13. SUPPLEMENTARY NOTES					
14. ABSTRACT We developed two computational network reconstruction methods, linear state space model and dynamic Bayesian network to infer transcriptional networks using the rat acute transcriptional time series of bolus administration of glucocorticoids. And this time series was re-profiled using Illumina gene expression BeadChip for a much broader coverage. We have tested multiple repeated injection models for inducing asynchronous regeneration in normal mouse muscles. Based on the analysis of injured muscles, we found that the reinjury model with 10 days in between two injuries lead to pathological damages that most closely resemble the muscle pathology observed in untreated mdx muscles and human DMD muscles. We are using the 10 day reinjury model to induce asynchronous regeneration in normal mouse muscles, and are using glucocorticoids to treat the injured muscles. Based on part of the work accomplished in this grant, we have been awarded several new grants focusing on studying glucocorticoid mechanism in treating DMD and asthma.

SYSTEMS BIOLOGY OF GLUCOCORTICOIDS IN MUSCLE DISEASE

Introduction

Duchenne muscular dystrophy (DMD) is the most common and incurable muscular dystrophy of childhood. Muscle regeneration fails with advancing age, leading to considerable fibrosis. Corticosteroid therapy in DMD has been shown to improve muscle strength and function both acutely and over long-time frames. The molecular mechanisms explaining the beneficial effect of glucocorticoids is unknown; and the beneficial response of DMD patients is enigmatic due to the deleterious wasting effects chronic glucocorticoids have on normal muscle. The goal of this proposal is to use computational systems biology approach to model the molecular responses, and to extend and validate the integration of signaling and transcriptional networks using our pre-existing high throughput mouse and rat data sets of transcriptional, proteomic, and PK/PD response to glucocorticoids and human neuromuscular diseases. We also use laboratory approaches to test the hypothesis that the effect of glucocorticoids on reducing inappropriate cross-talk in TGF β networks improves muscle regeneration. We anticipate that the computational models and experimental results resulted from the proposed research will provide a novel model for efficacy of steroids in DMD.

Body

Progress of Specific Aim 1

Specific Aim 1. Provide a multi-scale computational model on the integrated acute proteome (signaling) and transcriptional response regarding metabolic remodeling and TGF β cascades in muscle induced by glucocorticoids under bolus administration of glucocorticoids. (August 2009 – December 2010)

Re-profiling of rat acute transcriptional time series of bolus administration of glucocorticoids using Illumina BeadArray gene expression chip. (Year 2)

In order to effectively infer transcriptional networks, we have re-profiled the samples of the rat acute transcriptional time series of bolus administration of glucocorticoids using Illumina gene expression BeadArray chips. The cost was covered by a different funding resource. The old time series data were generated using Affymetrix U34A chip a number of years ago, this outdated chip contains only 5138 unique gene (8740 probe sets) while the new Illumina BeadChip contains 21675 unique genes/probes. From our initial analysis of the new Illumina time series, we have found many genes that are affected by glucocorticoids are in the Illumina chip but not in the old Affymetrix U34A chip (Figure 1 shows some examples). Although both state space model and Bayesian networks we used in our network reconstruction approach can use hidden variables to represent possible factors contributing to regulatory interactions that are not measured, introducing

Figure 1. Heat map of some transcripts that are contained in Illumina gene expression chip but not in Affymetrix chip and are significantly affected by glucocorticoids. Red color indicates up-regulated, and green for down-regulated.

excessive hidden variables may significantly increase the risk of model over-fitting. Given a larger number of measured transcripts in the new time series, we expect that we will obtain more reliable and complete network results.

