14. ABSTRACT Using the TRACK-TBI (<i>Transforming Research and Clinical Knowledge in TBI</i>) dataset we have created an Information Commons that integrates clinical, imaging, proteomic, genomic, and outcome biomarkers based upon the domains of the TBI Common Data Elements. The comprehensive TBI-CDE outcome measures allow for analyses of biomarker associations with a variety of measures. Available prognostic models have been evaluated against new prognostic models for TBI and found to be unsatisfactory using a multivariate approach that goes beyond the crude definitions of Mild, Moderate and Severe TBI. The latest neuroimaging methods including Quantitative CT, DTI, and resting-state functional MRI are surpassing other methods for predicting TBI patient outcomes. In emergency settings where high resolution neuroimaging is not available, rapid measurement of proteomic markers is appearing to be a valuable adjunct to current screening practices for ruling out TBI. Most importantly improving the collection of biomarkers in TBI patients will be vital to the design of future clinical trials. For future plans during Year 2 we are on target to complete the original tasks to conduct multivariate diagnostic and prognostic modeling across all aims and CDE domains.

1. INTRODUCTION

Traumatic Brain Injury (TBI) remains one of the greatest unmet needs in military and civilian medicine. The overall goal of the study is extensively analyze the *existing* data set from the multicenter pilot study entitled TRACK-TBI: *Transforming Research and Clinical Knowledge in TBI*. TRACK-TBI represents the largest multivariate TBI database across the injury spectrum from concussion to coma with CT/MRI imaging, blood biospecimens and outcome assessments. The DOD TRACK-TBI project is undertaking more extensive analysis of this highly granular cohort of TBI subjects. This work is vital to advancing our understanding of TBI and improving prognostic methods to identify individuals at risk for persistent cognitive and psychological health disorders following TBI. This is being achieved by the following aims:

Aim 1: To develop improved prognostic, diagnostic and outcome models for TBI.

Aim 2: To identify neuroimaging biomarkers for diagnosis and prognosis in TBI.

Aim 3: To identify proteomic and genomic associations with TBI phenotypes.

2. KEYWORDS

Traumatic Brain Injury; Common Data Elements; Prognosis; Outcomes

3. OVERALL PROJECT SUMMARY

Aim 1. To develop improved prognostic, diagnostic and outcome models for TBI.

Task 1: Cleaning baseline data.

Progress: Baseline data has been cleaned and relational inconsistencies corrected on schedule. This progress has enabled us to move along with the other tasks within Aim 1.

The details of the data cleaning results are provided in a 373 page report entitled “**TRACK-TBI Summary Statistics for Data Curation**” (Appendix A). This report also serves as a reference guide for current and future investigators conducting analyses using the TRACK-TBI Pilot Dataset. We also plan to submit this guide to FITBIR.

Task 2: Prognostic modeling.

Subtask 1: Validation of existing prediction models on the TRACK TBI data set.

Progress: Two existing models for predicting outcomes in mild TBI we validated with the TRACK-TBI and found to perform unsatisfactorily (Lingsma et al, 2014). A reprint of the published manuscript is provided in Appendix A.

Although the majority of patients with mild traumatic brain injury (mTBI) recover completely, some still suffer from disabling ailments at 3 or 6 months. We validated existing prognostic models for mTBI and explored predictors of poor outcome after mTBI. We selected patients with mTBI from TRACK-TBI Pilot, an unselected observational cohort of TBI patients from three centers in the United States. We validated two prognostic models for the Glasgow Outcome Scale Extended (GOS-E) at 6 months after injury. One model was based on the CRASH study data and another from Nijmegen, The Netherlands. Possible predictors of 3- and 6-month GOS-E were analyzed with univariate and multi-variable proportional odds regression models.

Of the 386 of 485 patients included in the study (median age, 44 years; interquartile range, 27-58), 75% (n = 290) presented with a Glasgow Coma Score (GCS) of 15. In this mTBI population, both previously developed models had a poor performance (Figure 1) with area

under the receiver operating characteristic curve, 0.49 [0.43–0.70]). The CRASH models performed poorly (Figure 2.) in the total mTBI population, including GCS 15 (AUROC basic model, 0.49; 95% CI, 0.43–0.70; AUROC CT model, 0.49; 95% CI, 0.42–0.66). However, performance was very well (Figure 3) with AUROCs of 0.90 (95% CI, 0.82–0.97; basic model) and 0.91 (95% CI, 0.85–0.98; CT model) in the population they were developed on. The proportion of unfavorable outcome in TRACK-TBI Pilot was overestimated by most models. For example, the predicted proportion of patients with unfavorable outcome by the CRASH CT model was 12%; however, the actual observation of unfavorable outcome at 6 months was 8%.

In multivariable analyses, the strongest predictors of lower 3- and 6-month GOS-E were older age, pre-existing psychiatric conditions, and lower education. Injury caused by assault, extracranial injuries, and lower GCS were also predictive of lower GOS-E. Existing models for mTBI performed unsatisfactorily. Our study shows that, for mTBI, different predictors are relevant as for moderate and severe TBI. These include age, pre-existing psychiatric conditions, and lower education. While development of a valid prediction model for mTBI patients will require additional subjects and further research efforts, the current study results will help to inform and guide this work.

Figure 1. Calibration plot of Nijmegen Jacobs combined model in 386 patients with GCS 14-15. X-axis shows predicted probabilities by the model in quintiles of patients (triangles with horizontal lines as 95% confidence intervals); y-axis shows observed probabilities. Dotted diagonal represents perfect predictions. Spikes along the x-axis are numbers of patients with favorable and unfavorable observed outcomes. ROC, receiver operating characteristic.

Figure 2. Calibration plot CRASH computed tomography model. X-axis shows predicted probabilities by the model in quintiles of patients (triangles with horizontal lines as 95% confidence intervals); y-axis shows observed probabilities. Dotted diagonal represents perfect predictions. Spikes along the x-axis are numbers of patients with favorable and unfavorable observed outcomes. ROC, receiver operating characteristic.

Figure 3. Calibration plot CRASH computed tomography model (original population). X- axis shows predicted probabilities by the model in quintiles of patients (triangles with horizontal lines as 95% confidence intervals); y-axis shows observed probabilities. Dotted diagonal represents perfect predictions. Spikes along the x-axis are numbers of patients with favorable and unfavorable observed outcomes. ROC, receiver operating characteristic.

Subtask 2: Univariable analysis of possibly relevant predictors of outcome in mild TBI

Progress: This work is proceeding as planned. As results continue to take shape they are being prepared for publication (Cooper et al.; Lingsma et al). Table 1 shows that most baseline variables had very few missing values. Alcohol intoxication was missing in 60% as it was not measured. Similarly patients discharged from the Emergency Department do not get included in trauma registries and almost 40% did have scores for the AIS and ISS or extracranial injury details

GCS, Glasgow Coma Scale; TBI, traumatic brain injury; ISS, Injury Severity Score; AIS, Abbreviated Injury Score;

In univariate analyses (Table 2), we identified a large number of characteristics as potential predictors of outcome both 3- and 6-month GOS-E: age; cause of injury; GCS; pupil reactivity; psychiatric medical history; hypoxia; hypotension; education; ISS; extracranial injury; SAH; midline shift; and third ventricle obliteration and contusions (all $p < 0.30$ for both 3- and 6-month GOS-E; Table 4). Some predictors had a different effect on 3-versus 6-month outcome. A GCS of 13 or 14 was a strong predictor for a lower 6-month GOS-E (odds ratio [OR] = 0.3; $p = 0.015$), but less predictive for lower 3-month GOS-E (OR = 0.5; 0.6; $p = 0.299$). In contrast, the CT characteristics were more predictive of 3-month outcome, compared with 6-month outcome (e.g., SAH: 3-month OR = 2.2, $p < 0.001$; 6-month OR = 1.3, $p = 0.224$).

Table 2. Univariate Predictors of 3 and 6 month GOSE-E (n=386).

Predictors	Common OR (95% CI) (3 months)	p value	Common OR (95% CI) (6 months)	p value

Subtask 3: Multivariable modeling of predictors identified in the univariable analysis

Progress: Multivariable modeling approaches are moving ahead as planned. Several papers demonstrate the utility of multivariable approaches for integrating TBI data (Lingsma et al, 2014; Ferguson et al., submitted; Pirracchio et al., submitted; Cooper et al., in-preparation).

In multivariable analyses (Table 3, Lingsma 2014), the strongest predictors of both lower 3- and 6-month GOS-E were older age (OR, 1.2; $p < 0.001$), history of psychiatric conditions (OR = 2.2; 2.4; $p < 0.001$), and lower education (OR, 0.4; 0.8; $p < 0.05$; Table 4). Injury

caused by assault and extracranial injury were important predictors of poorer outcome at both time points ($p = 0.05$ – 0.1). Finally, a lower GCS was predictive of lower 6-month GOS-E (OR, 0.3–0.4; $p = 0.039$).

Table 3. Multivariable Predictors of 3- and 6-Month Ordinal GOS-E.

Predictor	Common OR (95% CI) (3 months)	p value	Common OR (95% CI) (6 months)	p value
Age (per 10 years)	1.2 (1.1–1.4)	<0.001	1.2 (1.1–1.4)	<0.001

Subtask 4: Development of a preliminary prognostic model for mild TBI

Progress: The prognostic modeling approaches are moving ahead on several fronts as presented in this section and in Aim 3, Tasks 3 through 5 where we have harmonized the dataset across domains.

