodes in Blue Gene/L support a single user program using a minimal operating system. A limited number of POSIX calls are supported, and only one process may be run at a time. Green threads must be implemented to simulate local concurrency. C, C++, or FORTRAN are the supported languages and as is common with clusters, MPI is used for communication.

The Blue Gene/L system can be partitioned into electronically isolated sets of nodes to allow multiple programs to run concurrently. The major drawbacks seem to be that the hardware is not based on a commercially supported product, as are the cell processor implementations and the GPGPU accelerations, and on the potentially problematic programming environment.

Analysis

Out of scientific restraint, the authors have assiduously resisted the temptation to claim huge increases in

computational power or efficiencies in power consumption per unit computation. They note that while the NVIDIA processors in the 8800 through the C2050 series may have potential compute power that is nominally in the several hundred gigaFLOPS range, the issue of real interest is, “What will they do to accelerate the programs the T&E user needs?” In the authors’ case, early experiences on the simulations run by JFCOM speak to the evaluation segment of T&E because that is a major thrust at JFCOM.

The GPGPUs can attack some issues, most notably the spikes of activity occasioned by a data surge by the sensor being simulated or a new direction of travel for a large group. These spikes are tailor-made for resolution by GPU processing, bearing close resemblance to the visualization algorithms for which the GPU was designed. By easily handling the visualization (Lucas et al. 2007) and route-finding spikes (Tran et al. 2008), the GPGPUs do actually provide an effective overall doubling of effective computing for the cost of an approximately 30 percent increase in power. Clearly this is desirable at this level, and considering the newness of the approach, more impressive gains might be anticipated for later.

In the case of Joshua, one GPGPU for every eight cores was considered prudent, and experience has shown that the GPGPUs have not been insufficient to meet the needs imposed upon them. In this case, the power increase is more on the order of 5 percent, with the anticipated doubling of computational power. Should this ratio turn out to be valid in other, more constrained implementations, as described earlier, the benefits will be significant. Increased habitability, reduced heat signatures, increased battery life, reduced environmental stress on electronic components, and

other benefits would accrue with almost trivial energy costs.

Critically, the computing power that the T&E professionals need would be made available to them where they need it, on the range or in the field. This is not to say that the authors find that other approaches to heterogeneous high performance computing may not also hold promise. As with all new technologies, the costs in terms of availability, adoptability, and training must be kept in mind.

In more mundane settings, say a domestic computing center, the cost savings in power alone are significant. Because the numbers on power usage for large clusters such as Joshua are merely daunting in Virginia, in more remote areas such as the Maui High Performance Computing Center where they face electric rates that are literally multiples of what is common on the mainland, it is reasonable to look at the doubling of computational power as vital. It means that one's FLOPS per watt improvements may generate savings on the order of from \$2,500 per hour to \$5,000 per hour, at \$0.09 and \$0.20 per kilowatt hour, respectively, for the two centers.

Conclusions

T&E will face increasing demands for ever-growing computer systems. Many new technologies offer various paths to increasing computational power, while restraining the numerous and varied costs of power consumption. The authors maintain that even their conservative approach and carefully substantiated claims support the tenet that heterogeneous computing displays many attractive features of interest to the T&E community. □

DAN M. DAVIS is the director, JESPP Project, Information Sciences Institute (ISI), University of Southern California (USC), focusing on large-scale distributed DoD simulations. As the assistant director of the Center for Advanced Computing Research at Caltech, he managed Synthetic Forces Express, bringing HPC to DoD simulations. Prior experience includes work as a software engineer at the Jet Propulsion Laboratory and at a classified project at Martin Marietta. He saw duty in Vietnam as a cryptologist in the USMC, and he retired as a commander, cryptologic specialty, USNR. He received a bachelor of arts and a juris doctor degree in law from the University of Colorado in Boulder. E-mail: ddavis@isi.edu

DR. ROBERT F. LUCAS is the director of the Computational Sciences Division of ISI at the USC. There he manages research in computer architecture, VLSI, compilers, and other software tools. He's been the PI on the

JESPP project since 2002. Prior to joining ISI, he was the head of the High Performance Computing Research Department for NERSC at LBNL. Earlier he was the deputy director of DARPA's ITO and a member of the research staff of IDA's Center for Computing Sciences. Dr. Lucas received bachelor of science, master of science, and doctor of philosophy degrees in electrical engineering from Stanford University, Palo Alto, California. E-mail: rflucas@isi.edu

GENE WAGENBRETH is a systems analyst for parallel processing at the Information Sciences Institute at the University of Southern California, doing research in the Computational Sciences Division. Prior positions have included vice president and chief architect of Applied Parallel Research and Lead Programmer of Pacific Sierra Research, where he specialized in parallelization of FORTRAN programs. He is active in benchmarking, optimization, and porting of software, and has programmed on CRAY, SGI, Hitachi, Fujitsu, NEC, networked PCs, networked workstations, IBM SP2, as well as conventional machines. He received a bachelor of science degree in math/computer science from the University of Illinois, Champagne-Urbana. E-mail: genew@isi.edu

PAUL C. GREGORY, JR., is the Lockheed Martin senior program manager for modeling and simulation support task orders at the Joint Experimentation Directorate (J9) of the U.S. Joint Forces Command in Suffolk, Virginia. Mr. Gregory has supported J9 since August 1998 as an experiment planner, designer, control cell member, and as the contractor lead for the Joint Concept Development Pathway. Earlier, he retired from the Air Force as an electronic warfare officer in the F-4G Wild Weasel aircraft. He received a bachelor of science from the University of Tennessee, Knoxville, and a master of science degree at Embry-Riddle Aeronautical University, Long Beach, California. E-mail: paul.c.gregory@lmco.com