Development of proposed linear state space model for genetic network reconstruction (Year 1 and 2)

We developed a prototype of the proposed wavelet/linear state space model. As described in the proposal, this approach consists of two components. The first component is gene modulization by wavelet feature extraction, extracting transient features using wavelet transform¹⁻³ from time series signals and modulizing the genes. The second component is molecular network construction, in which we estimate the structure and parameters of a molecular network to quantify the interaction relationships among the identified genes/gene modules. In the proposal, we planned to use two alternative approaches for the second component. Approach A uses dynamic Bayesian network (DBN) to estimate the parameters and conditional probability distributions in Eq. (1)⁴⁻⁹ (reported in the following section). Our newly proposed Approach B uniquely combines wavelet transform (trend transform) and linear regression for estimating the parameters of the linear regulation model (Eq. (2)).

$$\mathbf{Y}_{t+1} = \mathbf{G}\mathbf{Y}_t + \mathbf{K}\mathbf{U}_t + \mathbf{W}_t, (t = 1, 2, \dots, T-1) \quad (1)$$

$$\mathbf{X}_{t+1} = \mathbf{G}\mathbf{X}_t + \mathbf{K}\mathbf{U}_t, \mathbf{Y}_t = \mathbf{C}\mathbf{X}_t + \mathbf{W}_t, (t = 1, 2, \dots, T-1) \quad (2)$$

Figure 2. Simulation experiment on genetic network reconstruction using Approach B wavelet/linear regulation model. (a) Simulated gene expression of six genes and an external stimulus. (b) The regulatory relationship among the genes and the external stimulus. The weight of the lines indicates the strength of regulation.

We developed and tested the combined wavelet analysis and linear regression method (Approach B) on simulated data, and obtained promising results. We generated an interaction model (Figure 2b) consisting of six genes (each with a times sequence representing its change in response to an external stimulus) according to the linear Markov model with given parameters and an external stimulus. We simulated different types of the regulatory relationship among the genes and the external stimulus, including positive stimulation and negative inhibition, self-stimulation and self-inhibition, and gene with no interaction with all others (Figure 2b). The thickness of the lines indicates the regulatory strength (regulatory coefficient). Random noises were also added to each signal. Then, we used this method to estimate the regulatory coefficients using the *noisy* signals (i.e., $\mathbf{G}$, and $\mathbf{K}$ in Eq. (2) for wavelet/linear regression). Finally, we used the estimated coefficients to reconstruct the signals, and compared them to the original signals. The closer the reconstructed signals (smooth curves, without noise) are to the original signals (fluctuating curves, with noise embedded), the better the parameters

are estimated. Figure 2a shows that our wavelet/linear state space method accurately reconstructed the signals, and precisely estimated the regulatory strength. The results agree with our expectation that Approach B effectively reduces the impact of large amount of noise and capture change patterns, which makes the estimation of the regulatory strength and relationship more precise.

This part of the project is still ongoing; we are testing Approach B on the re-profiled rat acute transcriptional time series of bolus administration of glucocorticoids.

Development of proposed dynamic Bayesian network for genetic network reconstruction (Year 3)

We have also developed Approach A, dynamic Bayesian network (DBN), and we are applying it to reconstructing genetic networks based on the rat muscle acute or chronic glucocorticoid transcriptional time series data sets. DBN is a graphical model of repeated segments to represent stochastic process. A DBN with hidden Markov model is illustrated in Figure 3. DBN is the most advanced tool for analyzing dynamic process and building dynamic probabilistic model. We will use DBN with the Markov model to analyze the regulatory effects of genes represented in the transcriptional time series. Note that each node in Figure 3 represents a vector of variables, e.g., external stimuli, hidden state variables, or observations.

Figure 3. A general diagram of dynamic Bayesian network.

DBN has a number of advantages. It is suitable to model complex hierarchical relationships and relationships with nonlinear properties using dynamic time series data. In addition, DBN does not make any restrictive assumptions such as independency among variables and linear interaction. On the contrary, DBN faithfully evaluates all possible regulatory network structures and identifies the most optimal one that is best supported by the data. Therefore, DBN does not suffer from common problems existing in most conventional statistical methods, such as confounding variables.