We have also explored novel and robust machine learning tools, in addition to the more traditional prediction modeling approach of Lingsma and colleagues. We identified clinically important predictors among a set of risk factors using a variable importance analysis conducted based targeted maximum likelihood estimators (TMLE) and on collaborative targeted maximum likelihood estimators (cTMLE), a machine learning method that optimizes the estimate of an association in the presence of potentially numerous confounders. As our analysis is focused on mild TBI, we included only patients with complete 3-month GOSE, and mild TBI as defined by the clinical standard of ED admission GCS of 13 to 15. Three different populations were considered separately: 1) the overall population ($n=365$); 2) the population of patients with genetic information ($n=261$); and 3) the population of patients without any PTSD 6 months after injury ($n=188$).

The primary outcome measure was the 8-point GOSE at 3 months post-injury, obtained through Secondary outcome measures included GOSE at 6 months, mortality at hospital discharge and 3-month outcome, as well as presence of post-traumatic stress disorder (PTSD) symptoms measured by the PTSD Checklist (civilian version, PCL-C) and classified by the Diagnostic and Statistical Manual of Mental Disorders, 4th Edition (DSM-IV) PTSD criteria at 6 months.

The goal was to estimate variable importance measures (VIM) with potential relevant clinical interpretations for many potential competing causes of the outcome which can be categorized as 1) pre-injury factors (e.g., age, gender, medical history, prior anticoagulant drugs, psychiatric history, previous TBI, educational level, marital status, employment status); 2) injury-related factors (e.g., trauma mechanism, PTA, loss of consciousness), 3) clinical factors (e.g., GCS, Injury Severity Score, heart rate, blood pressure, oxygen saturation, temperature) ; 4) biological factors (e.g., hemoglobin, platelet count, blood glucose); 5) and radiological factors. Information concerning some genotypic single nucleotide polymorphisms such as the ankyrin repeat and kinase domain containing 1 (ANKK1) candidate gene (rs1800497) involved in dopamine transmission of the dopamine D2 receptor and the Apolipoprotein E (ApoE) gene (rs7412, rs429358) were available for 270 patients. The variables explored as potential risk factors had to be dichotomized as follows: Marshall grade =1 vs. >1; Rotterdam grade 02 vs. >2; GCS=15 vs. <15; Systolic blood pressure <90 mmHg vs. ≥90 mmHg; Heart rate <100bpm vs. ≥100bpm; respiratory rate>18 cpm vs. ≤18cpm; Oxygen saturation<94% vs. ≥94%; ApoE polymorphism E2/E4, E3/E4, E4/E4 vs. others; and ANKK1 polymorphism T/T vs. others.

Based on cTMLE, two characteristics concerning patients' medical history were associated with a poor functional outcome as measured by risk difference (RD): history of psychiatric disease (RD=-0.103 [-0.156; -0.050], $p<0.001$) and history of liver disease (RD=-0.176 [-0.215; -0.136], $p<0.001$). The fact to be unemployed at the time of trauma was also associated with a lower value of the 3-month post-injury GOSE (RD=-0.066 [-0.113; -0.019], $p=0.010$). On the contrary, the fact to be married or living together at the time of injury tended to be associated with a better outcome (RD= 0.040 [-0.005; 0.084], $p=0.080$). At hospital admission, a tachycardia as defined by a heart rate >100bpm (RD=-0.045 [-0.083; -0.006], $p<0.001$) was associated with the 3-month post-injury GOSE. CT scan abnormalities, as evaluated by the Marshall (RD=-0.107 [-0.153; -0.062], $p<0.001$) and the Rotterdam (RD=-0.081 [-0.127; -0.036], $p<0.001$) classifications, were found to be significantly associated with the 3-month post-injury GOSE.

The same analysis was performed in the subsample of patients without PTSD at 6 months post-injury (Table 4). This led to similar results for the Marshall grade (RD= -0.205 [-0.275; -0.135], $p<0.001$), the Rotterdam grade (RD=-0.150 [-0.198; -0.103], $p<0.001$) and the history of hepatic disease (RD=-0.107 [-0.162; -0.052], $p<0.001$), which remained the most important predictors for the 3-month post-injury GOSE. However, when only considering the patients without PTSD at 6-months post-injury, the impact of being married or living together status (RD=0.017 [-0.038; 0.071], $p=0.545$), the employment status (RD=-0.063 [-0.130; 0.003], $p=0.063$) as well as for the history of psychiatric disorders (RD=-0.045 [-0.114; 0.024], $p=0.200$) on the 3-month GOSE were no longer significant.

Of the 270 patients with genomic information, the ANKK1 polymorphism T/T was found to be negatively associated with the 3-month post-injury GOSE (RD = -0.467 [-0.879; -0.056], $p=0.026$). On the contrary, no significant association was found between the polymorphism of the ApoE gene and the neurological outcome (RD = 0.001 [-0.307; 0.308], $p=0.997$) (Table 3).

These findings confirm the power of an automated cTMLE procedure that can target model selection via machine learning to estimate variable importance measures in complicated, high dimensional data.

Table 4. Variable Importance Measure results based on cTMLE. The estimates are adjusted for all measures confoundings and obtained using collaborative targeted maximum likelihood estimation. RD: risk difference; 95%CI: 95% confidence intervals; Apo E: Apolipoprotein

Task 3: Cleaning outcome data.

Progress: Outcome data has been cleaned and relational inconsistencies corrected on schedule. This progress has enabled us to move along with the other tasks within Aim 1. The details of the data cleaning results for outcomes data are provided beginning on page 273 of the attached report entitled "TRACK-TBI Summary Statistics for Data Curation" (Appendix A). This report also serves as a reference guide for investigators conducting analyses using the TRACK-TBI Pilot Dataset.

Task 4: Outcome analyses.

Subtask 1: Descriptive statistics and statistical assumption testing.

Progress: We are making progress with our descriptive statistics and statistical assumption testing of outcomes and the initial rounds of results appear within results and manuscripts provided and in the results for Subtasks 2 and 3.

Subtask 2: Imputation for missing values.

Progress: We are generating a full account of missing values and applying a variety of approaches to deal with missingness .

Table 5. Descriptive statistics, multivariate analysis of variance, and principal component analysis of multiple imputations for missing variable.

A				B

(A) Pre-imputation descriptive statistics shows some differences in baseline variables between Missing/incomplete Outcomes group (M/I) and Complete Outcomes group (Comp).
(B) After imputation, multivariate analysis of variance (MANOVA) demonstrates no significant differences in baseline and outcome variables between the original and imputed dataset.
(C-L) PCA of the non-imputed data was not measurably different from any of the imputed PCAs. * $p \leq 0.05$ level. †The PCA from imputation iteration 8 resulted in 3 PCs, with the 3rd component being an aggregate of PC 3 and PC 4. In order to maintain consistency across domains, factor pattern matching statistics were only performed for components 1 and 2.
1--the Pearson's product moment correlation coefficient. 2--the root mean square difference in PC loadings. 3--the coefficient of congruence. 4--the salient similarity index.

These results are reported in Cooper et al as shown above in Table 5. To address this possibility of sampling bias due to missing data we performed multiple imputations and compared imputed-missing datasets (n=599) to the complete dataset (n=263). Independent Samples Mann-Whitney U Test of age between the complete outcomes and missing/incomplete outcomes groups demonstrated that the missing/incomplete outcomes group was older than the complete outcomes group ($p=0.012$), however there were no statistically significant differences in GCS ($p=0.874$) and 6-month GOS-E ($p=0.160$, Tbl. 5A). A chi-squared test of categorical incidence of CT pathology between the completed outcomes and missing outcome groups demonstrated a marginally significant association ($\chi^2=3.856$, $p=0.050$, Supp. 2A). MANOVA demonstrates that the differences in all variables across the non-imputed and imputed datasets were minimal (Tbl. 5B), and the factor pattern matching statistics show that imputation for missing values did not measurably change the PCA results, suggesting that the multivariate results are not affected by a selection bias and are likely to cross-validate to broader patient populations (Tbl. 5C through L).

Subtask 3: Exploratory Factor Analysis/Nonlinear Principal Component Analysis (PCA) of the full set of outcome metrics to identify shared variance and outcome clustering.

Progress: This work is proceeding on schedule. Cooper et al. and Ferguson et al. report exploratory factor analysis and non-linear data-driven approaches respectively. Most recent data from genomic assays associations with outcomes are presented under Aim 3, Task 2.

Subtask 4: Evaluation of factor loading patterns to develop a working understanding of distinct outcome domains represented by the multivariable outcome sets.

Progress: This work is moving ahead on schedule. Factor loadings are reported in Cooper et al. The results are indicating that TBI outcome reliably partitions into distinct principal components representing psychosocial and cognitive outcome domains.

Examination of the principal component loadings (Figure 4) indicates that the first 4 PCs broadly represent the following outcome domains: Psychosocial Factors (PC1), Verbal Memory (PC2), Recall Error (PC3) and Processing Speed (PC4).

Figure 4. Path Diagrams illustrating the four principal components.

Each outcome variable's principal component score (arrows) positively (red) or negatively (blue) loads onto circles representing principal components 1-4: (A) Psychosocial Factors, (B) Verbal Memory, (C) Recall Error, and (D) Processing Speed.

The path diagrams (Fig. 4A-D) show all PC loadings gated at 0.5, the cut-off used in naming the PCs. Note that Psychosocial Factors were measured with all self-report measures including BSI-18 Somatization, BSI-18 Depression, BSI-18 Anxiety, SWLS, RPQ-3, RPQ-13, PCL-C. Verbal Memory was measured with CVLT-II Trials 1-5, Short Delay Free and Cued Recall, Long Delay Free and Cued Recall. Recall Error was measured with CVLT Free and Cued Recall Intrusions. Processing Speed was measured with TMT B-A, WAIS-PSI.

Subtask 5: Perturbation and subsampling analysis to assess model robustness and discriminant validity of outcome patterns.

Progress: This work is underway. Cooper et al. contains a variety of perturbation analyses including bootstrapping, feature sub-selection, multiple imputation and pattern matching across enrollment sites. The results indicate that we are identifying stable outcome patterns that replicate across a variety of data conditions.

The correlation matrix of all outcome variables (Table 6) identifies considerable correlations among multiple testing variables indicating that multiple tests may measure similar outcome domains. To assess the multidimensional structure of TBI outcomes we performed principal component analysis, a well-established approach that combines pattern detection with dimensionality reduction.

Table 6. Correlation Matrix of Core Outcome Variables.

Task 5: Diagnostic modeling.

Subtask 1: Integrative exploratory factor analysis (EFA)/Non-linear PCA to integrate outcome domains from Aims 1-3.

Progress: This work will proceed on schedule during Year 2.

Subtask 2: Confirmatory factor analysis (CFA) to begin testing generalization and test validity of the diagnostic battery.

Progress: This work will proceed on schedule during Year 2.

Subtask 3: CFA model re-specification and fit optimization.

Progress: This work will proceed on schedule during Year 2.

Subtask 4: Develop structural equation model.

Progress: This work will proceed on schedule during Year 2.

Aim 2. To identify neuroimaging biomarkers for diagnosis and prognosis in TBI

Task 1. Extract imaging common data elements (CDE) from CT and MRI exams.

Progress: All CT and MRI exams have been interpreted by a board-certified neuroradiologist, and pathoanatomic lesions have been recorded using the NIH Common

Data Elements (CDEs). The CT CDEs for all TRACK MTBI patients were included in the data analyzed for Ferguson et al.

Task 2. Quantitative CT.

Progress: Software written for analysis of head CT was used to analyze 50 TRACK head CT exams (*figure below at left* demonstrating epidural hematoma in blue, subarachnoid hemorrhage in red, midline falx plane as green line, and severely effaced basal cisterns as green dots). We thereby demonstrated successful application of the software, which was originally trained on CT exams from single row-detector CT, to exams obtained by 64 row-detector CT. We now expect the software to be generally applicable to all multislice CT scanners, including the most current 256+ detector-row models.

The software interpretations on 50 TRACK head CT exams were compared to the consensus interpretations of a board-certified neuroradiologist and a neurosurgeon. Presence or absence of midline shift was identified correctly in 47 of 50 (94%) cases, and presence or absence of cistern effacement identified correctly in 48 of 50 (96%) of cases when compared to the consensus interpretation. There were 5 subtle cases of missed acute intracranial hemorrhage. Four of these cases are shown below at right (Figure 5), yellow arrows. for the fifth case, a few very subtle foci of subarachnoid hemorrhage were missed on clinical interpretation and are visible only on a medical grade monitor). We will complete analysis of the full set of 650 TRACK head CT exams, and extract quantitative parameters for use in the outcome prediction models described in Aim 1.

Figure 5. Comparison of software and physician interpretation of CT findings.

Task 3. Diffusion tensor imaging (DTI) and resting-state fMRI preprocessing.

Progress: Brain extraction, eddy-current correction and motion correction, and extraction of DTI parameters using the FMRIB software library have been performed on all TRACK-TBI brain MRI exams. The preprocessed data were used in DTI analyses described in Tasks 4 and 5 below. We will next proceed with independent component analysis on resting-state fMRI exams employing the FMRIB MELODIC algorithm.

Task 4. DTI and resting-state fMRI analysis using voxelwise nonparametric permutation testing.

Progress: We evaluated 3T diffusion tensor imaging (DTI) for white matter injury in 76 adult mild traumatic brain injury (mTBI) patients at the semiacute stage (11.2 $\pm$ 3.3 days), employing both whole-brain voxel-wise and region-of-interest (ROI) approaches. The subgroup of 32 patients with any traumatic intracranial lesion on either day-of-injury computed tomography (CT) or semiacute magnetic resonance imaging (MRI) demonstrated

reduced fractional anisotropy (FA) in numerous white matter tracts, compared to 50 control subjects. In contrast, 44 CT/MRI-negative mTBI patients demonstrated no significant difference in any DTI parameter, compared to controls. To determine the clinical relevance of DTI, we evaluated correlations between 3- and 6-month outcome and imaging, demographic/socioeconomic, and clinical predictors (Table 7). Statistically significant univariable predictors of 3-month Glasgow Outcome Scale-Extended (GOS-E) included MRI evidence for contusion (odds ratio [OR] 4.9 per unit decrease in GOS-E; $p = 0.01$), ≥ 1 ROI with severely reduced FA (OR, 3.9; $p = 0.005$), neuropsychiatric history (OR, 3.3; $p = 0.02$), age (OR, 1.07/year; $p = 0.002$), and years of education (OR, 0.79/year; $p = 0.01$). Significant predictors of 6-month GOS-E included ≥ 1 ROI with severely reduced FA (OR, 2.7; $p = 0.048$), neuropsychiatric history (OR, 3.7; $p = 0.01$), and years of education (OR, 0.82/year; $p = 0.03$). For the subset of 37 patients lacking neuropsychiatric and substance abuse history, MRI surpassed all other predictors for both 3- and 6-month outcome prediction. This is the first study to compare DTI in individual mTBI patients to conventional imaging, clinical, and demographic/socioeconomic characteristics for outcome prediction. DTI demonstrated utility in an inclusive group of patients with heterogeneous backgrounds, as well as in a subset of patients without neuropsychiatric or substance abuse history.

Table 7. Spearman's Correlation Coefficients (q) Between Outcome Measures and Demographic, Socioeconomic, Clinical, and Imaging Predictors^b in 76 mTBI Patients.

	Demographic, clinical, socioeconomic				Day-of-injury head CT					Early brain MRI (11.2 ± 3.3 days postinjury)

fMRI preprocessing and analysis. Resting-state fMRI data were processed using probabilistic independent component analysis (ICA), implemented in MELODIC as part of FSL (<http://fsl.fmrib.ox.ac.uk/fsl>). MELODIC decomposes the fMRI data into a set of Independent Components (ICs), where each IC represents patterns of spatiotemporal independent networks that are common across all the subjects. Previous to ICA, preprocessing included motion correction using MCFLIRT, removal of non-brain structures with Brain Extraction Tool (BET), spatial smoothing by using a Gaussian kernel of 6 mm FWHM and high pass temporal filtering using a cut-off of 160sec. Functional scans were then registered to the subjects high-resolution MPRAGE scan using affine linear registration (FLIRT) with 6 degrees of freedom and further registered to the common MNI standard space also using linear affine registration with 12 degrees of freedom (Jenkinson & Smith 2001).

Independent Component Analysis (ICA) was performed using temporal concatenation of fMRI data from all the subjects. Using MELODIC (Beckmann et al. 2005), we defined a set of common 35 Independent Components (ICs). We excluded the ICs potentially representing artifacts such as motion and considered for the study only the 14 components corresponding to resting state functional connectivity networks previously identified in the literature (Smith et al., 2009).

A Dual regression approach (Filippini et al. 2009) was then used in order to investigate group-differences in the IC spatial maps. In dual regression, group-ICA maps are projected against each individual preprocessed timeseries to obtain subject-level maps of the each IC. Then, these maps are compared between mTBI and control groups in a voxel-wise analysis using permutation testing for statistical inference and threshold-free cluster enhancement for multiple comparisons correction (Nichols & Holmes 2002). In our case, we restricted the comparisons to be performed only within the voxels belonging to each IC. For that, we created IC-masks using a threshold of $Z > 2.3$ in the group-ICA spatial maps.

Results. The 14 ICs derived from resting state fMRI that correspond to functional connectivity networks are shown in **Figure 6**. We found significant differences between mTBI and control groups in the functional connectivity of several networks. Patients showed decreased functional connectivity in several networks involving mainly frontal and temporal areas (**Figure 7**). Further work is ongoing in the resting state fMRI analysis to account for group differences between the mTBI and control cohorts in education and other demographic and clinical variables. Additional analysis is also underway to determine the association of functional connectivity with clinical and neuropsychological outcome measures.

Figure 6. Fourteen resting state functional connectivity networks examined for differences between mTBI patients and controls, including independent components corresponding to the default mode network (*a, h, i*), the auditory/temporal network (*b*), the cerebellar network (*c*), the motor network (*d*), the ventromedial prefrontal network (*e*), the somatosensory/parietal network (*f*), the visual network (*g*), the executive control network (*j, m*), the left (*k*) and right (*l*) attention networks, and the salience network (*n*).