Despite the important advantages of Bayesian network method, it has a major challenge, it demands a large sample size that is often hard to obtain.¹⁰⁻¹² To maintain a balance between variable size and sample size and avoid overfitting, we selected salient variables that have the strongest influence on the outcomes of interest based on the mutual information criterion, $m(X, Y) = \sum_{x,y} P(x, y) \log \left[\frac{P(x, y)}{P(x)P(y)} \right]$, where $P(x, y)$, $P(x)$, and $P(y)$ are, respectively, the joint and marginal probabilities of variable X and Y , and X and Y are variable and outcome. If variable X is independent from outcome, Y , the mutual information is zero. The larger the mutual information is, the stronger the influence of X on Y is. Because that we are modeling a dynamic process, we use the generalized mutual information $m(X, Y) = \sum_{t=1}^T \sum_{x,y} P_t(x, y) \log \left[\frac{P_t(x, y)}{P_t(x)P_t(y)} \right]$, where $P_t(x, y)$, $P_t(x)$, and $P_t(y)$ are, respectively, the joint and marginal probability of variable X and Y at time point t . This generalized mutual information given equal weight to those at every time point. We are trying to select a set of variables according to the available number of samples and time points in the time series, so that our DBN model has a sound statistical support by the available samples. Moreover, we have developed a novel variable ranking and selection method, the Bayesian Network with Variable Combination (BNVC).¹³ We will also use BNVC to rank the candidate input variables (genes) and select the variables that have the strongest influence on the desired outcomes.

We are using the recently developed DBN software to analyze the rat muscle acute or chronic glucocorticoid transcriptional time series data sets. The main results are the transition matrix $P_t(\mathbf{X}_{t+1}|\mathbf{X}_t)$ where $\mathbf{X}_t$ is the set of selected variables (genes) at time point, t . The transition matrix is the probabilistic trajectory, and it describes the regulatory effect of selected variables (genes) at the current time point on the values of variables (genes) at the next time point. With the transition matrix, we can derive genetic regulatory networks.

Progress of Specific Aim 2

Specific Aim 2. Model the beneficial effects of daily bolus vs. detrimental effects of chronic administration of glucocorticoids.

As discussed above, since we recently re-profiled the rat acute transcriptional time series set and two computational network reconstruction algorithms, we are working on network reconstruction using the new time series and the algorithms. The results will be needed to complete the proposed work in Aim 2, the work on Aim 2 is ongoing.

Identification of commonly shared canonical pathways related to DMD pathogenesis at different age/disease stages across human DMD, and mouse and dog models of DMD (Year 2)

Aim 2d is to find which genes potentially lead to asynchronous regeneration in Duchenne muscle and how glucocorticoids rescue the issue. The more we study on this topic, the more we realize that it is important to trace the upstream of the disease pathogenesis, i.e., the genes that are affected in the early or presymptomatic stage (such as fetus or infant) and may become seeds leading to broader molecular deregulation. Studying these upstream genes not only will increase our understanding of how the disease is initiated and develop, but also it is important for design better glucocorticoids regimen.

Our lab has multiple muscle transcriptional profiling data sets of human DMD, and animal DMD animal models (e.g., mouse mdx, and dog GRMD (Golden Retriever Muscular dystrophy)) that contain subjects of different age stages (see list below). Based on these data, we have identified a series of commonly shared canonical pathways related to DMD pathogenesis at different age/disease stages across human, mouse and dog (Table 1). Two age stages are matched across human, mouse and dog: presymptomatic/young stage (human 0-2 year-old, mouse 1 week-old, dog 4-9 week-old), postsymptomatic/old stage (human 2-10 year-old, mouse 3 week-old, dog 6 month-old).

List of transcriptional data sets used in this analysis:

1. Multi-group human neuromuscular diseases: 10 groups, 109 samples, profiled on Affymetrix Human Genome U133 plus 2.0 microarray. The data set includes DMD and control subjects.
2. Early stage human DMD muscle time series: control and DMD fetus and infant subjects, total 11 samples, profiled on Affymetrix Human Genome U95Av2 microarrays.
3. Mdx mouse early muscle necrosis time series: wild type and mdx mice, 4 age groups (5 days, 2, 3, and 6 weeks), total 24 samples, profiled on Affymetrix Mouse Genome 430 v2.0 microarray.
4. GRMD dog muscle time series: wild type and GRMD dogs, 3 muscle types (vastus lateralis, cranial sartorius, long digital extensor), 2 age groups (4-9 weeks and 6 months), total 72 samples, profiled on Affymetrix Canine Genome 2.0 microarray.