Figure 7. Statistically significant group differences in functional connectivity between mTBI patients and controls (*blue*) within five different resting state networks (*copper*), including the executive control network (*a, c*), motor network (*b*), ventromedial prefrontal network (*d*), auditory/temporal network (*e*) and the default mode network (*f*).

Task 5. DTI and fMRI region-of-interest (ROI) analysis.

Progress: We evaluated 3-Tesla DTI in 76 TRACK-TBI MTBI patients at less than 3 weeks after injury using a region-of-interest (ROI) approach. Both conventional MRI CDEs and individual patient DTI parameters extracted using DTI ROI analysis were statistically significant predictors of 3- and 6-month outcome measures (Yuh et al.). We will next proceed with resting-state fMRI data analysis using seed region correlation analysis.

After eliminating exclusion criteria based on prior substance abuse or neuropsychiatric history, the sample size more than doubled from 37 patients to 76 patients, but included a much more diverse, heterogeneous population. Although this population was more

challenging to analyze, we showed the utility of DTI for outcome prediction in both the *inclusive* group of patients with heterogeneous backgrounds, as well as in the *subset* of patients without neuropsychiatric or substance abuse history (the latter group constituting the study population in the original version of the manuscript).

This is the first study to our knowledge that compares diffusion tensor imaging in individual mild traumatic brain injury patients to conventional structural CT and MRI, clinical variables, and demographic and socioeconomic characteristics for the purpose of 3- and 6-month outcome prediction.

We used both region of interest (ROI) and whole-brain voxelwise approaches to identify extensive areas of white matter injury in complicated mild traumatic brain injury (MTBI) patients. Uncomplicated MTBI patients showed no statistically significant evidence of white matter injury compared to control group.

Aim 3. To identify proteomic and genomic associations with TBI phenotypes.

Task 1. Biospecimen Proteomic Analyses.

Progress: We have completed analysis of glial fibrillary acidic protein (GFAP) and ubiquitin c-terminal hydrolase L1 (UCH-L1) levels in all acute TRACK-TBI plasma samples (n=215). We are generating additional analyses to build upon the 2 manuscripts in print from TRACK-TBI regarding GFAP and UCH-L1 (Okonkwo et. al., PMID 23489259, Diaz-Arrastia et. al., PMID 23865516). Our manuscript in preparation by McMahon et. al. illustrates the novel diagnostic and prognostic utility of GFAP with potential to reduce unnecessary CT scans in emergency settings as a biomarker of brain injury. We are in the process of evaluating the feasibility of using multi-analyte profiling (MAP) technology platforms in order to maximize the utility of our plasma samples: a subset of 60 out of 215 plasma samples have been analyzed using the MAP platform as a pilot. It is known that a history of TBI may generate auto-antibodies to GFAP (GFAP-AutoAb) and assessments of the correlation of GFAP-AutoAb to a history of prior TBI are underway using the TRACK-TBI dataset.

We ran a multi-analyte panel of 87 biomarkers (HumanMap v.2.0, MyriadRBM, Austin, Texas) on a cohort of 62 participants in the TRACK-TBI Pilot Study. 20 biomarkers from the HumanMap v.2.0 panel were included in the analysis. Binary logistic regression was used, with full recovery at 6 months after injury (GOSE=8) as the dependent variable. A model including only age, admission GCS, and CT findings correctly classified only 72 % of cases, and explained only a trivial fraction of variance (Cox and Snell R^2 (CSR²) = 0.020, Nagelkerke R^2 (NR²) = 0.029). Adding UCHL-1 and GFAP to the model did not significantly improve the model (classification 73%, CSR² = 0.122, NR² = 0.174). Adding the 20 HumanMap v.2.0 biomarkers substantially improved the model (classification 100%, CSR² = 0.690, NR² = 1.00). These findings are preliminary and must be replicated in a larger, independent cohort, but indicate that multiplex assays of biomarkers are potentially useful for identifying patients with mTBI who fail to make a complete recovery.

We expanded our GFAP autoantibody study include TRACK-TBI patients, and a second cohort of 21 chronic TBI subjects (average 188 days post-injury). We identified that those subjects with self-reported prior TBI and loss of consciousness (LOC) had higher day 1 anti-GFAP autoAb (mean 9.11 arbitrary unit, n=43) when compared to normal controls (mean 2.89; n=16; p < 0.012). This data suggest that exposure to TBI could trigger long-lived anti-GFAP autoantibody responses. Importantly, anti-GFAP autoAb levels in plasma collected during the rehabilitation stage after TBI are significantly higher (mean 15.08; n=21) than

normal controls, suggesting persisted up-regulation of autoimmune response to brain antigen(s) following TBI.

We analyzed concurrent plasma GFAP and C-Reactive Protein (CRP) in a cohort of 61 patients TRACK-TBI Pilot Study. In patients with intracranial lesions on brain CT (+CT), GFAP (-CT: 0.1ng/ml (IQR 0.0-1.7), n=31; +CT: 2.0ng/ml (0.4-3.3), n=30) and CRP (-CT: 0.5ug/ml (IQR 0.3-1.7), +CT: 27.5ug/ml (IQR 6.3-50.0)) were significantly higher ($p<0.0001$, Mann-Whitney U). Logistic regression of the combined GFAP-CRP model (GFAP Odds Ratio (OR) 12.9, CRP OR 1.6, Nagelkerke R^2 (NR^2) 0.87, $p<0.01$) performed better than GFAP (OR 7.5, NR^2 0.54, $p<0.01$) or CRP (OR 1.5, NR^2 0.70, $p<0.01$) alone in detecting +CT. Likewise the receiver-operating characteristic (ROC) curve of the combined model had a higher area under the curve (AUC) of 0.986 ($p<0.0001$) compared to GFAP (AUC 0.891) or CRP (AUC 0.931) individually. Our data suggests that GFAP and CRP are part of distinct physiological cascades in response to injury (Pearson's r 0.272, $p=0.034$), and supports the development of a combined panel of biomarkers to improve acute TBI detection.

Task 2. Biospecimen Genomic Analyses.

Progress: We have validated the genetic stability of all 419 TRACK-TBI patients with DNA specimens. We have sequenced single nucleotide polymorphisms (SNPs) in 5 genes with known or high likelihood of association to TBI (ANKK1, COMT, APOE, OPRM, GABRA). We have analyzed the allelic variation of these genes to the deeply phenotyped data from the other TRACK-TBI domains: baseline demographics, clinical course, neuroimaging on CT and MRI, and outcomes, which has led to 3 manuscripts in preparation (Yue et. al, Pirracchio et. al.).

We examined the association between COMT genotype and post-traumatic stress disorder (PTSD) assessed by the PTSD Checklist i Civilian Version (PCL-C) at six months post-TBI in 102 isolated, uncomplicated acute mild TBI patients. Secondary outcome measures included global outcome (Glasgow Outcome Scale Extended (GOSE)) and processing speed (Wechsler Adult Intelligence Scale, Processing Speed Index (WAIS-PSI)).

Association of COMT Genotype with PTSD

Our primary analysis was to test for the association between COMT and qualification for PTSD screening criteria at six-months post-TBI. **Figure 8** shows that COMT G/G had a statistically significant association with PTSD ($p=0.008$, Pearson χ^2), with 52% of G/G individuals qualifying for PTSD screening criteria compared to 20% of A-carriers.

Figure 8. Association of COMT Genotype with Six-Month PTSD.

	COMT A N=79	COMT G/G N=23	Sig. (p)
No PTSD	63 (80%)	12 (52%)	0.008
Yes PTSD	16 (20%)	11 (48%)	

Distribution of patients qualifying for DSM-IV screening criteria for PTSD using the PCL-C at six months after TBI, by COMT genotype. Significance (p) is assessed using Pearson χ^2 . COMT = Catechol-O-Methyltransferase; DSM-IV = Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition; PTSD = Post-Traumatic Stress Disorder; PCL-C = PTSD Checklist i Civilian Version

Association of COMT Genotype with PTSD in the Presence of Prior Psychiatric History

In order to test for the association of COMT G/G in the presence of prior psychiatric history, we took a two-tiered approach. First, we performed a univariable logistic regression of each predictor with PTSD as the dependent variable (**Table 8A**). COMT G/G had a univariable odds ratio (OR) of 3.6 (95% CI 1.3-9.7, $p=0.011$), and explained between 6.1% (Cox and Snell pseudo- X^2 (CSR2)) and 8.9% (Nagelkerke pseudo- R^2 (NR2)) of the variability in PTSD. Prior psychiatric history had a univariable OR of 5.5 (95% CI 2.1-14.2, $p=0.000$), and explained 12.3% (CSR2) to 17.9% (NR2) of the variability in PTSD. We confirmed that there was no interaction between COMT G/G and prior psychiatric history ($p=0.093$, Pearson X^2).

Table 8A. Univariable Association of COMT and Prior Psychiatric History with Six-Month PTSD.

Predictor	Univariable OR (95% CI)	Predictor Sig. (p)	Cox & Snell Pseudo- R^2	Nagelkerke Pseudo- R^2
COMT A	0.3 (0.1-0.7)	0.011	6.1%	8.9%
Prior Psych Hx	5.5 (2.1-14.2)	4.35E-4	12.3%	17.9%

We then performed a multivariable logistic regression with COMT G/G and prior psychiatric history as predictors, and PTSD as the dependent variable (**Table 8B**). This model was highly statistically significant ($p=0.000$) and explained between 15.9% (CSR2) and 23.2% (NR2) of the variability in PTSD which was an improvement from both COMT and prior psychiatric history alone. Both COMT G/G and prior psychiatric history emerged as statistically significant predictors of PTSD. Although prior psychiatric history emerged as the stronger predictor with a multivariable OR of 5.0 (95% CI 1.9-13.3, $p=0.002$), COMT was able to survive the regression with a multivariable OR of 3.1 (95% CI 1.1-8.9, $p=0.037$).

Table 8B. Multivariable Association of COMT and Prior Psychiatric History with Six-Month PTSD

Predictor	Multivariable OR (95% CI)	Predictor Sig. (p)	Model Sig. (p)	Cox & Snell Pseudo- R^2	Nagelkerke Pseudo- R^2
COMT A	0.3 (0.1-0.9)	0.037	1.48E-4	15.9%	23.2%
Prior Psych Hx	5.0 (1.9-13.3)	0.001			

Association of COMT on Secondary Outcome Measures

We assessed the association between COMT genotype on GOSE and WAIS-PSI. **Figure 9** shows a significant association between COMT and GOSE ($p=0.041$, Mann-Whitney U), with a one point IQR (7-8) for A-carriers compared to three points (5-8) for G/G. **Figure 10** shows a significant association between COMT and WAIS-PSI ($F=7.141$, $p=0.009$), with A-carriers composite scores at 103.6 (95% CI 100.4-106.7), which translates to performance between 55th to 63rd percentile [WAIS]. In contrast the mean composite score for G/G was 94.2 (95% CI 86.4-102.0), which falls at the 34th percentile.

Figure 9. Distribution of global outcome scores on GOSE by COMT genotype. Significance (p) is assessed using the Pearson chi-squared statistic.

Figure 10. Association of COMT Genotype with Six-Month Processing Speed.

Distribution of WAIS-PSI composite scores by COMT genotype. Significance (p) is assessed using ANOVA. For reference, WAIS-PSI = 89 (23rd %tile), 94 (34th %tile), 100 (50th %ile), 105 (63rd %ile). WAIS-PSI = Wechsler Adult Intelligence Scale, Fourth Edition Processing Speed Index; %ile = percentile

During the fourth quarter the following SNPs were sequenced (results in Tasks 4 and 5):

Dopaminergic:

- Rs11604671 and rs4938016 are SNPs within the DRD2 gene that form a haploblock with the already sequenced ANKK1 rs1800497 and associate with poor cognitive outcome after TBI.
- Rs6277 is a SNP within the DRD2 gene where the C allele associates with increased PTSD risk.

Serotonergic:

- Rs6311 is a SNP within the HTR2A gene in the serotonergic pathway that possibly associates with PTSD after trauma [PMID 19842167].

- Rs4795541 is a SNP within the SLC6A4 gene that associates with depression and PTSD.

Neurodegenerative:

- Rs6265 is a SNP within the BDNF gene. The A allele confers increased risk to motor skill impairment [PMID 19745020] and introversion.

Additional SNPs based on current literature:

BCL2

- Rs17759659 is a SNP within the BCL2 gene which encodes a pro-survival protein in the apoptosis pathway. The SNP associates with poorer outcomes and higher mortality by GOS after severe TBI.

PARP-1

- Rs3219119 is a SNP within Poly(ADP-ribose) polymerase-1 (PARP-1) which plays an important role in cellular response to DNA damage. The AA genotype has been found to associate with favorable neurologic outcome by 6-month GOS after TBI.

Task 3. Data Analysis.

Progress: Please refer to Tasks 1 and 2 for respective details.

Tasks 4 and 5. Prognostic and Diagnostic Modeling. Multivariate statistics including PCA and SEM (Aim 1), and CT and MRI imaging data (Aim 2) will be performed in order to establish models for specific diagnostic classifications and prognostic biomarkers.

Progress: **Figure 11** illustrates the results of diagnostic and prognostic modeling that integrates data across all genomic and outcome measures.

Figure 11. Harnessing TRACK-TBI Pilot samples for multivariate data-driven-discovery of biomarker-function associations. A) Single nucleotide polymorphisms, proteomic biomarkers and outcomes from cognitive, affective and clinical scales were correlated using non-linear principal component analysis (NL-PCA). This approach combines optimal scaling transformations with variance maximization using alternating least-squares to discover emergent multivariate patterns, the principal components (PCs). B) The first 3 PCs (PC1-3) accounted for 38.8% of the observed variance. The PC loading matrix depicts the bivariate correlation (loading) between individual variables and the PCs. Note that each of the PCs had significant loadings $>|0.3|$ from several SNPs as well as functional measures. Based on the loadings we calculate unique PC scores for each patient on PC1, PC2 and PC3.

To assess the sensitivity of the PC clusters to TBI severity, we performed two distinct waves of analyses. First, we tested impact of intracranial CT findings for predicting PC1-3 scores using general linear models (GLM) at the multivariate and univariate level (Tables 9-10). Second, we performed correlational analyses to test whether the Glasgow Coma Score (GCS) predicts PC scores (convergent validity testing) of the PC patterns as measures of TBI severity (Table 11). Both validation tests suggested that PC3 was highly sensitive to TBI, especially at the severe end of the spectrum. PC1 was showed non-significant trends for our signatures of severe TBI, suggesting that it may reflect the mild end of the spectrum. Further work is needed to fully assess this possibility.

4. KEY RESEARCH ACCOMPLISHMENTS

- Publication of the first study to compare DTI in individual mild TBI patients to conventional imaging, clinical, and demographic/socioeconomic characteristics for outcome prediction. DTI demonstrated utility in an inclusive group of patients with heterogeneous backgrounds, as well as in a subset of patients without neuropsychiatric or substance abuse history. Significant predictors of 6-month GOS-E included region of interest with severely reduced fractional anisotropy, neuropsychiatric history, and years of education. For the subset of 37 patients lacking neuropsychiatric and substance abuse history, MRI surpassed all other predictors for both 3- and 6-month outcome prediction (Yuh et al).
- Reliable outcome prediction in mild TBI is important for clinical practice. Identifying patients at increased risk of unfavourable outcome permits targeting closer observation and early intervention, which may reduce the psychological burden of injury on the patients, and the related economic burden on society. Our study demonstrates that existing models for mild TBI perform unsatisfactorily. We tested 21 variables in ordinal analysis of 386 patients, which is 1 in 18 and thus reasonable from a statistical perspective. Although we have found some strong predictors of poor outcome, such as age and history of psychiatric condition, given the sample size, we consider the results of our prognostic analysis as hypothesis generating. These predictors will need further validation in ongoing prospective longitudinal studies, such as those that are part of the International TBI Research Initiative (Lingsma et al).
- In a broad range of patients with mild to severe TBI measurement of GFAP-BDP yielded a net benefit above clinical screening alone and a net reduction in unnecessary scans by 12 to 30%. Used in conjunction with other clinical information, rapid measurement of GFAP-BDP is useful in establishing or excluding the diagnosis of radiographically apparent intracranial injury throughout the spectrum of TBI. As an adjunct to current screening practices, GFAP-BDP may help avoid unnecessary CT scans without sacrificing sensitivity (McMahon).

5. CONCLUSIONS

We have demonstrated progress across all aims which are of significance to civilian and military TBI clinical care. We have successfully created an Information Commons for the TBI CDE domains across the injury spectrum from concussion to coma. Most importantly these biomarkers will be vital to the design of future clinical trials for TBI. For future plans during year 2 we are on target to complete the original tasks to conduct multivariate diagnostic and prognostic modeling across all aims.