Table 1. List of commonly shared canonical pathways related to DMD pathogenesis at different age/disease stages across human, mouse and dog.

Production of Nitric Oxide and Reactive Oxygen Species in Macrophages	GM-CSF Signaling
Germ Cell-Sertoli Cell Junction Signaling	PI3K Signaling in B Lymphocytes

Leukocyte Extravasation Signaling	Actin Cytoskeleton Signaling
LXR/RXR Activation	RhoA Signaling
Antigen Presentation Pathway	Ephrin Receptor Signaling
Molecular Mechanisms of Cell Proliferation	IL-4 Signaling
Role of NFAT in Muscle Hypertrophy	Cellular Effects of Sildenafil (Viagra)
α -Adrenergic Signaling	VEGF Signaling
Integrin Signaling	Complement System
Fibrosis	HGF Signaling
P2Y Purigenic Receptor Signaling Pathway	Fc γ Receptor-mediated Phagocytosis in Macrophages and Monocytes
	fMLP Signaling in Neutrophils
	Regulation of Actin-based Motility by Rho

All of the listed pathways (Table 1) are sporadically or not affected at the presymptomatic stage in human, mouse and dog, but they are much more broadly affected at the postsymptomatic stage.

Development of experimental model of repeated injury to induce asynchronous regeneration in normal mouse muscle (Year 1, 2 and 3)

We have made significant progress in testing and comparing several different experimental models of multiple staged injections of notexin for inducing asynchronous (Figure 4). To date, 13 mice were bilaterally injected in gastrocnemii, with 0, 1, 2, 4, 5, or 10 days between the first and second injections (at least 2 mice/group). The mice were given BrdU on the third day after the second injection, and were sacrificed 13 days after the second injection (the time when regeneration due to the second injection should largely be complete). The purpose of this spacing was to see if the stage of the regenerating muscle from the first injury resulted in different effects on the second injury. The stages of the first injury when the second injection was placed were myoblast activation, myoblast proliferation, myoblast differentiation, myotube fusion, and myotube maturation, respectively.

Figure 4. Study design for feasibility test of repeated injections for inducing asynchronous regeneration in normal mouse muscle. As indicated in the figure, spacing between the two injections was designed based on interfering with specific stages of regeneration by the second injection/injury.

Placement of repeated injection of notexin to muscles.

We learned a few methods that are important for giving proper repeated injections of notexin to muscles. We found that dipping the needle in tattoo dye resulted in the surface of the gastrocnemius being covered in dye. The dye on the muscle surface interfered with our ability to place the successive injection accurately because we could not see the original insertion site and only portions of the injection tract through the muscle. Additionally, the tattoo dye on the surface of the muscle dried into a layer of plastic that inhibited proper wound healing. Although we were able to remove the majority of this excess dye during the second surgery, the skin

of some of the animals did not heal together properly. This may have also caused an immune reaction and slowed the muscle regeneration – it is not possible for us to determine the specific effects the excess tattoo dye had. As a result of these two complications, analyzing the tissues has been an extremely slow process. Importantly, we have found that we cannot be sure if the tissue section we are analyzing has been damaged more than once. Based on all of these observations, we mixed tattoo dye with the notexin and injected into the muscle. While dye dispersion through the tissue may not be to the same extent as the notexin, the dye will mark at least a portion of the tissue damaged. Each round of damage will be marked with a different color tattoo dye to enable us to distinguish regions of regeneration. Including the tattoo dye in the injection material will guarantee that the area of the tissue being analyzed has overlapping regions of regeneration because we will be able to see more than one color of dye particles. Notably, we have tested the tattoo dyes and found that they do not interfere with fluorescent immunohistochemical analysis of regeneration.