Other Person

Falls (Accidental)

- ☐ 884 Fall from one level to another
- ☐ 885 Fall on same level from slip, trip, or stumble
- ☐ 886 Fall on same level from contact with person
- ☐ 888 Fall, general

Striking against or struck by person or object (Accidental)

- ☐ 917.0 In sports (tackles)
- ☐ 917.1 Caused by crowd, collective fear or panic
- ☐ 917.9 Other

Cutting and piercing instruments (Accidental)

- ☐ 920.0 Powered lawn mower
- ☐ 920.1 Other powered hand tools
- ☐ 920.2 Powered household appliances
- ☐ 920.3 Knives, swords, and daggers
- ☐ 920 Cutting and piercing, general
- ☐ 986 Undetermined if accidental or intentional

Cause of Injury (2)

Injury Purposely Inflicted by Other Persons

- ☐ 960.0 Unarmed fight or brawl
- ☐ 960.1 Rape
- ☐ 961 Assault by corrosive or caustic substance
- ☐ 965 Assault by firearms and explosives
- ☐ 966 Assault by cutting and piercing instruments
- ☐ 967 Child and adult battering/other maltreatment
- ☐ 968 Assault by other or unspecified means
- ☐ 968.0 Assault by fire
- ☐ 968.1 Assault by pushing from a high place
- ☐ 968.2 Assault by striking by blunt or thrown object
- ☐ 968.3 Assault by hot liquid
- ☐ 968.4 Assault by criminal neglect
- ☐ 968.5 Assault by transport vehicle
- ☐ 968.6 Assault by air gun
- ☐ 968.7 Assault by human bite
- ☐ 968.8 Assault by OTHER SPECIFIED means
- ☐ 968.9 Assault by UNSPECIFIED means

Other accidental causes of injury

- ☐ 807 Railway accident
- ☐ 821 Motor vehicle off-road non-traffic accident
- ☐ 825 Motor vehicle accident – not traffic related
- ☐ 829 Other vehicle accident
- ☐ 876 Misadventure during medical care
- ☐ 899 Accident caused by fire
- ☐ 900 Environmental – excessive heat
- ☐ 906 Injury caused by animal
- ☐ 910 Accidental drowning and submersion
- ☐ 913 Accidental mechanical suffocation
- ☐ 916 Struck accidentally by falling object
- ☐ 918 Accidentally caught in or between objects
- ☐ 919 Accident caused by machinery
- ☐ 924 Accident caused by hot or caustic liquids or gases
- ☐ 925 Accident caused by electrical current
- ☐ 928 Other environmental or accidental causes
- ☐ 929 Late effects of accidental injury

Cause of Injury (3)

Firearms, air guns, and explosives

- ☐ 922 Accident caused by firearm and air gun missile
- ☐ 923 Accident caused by explosive material
- ☐ 985 Unknown if accidental or intentional

Suicide and Self-Inflicted Injury

- ☐ 950 Poisoning by solid and liquid substances
- ☐ 953 Hanging, strangulation, suffocation
- ☐ 955 Firearms, air guns, and explosives
- ☐ 956 Cutting and piercing instrument
- ☐ 958 Other and unspecified means
- ☐ 959 Late effects of self-inflicted injury

Screening for Previous TBI

Patient Number

Form Completion Note

Form Completion Status

☐ In Progress

☐ Complete

1. Have you ever been [hospitalized or treated in an emergency room](#) following an injury to your head or neck? Think about any childhood injuries you remember or were told about.
☐ Yes ☐ No
2. Have you ever injured your head or neck in a [car accident](#) or from some other moving vehicle accident, e.g., car, truck, bicycle, van, all terrain vehicle?
☐ Yes ☐ No
3. Have you ever injured your head or neck in a [fall or from being hit by something](#)? For example slipping on ice, a wet floor, the street, etc, or while walking. Falling from a curb, stairs, stair, roof, etc. Falling on a hard floor, ice, rocks, etc.
☐ Yes ☐ No
4. Have you ever injured your head or neck in [sports](#), e.g., football, soccer, skiing, blading, boarding, basketball, baseball, biking, horse back riding?
☐ Yes ☐ No
5. Have you ever injured your head or neck in a [fight, assault, from being hit by someone](#) or being shaken violently?
☐ Yes ☐ No
6. Have you ever been nearby when [an explosion or a blast](#) occurred? If you served in the military, think about any combat-related incidents.
☐ Yes ☐ No

If all above are “no” then stop. If answered “yes” to any of the questions above, ask:

7. Were you [knocked out or unconscious](#) following any of the injuries you mentioned above?
DO NOT INCLUDE LOSING CONSCIOUSNESS DUE TO DRUG OVERDOSE OR FROM BEING CHOKED (see #9, below).
☐ Yes ☐ No

Screening for Previous TBI (2)

If answer to #7 is “Yes”, ask:

7A. How long were you knocked out or did you lose consciousness? (If identified multiple injuries with loss of consciousness, ask for each. If not sure of the time frame, encourage them to make their best guess.)

Injury #	1	2	3	4	5
How long were you knocked out?					
How old were you?					
If more than 5, how many more?					
Longest period of unconsciousness?					
How many ≥ 30 mins.?					
Youngest age?					

If answer to #7 is “No”, ask:

8. Were you [dazed, confused](#) or do you or have a gap in your memory from the injury(ies) you mentioned above? [RULE OUT ALCOHOL BLACKOUTS]
☐ Yes ☐ No

8A. How long were you dazed or confused? (If identified multiple injuries with period of confusion, ask for each. If not sure of the time frame, encourage them to make their best guess.)

Injury #	1	2	3	4	5
How long were you dazed & confused?					
How old were you?					
If more than 5, how many more?					
Longest period confused?					
How many ≥ 30 mins.?					
Youngest age?					

9. Have you ever lost consciousness from a drug overdose or being choked?

Number of times from a drug overdose	
Number of times from being choked

Civilian PTSD Check List (1)

Patient Number

Below is a list of problems and complaints that veterans sometimes have in response to stressful life experiences. Please read each one carefully, and indicate how much you have been bothered by that problem in the last month.

Form Completion Status

- ☐ In Progress
- ☐ Complete
- ☐ Not Complete

1. Repeated, disturbing memories, thoughts, or images of a stressful experience from the past?
☐ 1- Not at all ☐ 2- A little bit ☐ 3- Moderately
☐ 4- Quite a bit ☐ 5- Extremely
2. Repeated, disturbing dreams of a stressful experience from the past?
☐ 1- Not at all ☐ 2- A little bit ☐ 3- Moderately
☐ 4- Quite a bit ☐ 5- Extremely
3. Suddenly acting or feeling as if a stressful experience were happening again (as if you were reliving it)?
☐ 1- Not at all ☐ 2- A little bit ☐ 3- Moderately
☐ 4- Quite a bit ☐ 5- Extremely
4. Feeling very upset when something reminded you of a stressful experience from the past?
☐ 1- Not at all ☐ 2- A little bit ☐ 3- Moderately
☐ 4- Quite a bit ☐ 5- Extremely
5. Having physical reactions (e.g., heart pounding, trouble breathing, or sweating) when something reminded you of a stressful experience from the past?
☐ 1- Not at all ☐ 2- A little bit ☐ 3- Moderately
☐ 4- Quite a bit ☐ 5- Extremely
6. Avoid thinking about or talking about a stressful experience from the past or avoid having feelings related to it?
☐ 1- Not at all ☐ 2- A little bit ☐ 3- Moderately
☐ 4- Quite a bit ☐ 5- Extremely
7. Avoid activities or situations because they remind you of a stressful experience from the past?
☐ 1- Not at all ☐ 2- A little bit ☐ 3- Moderately
☐ 4- Quite a bit ☐ 5- Extremely
8. Trouble remembering important parts of a stressful experience from the past?
☐ 1- Not at all ☐ 2- A little bit ☐ 3- Moderately
☐ 4- Quite a bit ☐ 5- Extremely

CHART-SF (1)

Patient Number

Form Completion Status

☐ In Progress

☐ Complete

☐ Not Complete

1. How many hours in a typical 24-hour day do you have someone with you to provide physical assistance for personal care activities such as eating, bathing, dressing, toileting and mobility?

Hours Paid Assistance

Hours unpaid (family, others)

2. How much time is someone with you in your home to assist you with activities that require remembering, decision making, or judgment?

- ☐ Someone else is always with me to observe or supervise
☐ Someone else is always around, but they only check on me now and then
☐ Sometimes I am left alone for an hour or two
☐ Sometimes I am left alone for most of the day
☐ I have been left alone all day and all night, but someone checks in on me
☐ I am left alone without anyone checking on me

3. How much of the time is someone with you to help you with remembering, decision making, or judgment when you go away from your home?

- ☐ I am restricted from leaving, even with someone else
☐ Someone is always with me to help with remembering, decision making, or judgment when I go anywhere
☐ I go to places on my own as long as they are familiar
☐ I do not need help going anywhere

4. On a typical day, how many hours are you out of bed?

5. In a typical week, how many days do you get out of your house and go somewhere?

6. In the last year, how many nights have you spent away from your home (excluding hospitalizations)?

- ☐ None
☐ 1-2
☐ 3-4
☐ 5 or more

CHART-SF (2)

7. How many hours per week do you spend working in a job for which you get paid? Occupation:
8. How many hours per week do you spend in school working toward a degree or in an accredited technical training program (including hours in class and studying)?
9. How many hours per week do you spend in active homemaking including parenting, housekeeping, and food preparation?
10. How many hours per week do you spend in home maintenance activities such as gardening, house repairs or home improvement?
11. How many hours per week do you spend in recreational activities such as sports, exercise, playing cards, or going to movies? Please do not include time spent watching TV or listening to the radio
12. How many other people do you live with?
13. Is one of them your spouse or significant other?
☐ Yes
☐ No
☐ N/A (lives alone)
14. Of the people you live with, how many are relatives (not including your spouse)?
15. How many business or organizational associates do you visit, phone, or write to at least once a month?
16. How many friends (non-relatives contacted outside business or organizational settings) do you visit, phone, or write to at least once a month?
17. With how many strangers have you initiated a conversation in the last month (for example, to ask information or place an order)?
☐ None
☐ 1-2
☐ 3-5
☐ 6 or more

CHART-SF (3)

18. Approximately what was the combined annual income, in the last year, of all family members in your household?
- ☐ a. Less than 25,000 - If no ask e; if yes ask b
 - ☐ b. Less than 20,000 - If no select a; if yes ask c
 - ☐ c. Less than 15,000 - If no select b; if yes ask d
 - ☐ d. Less than 10,000 - If no select c; if yes select d
 - ☐ e. Less than 35,000 - If no ask f; if yes select e
 - ☐ f. Less than 50,000 - If no ask g; if yes select f
 - ☐ g. Less than 75,000 - If no select h; if yes select g
 - ☐ h. 75,000 or more
19. Approximately how much did you pay last year for medical care expenses?
- ☐ Less than 1000
 - ☐ Less than 2500
 - ☐ Less than 5000
 - ☐ Less than 10000
 - ☐ 10000 or more

Scoring

Self Sufficient Total

Extended Glasgow Outcome Scale (1)

Patient Number

Respondent:

- ☐ Patient alone
☐ Relative/friend/caretaker alone
☐ Patient plus relative/friend/caretaker

Form Completion Status

- ☐ In Progress
☐ Complete
☐ Not Complete

Consciousness:

1. Is the head-injured person able to obey simple commands or say any words?
☐ No (VS) ☐ Yes

Independence at home:

- 2a. Is the assistance of another person at home essential every day for some activities of daily living?
☐ No ☐ Yes
- 2b. Do they need frequent help of someone to be around at home most of the time?
☐ No (Upper SD) ☐ Yes (Lower SD)
- 2c. Was assistance at home essential before the injury?
☐ No ☐ Yes

Independence outside home:

- 3a. Are they able to shop without assistance?
☐ No (Upper SD) ☐ Yes
- 3b. Were they able to shop without assistance before?
☐ No ☐ Yes
- 4a. Are they able to travel locally without assistance?
☐ No (Upper SD) ☐ Yes
- 4b. Were they able to travel locally without assistance before the injury?
☐ No ☐ Yes

Work:

- 5a. Are they currently able to work (or look after others at home) to their previous capacity?
☐ No ☐ Yes
- 5b. How restricted are they?
☐ Reduced work capacity (Upper MD)
☐ Able to work only in a sheltered workshop or non-competitive job or currently unable to work (Lower MD)
- 5c. Were they either working or seeking employment before the injury (answer 'yes') or were they doing neither (answer 'no')?
☐ No ☐ Yes

Extended Glasgow Outcome Scale (2)

Social and Leisure activities:

- 6a. Are they able to resume regular social and leisure activities outside home?
☐ No ☐ Yes
- 6b. What is the extent of restriction on their social and leisure activities?
☐ Participate a bit less; at least half as often as before injury (Lower GR)
☐ Participate much less; less than half as often (Upper MD)
☐ Unable to participate; rarely, if ever, take part (Lower MD)
- 6c. Did they engage in regular social and leisure activities outside home before the injury?
☐ No ☐ Yes

Family and friendships:

- 7a. Has there been family or friendship disruption due to psychological problems?
☐ No ☐ Yes
- 7b. What has been the extent of disruption or strain?
☐ Occasional - less than weekly (Lower GR)
☐ Frequent - once a week or more, but not tolerable (Upper MD)
☐ Constant - daily and intolerable (Lower MD)
- 7c. Were there problems with family or friends before the injury?
☐ No ☐ Yes

Return to normal life:

- 8a. Are there any other current problems relating to the injury which affect daily life?
☐ No (upper GR) ☐ Yes (Lower GR)
- 8b. Were similar problems present before the injury?
☐ No ☐ Yes

Epilepsy:

Since the injury has the head injured person had any epileptic fits?
☐ No ☐ Yes

Have they been told that they are currently at risk of developing epilepsy?
☐ No ☐ Yes

Outcome

What is the most important factor in outcome?

- ☐ Effects of head injury
- ☐ Effects of illness or injury to another part of the body
- ☐ A mixture of these

Scoring: The patient's overall rating is based on the lowest outcome category indicated on the scale. Refer to Guidelines for further information concerning administration and scoring

GOSE Score

- ☐ 1-Dead
- ☐ 2-Vegetative State (VS)
- ☐ 3-Lower Severe Disability (Lower SD)
- ☐ 4-Upper Severe Disability (Upper SD)
- ☐ 5-Lower Moderate Disability (Lower MD)
- ☐ 6-Upper Moderate Disability (Upper MD)
- ☐ 7-Lower Good Recovery (Lower GR)
- ☐ 8-Upper Good Recovery (Upper GR)

Extended Glasgow Outcome Scale Pediatric

Patient Number

Respondent:

- ☐ Patient alone
- ☐ Relative/friend/caretaker alone
- ☐ Patient plus relative/friend/caretaker

Form Completion Status

- ☐ In Progress
- ☐ Complete
- ☐ Not Complete

Consciousness:

1a. Is the head-injured person able to obey simple commands or say any words? OR Can he or she act/react/interact beyond reflexes?

- ☐ Yes ☐ No (VS)

Independence at home:

2a. Is the assistance of another person at home essential every day for some activities of daily living? OR Is the child dependent upon a caretaker more so than is expected based on age?

- ☐ Yes ☐ No

2b. Does the child need frequent help or for someone to be around at home most of the time? OR Does the child need frequent help from a caretaker to accomplish tasks that a child this age should be able to accomplish

- ☐ Yes (Lower SD) ☐ No (Upper SD)

Independence outside home:

3a. Is the child able to shop and travel without assistance? OR Does the child behave age appropriately outside the home?

- ☐ Yes ☐ No (Upper SD)

School/Work:

4a. Can the child function at work or in school at his or her previous capacity?

- ☐ Yes ☐ No

4b. Level of restriction:

i) Able to work only in a sheltered workshop or non-competitive job, in a school setting for severely impaired children or tutored at home, or currently unable to work or go to school.

- ☐ Yes (Lower MD) ☐ No

ii) Reduced work or school capacity.

- ☐ Yes (Upper MD) ☐ No

Extended Glasgow Outcome Scale Pediatric (2)

Social and Leisure activities:

5a. Is the child able to resume regular social and leisure activities?

☐ Yes

☐ No

5b. What is the extent of restrictions on social and leisure activities?

☐ Participate a bit less; at least half as often as before injury (Lower GR)

☐ Participate much less; less than half as often (Upper MD)

☐ Unable to participate; rarely, if ever, take part (Lower MD)

Family and friendships:

6a. Are there psychological problems that have resulted in ongoing disruption with respect to either family or friendships?

☐ Yes

☐ No

6b. What is the extent of disruption or strain?

☐ Occasional - less than weekly (Lower GR)

☐ Frequent - once a week or more, but not tolerable (Upper MD)

☐ Constant - daily and intolerable (Lower MD)

Return to normal life:

7a. Are there any other problems relating to the injury that affect daily life?

☐ Yes (Lower GR)

☐ No (Upper GR)

Scoring: The patient's overall rating is based on the lowest outcome category indicated on the scale. Refer to Guidelines for further information concerning administration and scoring

GOSE Score

☐ 8-Dead

☐ 7-Vegetative State (VS)

☐ 6-Lower Severe Disability (Lower SD)

☐ 5-Upper Severe Disability (Upper SD)

☐ 4-Lower Moderate Disability (Lower MD)

☐ 3-Upper Moderate Disability (Upper MD)

☐ 2-Lower Good Recovery (Lower GR)

☐ 1-Upper Good Recovery (Upper GR)

Rivermead Post-concussion Symptoms Questionnaire (1)

Patient Number

After a head injury or accident some people experience symptoms that can cause worry or nuisance. We would like to know if you now suffer any of the symptoms given below. Because many of these symptoms occur normally, we would like you to compare yourself now with before the accident. For each symptom listed below please select the number that most closely represents your answer.

Compared with **before** the accident, do you **now** (i.e., over the last 24 hours) suffer from:

Form Completion Status

Abstract

We evaluated 3T diffusion tensor imaging (DTI) for white matter injury in 76 adult mild traumatic brain injury (mTBI) patients at the semiacute stage (11.2 ± 3.3 days), employing both whole-brain voxel-wise and region-of-interest (ROI) approaches. The subgroup of 32 patients with any traumatic intracranial lesion on either day-of-injury computed tomography (CT) or semiacute magnetic resonance imaging (MRI) demonstrated reduced fractional anisotropy (FA) in numerous white matter tracts, compared to 50 control subjects. In contrast, 44 CT/MRI-negative mTBI patients demonstrated no significant difference in any DTI parameter, compared to controls. To determine the clinical relevance of DTI, we evaluated correlations between 3- and 6-month outcome and imaging, demographic/socioeconomic, and clinical predictors. Statistically significant univariable predictors of 3-month Glasgow Outcome Scale-Extended (GOS-E) included MRI evidence for contusion (odds ratio [OR] 4.9 per unit decrease in GOS-E; $p=0.01$), ≥ 1 ROI with severely reduced FA (OR, 3.9; $p=0.005$), neuropsychiatric history (OR, 3.3; $p=0.02$), age (OR, 1.07/year; $p=0.002$), and years of education (OR, 0.79/year; $p=0.01$). Significant predictors of 6-month GOS-E included ≥ 1 ROI with severely reduced FA (OR, 2.7; $p=0.048$), neuropsychiatric history (OR, 3.7; $p=0.01$), and years of education (OR, 0.82/year; $p=0.03$). For the subset of 37 patients lacking neuropsychiatric and substance abuse history, MRI surpassed all other predictors for both 3- and 6-month outcome prediction. This is the first study to compare DTI in individual mTBI patients to conventional imaging, clinical, and demographic/socioeconomic characteristics for outcome prediction. DTI demonstrated utility in an inclusive group of patients with heterogeneous backgrounds, as well as in a subset of patients without neuropsychiatric or substance abuse history.