Evidences that show repeated injection induced muscle injuries and asynchronous muscle regeneration in normal mouse muscles

Using the gastrocnemii isolated from the repeated injection area, we sectioned the tissues for histological analysis. We analyzed the images from H&E, Van Gieson, and BrdU stained slides, and this work is still ongoing. Based on the following evidences, our initial analysis showed that we have successfully interfered with the regeneration process in muscles from the groups where the second injection occurred during a later stage of regeneration (e.g. 10 day reinjury group).

1. The tissues that should be completely regenerated were still undergoing rounds of regeneration (Figure 5)
2. An increase in degenerating fibers was found in groups with more than one day between injections (Figure 6).
3. We evaluated fiber diameter sizes, focusing solely on the fibers that have regenerated at least one time (we measured only fibers with centralized nuclei). We found that the 10 day reinjury group had smaller fibers and more of these small fibers than any other group, while still maintaining larger fibers. This greater range in fiber sizes mimics what is seen in patients with DMD (Figure 6).
4. We used Van Gieson staining to visualize connective tissue, and to determine if any of the reinjury groups have an increase incidence of fibrosis. Cursory examination suggests that the muscle of the reinjury groups with more days in between two injuries have an increase in collagen (Figure 7).

Figure 5. Simultaneous muscle regeneration and degeneration observed in repeated injured muscles. This gastrocnemius from the day 10 reinjury model/group still had regeneration and degeneration at 13 days after the second injury. Normal muscles with single injury should almost fully regenerate at this stage. However, in this case, there is an increase in degenerating fibers (yellow arrow) and regeneration is still ongoing: presence of myoblast fusion (blue arrow) and dividing myoblasts (green arrow).

5. Fibrosis is a major concern in DMD muscles because fibroblasts migrate into the muscle tissue and replace the area that had been used to generate contractile force with connective tissue. In order to determine if the timing of the reinjury affects the amount of fibrosis, we performed Van Gieson staining to measure the amount of interstitial connective tissue present in muscle sections. We analyzed the images of the stained muscle sections using Image J software to determine the percentage of muscle tissue per image field that is occupied by connective tissue. We found that the 10 day reinjury group has the greatest increase in connective tissue compared to other groups (Figure 8). The 5 days injury

Figure 6. Cumulative frequency distribution of centrally nucleated fibers shows that 10 day reinjury group has the smallest and largest range of fibers. y-axis is cumulative frequency distribution, x-axis is Feret's minimum diameter (um).

Figure 7. Significant increase of fibrosis due to repeated injuries. Considerable fibrosis (light pink staining between fibers and dark red) exists in this image of gastrocnemius from an 8 wk old BL6 mouse from the day 10 reinjury group. Although the analysis of the Van Gieson data is in progress, the preliminary data suggest there is a significant increase in fibrosis in the day 10 reinjury group over groups with 2 or fewer days between injuries.

group also had an increase in interstitial connective tissue. Next, we tried to determine if this change in connective tissue was permanent. When connective tissue becomes a permanent fixture of the muscle it is considered fibrosis, which is characterized by a transition from collagen III, a plastic collagen that is often involved in remodeling, to collagen I. To determine if this switch is occurring, we stained for collagen III and collagen I. We found that there was some degree of conversion from collagen III to collagen I in all groups except the 0 day and 10 day reinjury. This is understandable because the 0 day injury group regenerates its muscle in the stage-specific manner that produces successful regeneration. There is a potential explanation for the lack of collagen I in the 10 day reinjury group: fresh rounds of the regeneration-degeneration cycle are ongoing – resulting in continued remodeling inhibiting conversion of collagen III to collagen I.

6. We have also noticed that two of the samples from the 10 day reinjury group have calcified fibers (Figure 9). We are planning to look further into what their presence means. The calcified fibers are also seen in human DMD muscles.

Figure 8. There is an increase in interstitial connective tissue in 10 day reinjury group. y-axis is ratio of fibrosis to total tissue area per field.

Laser capture microdissection (LCM) for sectioning muscle regions with different regeneration stages induced by repeated injury

We used LCM to section the areas from staged injuries, and completed RNA and protein isolation from the sectioned tissues in order to measure the levels of various markers of regeneration, adipogenesis, fibrosis, and regeneration. This will further our understanding of the molecules involved in the cross-talk between neighboring injuries and elucidate the localization of these molecules within the injury microenvironments. Whole genome mRNA expression profiling has been performed on microdissected sections captured from two injured adjacent regions and the middle area to identify molecular signature in each region (Figures 10B, 10C and 10D) and thus evaluate their involvement in cross-talk between neighboring injury foci. We have sectioned a representative of each of the reinjury groups for LCM. These representatives were chosen because at least one, preferably both, of the tattoo dyes that labeled the injection tracts was seen in our aforementioned H&E images. LCM was used to isolate small areas of tissue associated with each individual injection, as well as the region between. From these sections we have purified good quality RNA. We are analyzing the mRNA profiling data determine if we can elucidate what molecules are involved in crosstalk. This work is being partially supported by other funding resources.

Figure 9. Calcified fibers were seen in 10 day reinjury muscle samples.

Show that daily glucocorticoids result in more successful regeneration in both normal asynchronous regeneration and mdx mice.

Based on the above results suggesting that we are able to create some of the hallmarks of DMD using repeated injury model, we are planning to perform Aim 3b spacing injuries using the 10 day reinjury model. The IACUC protocol for this experiment has been submitted and is currently under review. We are using glucocorticoids in treating these repeated injury groups.

In addition, we have conducted a study to determine the effects of time of glucocorticoid administration with respect to the animals' endogenous circadian rhythm (we used the light and dark cycle of the animal facility as our benchmark). Animals were treated with prednisone orally at lights ON (circadian nadir) or lights OFF (circadian peak) for five weeks. While we did not see a significant difference in our functional assays, we found histologically that administering glucocorticoids at the animals' endogenous circadian nadir, rather than its endogenous peak, resulted in a significant increase in fiber size and a significant decrease in inflammation and fibrosis (Figure 11). This result has been included in one of our recent publications¹⁴

Figure 10. Laser capture microdissection of muscle regions with different regeneration stages.

Additional ongoing

experiments:

We will be continuing our histological characterization of these tissues. We plan to assess the inflammation and continued regeneration-degeneration seen in the 10 day reinjury. We will use a general macrophage stain to measure the degree of inflammation in muscle sections.

Then we will further characterize the macrophages present by staining for markers of specific macrophage types because some macrophages (type 2) are

necessary for regeneration. We also plan to do a stain specific for degenerating fibers to confirm the increase we saw in the H&E counts we previously performed.

Figure 11. Effect of timing of administering glucocorticoids. The muscles of mice treated at the endogenous circadian nadir (A) results in significantly larger fibers and less inflammation and fibrosis compared to treated at the endogenous circadian peak (B).

Key Research Accomplishments

1. We have successfully developed and tested the computational genetic network reconstruction algorithms proposed in Aim 1. Using simulation data, we showed that the methods are very effective in reducing noise and estimating regulatory strength and relationship among genes.
2. We have re-profiled rat time series rat acute transcriptional time series of bolus administration of glucocorticoids using Illumina gene expression BeadChip that measures four times of genes relative to the old Affymetrix chip used to generate the existing time series. We are using the new Illumina time series to reconstruct regulatory networks as originally proposed in the grant.
3. By integrating our pre-existing multiple muscle transcriptional profiling data sets of human DMD, mouse mdx, and dog GRMD, we have identified a series of commonly shared canonical pathways related to DMD pathogenesis at different age/disease stages across human, mouse and dog. All these pathways (Table 1) are sporadically or not affected at the presymptomatic stage in human, mouse and dog, but they are much more broadly affected at the postsymptomatic stage.
4. We have tested multiple injection models for inducing asynchronous regeneration in normal mouse muscle. Based on the results reported above, we found the reinjury model with 10 days in between two injections of notexin lead to pathological damages that most closely resemble the muscle pathology observed in mdx. We plan to use this injury model to induce asynchronous muscle regeneration, and then use the injured muscles in testing the effect of glucocorticoids in resynchronizing regeneration.
5. We have tested and compared the effect of timing of glucocorticoids administration with respect to the animal's endogenous circadian rhythm. Our preliminary results show significant histological difference in terms of success of muscle recovery from repeated injuries in comparing muscles treated with prednisone orally at lights ON (circadian nadir) or lights OFF (circadian peak) for five weeks. This result implies the connection of the action of glucocorticoid drug and the circadian rhythm.

Reportable Outcomes

1. Evolved from this award, an MDA grant has been awarded, it is a comprehensive project with emphasis on biological validation: Mechanism of steroid action in DMD, grant # 15914, 1/1/2010 – 12/31/2012. The goal is to understand the effects of glucocorticoids on muscle and enable the development of better targeted and more effective therapies for Duchenne muscular dystrophy dynamically. This MDA grant proposal is led by Dr. Eric Hoffman, and it supports a doctoral student's dissertation project.

2. The PI, Dr. Zuyi Wang, was awarded a grant in June 2011 by PPMD (Parent Project Muscular Dystrophy), a private foundation dedicating to DMD research. The purpose of the grant is to prioritize FDA-approved drugs for human and animal testing for DMD. The work in this grant has strong connections with the newly awarded PPMD grant in many aspects.
3. The PI, Dr. Zuyi Wang, was awarded a pilot grant in February 2011 by Clinical and Translational Science Institute at Children's National (CTSI-CN) funded by NIH CTSA program. This pilot grant focuses on studying glucocorticoids action in treating asthma. Chronic inflammation is a shared feature in many disorders of various tissues (including muscle and lung) for which glucocorticoids provide the standard of care. The PI's research on glucocorticoid action in muscle has provided valuable resources of experiences and methods to the proposed study on asthma.
4. The PI, Dr. Zuyi Wang, received two grants from the Junior Faculty Fund program of Center for Genetic Medicine/Department of Integrative Systems Biology in 2011 and 2012 respectively. The two grants are designed to establish in vitro model for studying the effects of glucocorticoid drugs in human asthmatic airway epithelial cells. This is a systems biology study of molecular effects on glucocorticoid drug action in asthma.

"Δ-9,11 steroidal compounds dissociate NF-κB transrepression from GRE-mediated transactivation." *J. Pharmacology and Experimental Therapeutics*, 2012, in press.

Conclusion

We developed the two proposed computational network reconstruction methods, linear state space model and DBN, to infer transcriptional networks using the rat acute transcriptional time series of bolus administration of glucocorticoids. We have re-profiled the samples of the rat acute transcriptional time series of bolus administration of glucocorticoids using Illumina gene expression BeadChip to obtain a much larger number of measured genes. It is well recognized that reconstructing large scale genetic network is a very complex task. One major obstacle is that the transcriptional microarray data often contain considerable noise that may lead to false estimation of regulatory relationships among genes. We are testing and comparing the two developed methods on the transcriptional time series data sets about the performance in reliably and correctly reconstructing the regulatory networks. This work is ongoing.

Through integrating multiple muscle data sets of human DMD, mdx and GRMD, we have identified a series of commonly shared canonical pathways related to DMD pathogenesis at different age/disease stages across human DMD, mouse and dog models of DMD. These canonical pathways are very differentially affected at the presymptomatic and postsymptomatic stages, we are studying these pathways and relevant genes to gain in depth understanding of disease progression.

We have tested multiple injection models for inducing asynchronous regeneration in normal mouse muscle. Based on the analysis of injured muscles, we found the reinjury model with 10 days in between two injuries lead to pathological damages that most closely resemble the muscle pathology observed in untreated mdx muscles and human DMD muscles. We are using the 10 day reinjury model to introduce asynchronous regeneration in normal mouse muscle and study the effect of glucocorticoids in resynchronizing the regeneration.

Finally, based on part of the work accomplished in this grant, we have been awarded several new grants focusing on studying glucocorticoid mechanism in treating DMD and asthma, and published one journal article and one conference abstract.