Key words: axonal injury; computed tomography; diffusion tensor imaging; magnetic resonance imaging; traumatic brain injury

Introduction

MILD TRAUMATIC BRAIN INJURY (mTBI) comprises 75% of the estimated 1.7 million patients who seek medical attention annually in the United States for acute head injury.¹ The most widely

accepted definitions of mTBI^{2–4} include patients with 1) non-penetrating head trauma resulting in one or more of the following: confusion/disorientation; loss of consciousness (LOC) <30 min in duration, post-traumatic amnesia (PTA) <24 h in duration; and transient focal neurological signs or seizure and 2) Glasgow Coma

Scale (GCS) score of 13–15 upon acute medical evaluation. Previous studies suggest that many mTBI patients have significant alterations in cognitive and/or behavioral functioning within weeks to months of injury, and approximately 15–20% have persistent measurable deficits at 1 year.^{5–12} There is also growing recognition that current classification schemes for mTBI/concussion based solely on GCS, PTA, and LOC are severely limited, with small *mean* effect sizes in long-term impairment obscuring differences among diverse subgroups of mTBI patients with very different prognoses.^{13,14} To date, there remains a need for practical, widely available clinical, laboratory, and/or imaging markers that identify patients who will experience persistent dysfunction after mTBI.

Many studies have reported changes in white matter diffusion tensor imaging (DTI) parameters in acute, subacute, and chronic time frames after mTBI.^{15–37} The clinical significance of acute traumatic intracranial findings on conventional computed tomography (CT) and magnetic resonance neuroimaging has also been explored.^{38,39} However, little is known about the relationship between conventional CT and magnetic resonance imaging (MRI) findings and DTI evidence of white matter injury within the mTBI spectrum. In addition, there has been little exploration of the use of acute or subacute DTI data for prediction of outcome in individual patients, after controlling for demographic, clinical, and CT and conventional MRI predictors. Although group differences in DTI parameters between mTBI patients and controls have been demonstrated, no consensus yet exists on the practical application of these techniques to outcome prediction in the individual patient. Finally, nearly all previous studies of DTI in mTBI have excluded patients with any history of substance abuse or other neuropsychiatric disorder, and the generalizability of their results to the general mTBI population is uncertain.

In this study, we used both whole-brain voxel-wise and region-of-interest (ROI) analyses to assess for an association between CT and conventional MRI abnormalities and early DTI measures of white matter integrity after mTBI. To determine the clinical relevance, if any, of DTI measures to outcome in mTBI, we then assessed for correlations between DTI measures and 3- and 6-month outcome. We compared the strengths of these correlations to those between outcome and conventional imaging, demographic, and clinical predictors previously found to influence outcome, based on the assumption that any utility of DTI in outcome prediction would require a *differential* increase in predictive power over predictors that are routinely assessed in current practice. To our knowledge, this is the first study to compare the relative strengths of DTI features in individual mTBI patients to conventional MRI, CT, clinical, demographic, and socioeconomic features for the prediction of 3- and 6-month outcome. In order to maximize the generalizability of study conclusions, we analyzed both an inclusive sample of 76 mTBI patients with very few exclusion criteria, as well as a subset of 37 patients with no significant drug, alcohol, or neuropsychiatric history.

Methods

Study population

mTBI patients were enrolled at San Francisco General Hospital (SFGH; San Francisco, CA) as part of the prospective multi-center TRACK-TBI (Transforming Research and Clinical Knowledge in Traumatic Brain Injury) pilot study.⁴⁰ The primary inclusion criterion for the TRACK-TBI pilot study was performance of non-contrast head CT to assess for evidence of acute TBI within 24 h of injury, based on criteria from the American College of Emergency Physicians/Centers for Disease Control (ACEP/CDC) evidence-based joint practice guideline (Supplementary Table S1) (see online

supplementary material at <http://www.liebertpub.com>).⁴¹ The TRACK-TBI pilot study exclusion criteria were limited and consisted of nonfluency in English, contraindication to MRI, pregnancy, and current incarceration/legal detention or placement on psychiatric hold.⁴⁰

For the current study of DTI of mTBI, additional inclusion criteria were GCS 13–15 upon emergency department (ED) arrival, LOC <30 min, PTA duration <24 h, and age 18–55 years (inclusive); an additional exclusion criterion was any reported history of earlier TBI resulting in LOC >5 min. Of 190 mTBI patients in the 18- to 55-year age range enrolled at SFGH for the TRACK-TBI pilot study, 87 patients did not undergo brain MRI. Of the remaining 103 patients, 18 reported a history of earlier TBI with LOC >5 min or of unknown duration; 5 had a technically inadequate brain MRI exam (because of motion or, in 1 case, because of severe susceptibility artifact resulting from a metallic shunt valve within the scalp); 1 patient had an extensive area of encephalomalacia likely the result of an earlier TBI; 1 had an acute large-territory infarct resulting from acute traumatic arterial dissection; and 2 were excluded because their performance on the Trail Making Test (TMT) B and other outcome measures were extreme outliers, despite a GCS of 15 upon ED arrival, no LOC or PTA, and no CT or conventional MRI evidence of traumatic intracranial injury. The final patient group for the current study therefore consisted of 76 mTBI patients enrolled at SFGH who underwent brain MRI on a single 3T MRI scanner within 3 weeks of TBI. In addition, a control group consisted of 50 healthy subjects, ages 18–55 years, with no self-reported history of drug or alcohol abuse, neuropsychiatric illness, or earlier TBI, who underwent brain MRI on the same 3T scanner over the same time period, employing the same MRI protocol and software version. All study protocols were approved by the University of California at San Francisco Institutional Review Board, and all patients and control subjects or their legal representatives gave written informed consent.

Table 1 summarizes demographic, socioeconomic, and clinical characteristics of participants and control subjects. We assessed for statistically significant differences in demographic, socioeconomic, and clinical features at $p < 0.05$ among the following groups: 1) CT/MRI-positive patients, defined as patients with any acute traumatic intracranial lesion or depressed skull fracture on day-of-admission CT or semiacute 3T MRI; 2) CT/MRI-negative patients, defined as patients without any such abnormality; and 3) control subjects. We used analysis of variance (ANOVA) for scale variables without significant deviation from a normal distribution, and Mann-Whitney U test for ordinal and non-normal variables. Differences in nominal variables were assessed by chi-square (χ^2) test for independence or by Fisher's exact test for nominal variables with an expected count of fewer than 5 subjects in any cell. All statistical analyses were performed using SPSS Statistics (version 21; SPSS, Inc., Chicago, IL).

CT and MRI protocols

CT was performed within 2 h 42 min $\pm$ 3 h 9 min of TBI. MRI was performed within 11.2 $\pm$ 3.3 days (range, 5–18) postinjury. All CT exams were performed on a GE Lightspeed 64-row-detector CT scanner, and all MRI exams were performed on the same 3T GE Signa EXCITE scanner equipped with an eight-channel phased-array head radiofrequency coil (GE Healthcare, Waukesha, WI), using the same scanner software version. Whole-brain DTI was performed with a multi-slice single-shot spin echo echoplanar pulse sequence (echo time [TE] = 63 ms; repetition time [TR] = 14 sec) using 55 diffusion-encoding directions, isotropically distributed over the surface of a sphere with electrostatic repulsion, acquired at $b = 1000 \text{ sec/mm}^2$, seven acquisitions at $b = 0 \text{ sec/mm}^2$, 72 interleaved slices of 1.8-mm thickness each with no gap between slices, a 128×128 matrix, and a field of view (FOV) of $230 \times 230 \text{ mm}$.

TABLE 1. DEMOGRAPHIC, SOCIOECONOMIC, AND CLINICAL PREDICTORS FOR 76 mTBI PATIENTS AND 50 CONTROL SUBJECTS

Predictors	CT/MRI-negative mTBI (no acute traumatic intracranial abnormality or depressed skull fracture on CT and/or conventional MRI) (44 subjects)		CT/MRI-positive mTBI (acute traumatic intracranial abnormality and/or depressed skull fracture on CT and/or conventional MRI) (32 subjects)		Controls (50 subjects)	Analysis for group differences among CT/MRI-negative mTBI, CT/MRI-positive mTBI, and control subjects

Gray shaded boxes indicate statistically significant difference at p < 0.05.^aOne CT/MRI-positive mTBI patient with unknown employment status was not included in this analysis.^bOne control with unknown handedness was not included in this analysis.^cFour CT/MRI-positive mTBI patients with PTA < 24 h, but not otherwise specified, were not included in this analysis.^{d–i}Each superscript denotes a subset of participants whose proportions do not significantly differ from each other at p < 0.05 by Pearson's χ^2 test (or Fisher's exact test when expected cell count < 5). mTBI, mild traumatic brain injury; ANOVA, analysis of variance; GCS, Glasgow Coma Scale; PTA, post-traumatic amnesia; LOC, loss of consciousness; N/A, not available.

Parallel imaging was employed using the array spatial sensitivity encoding technique (ASSET) with an acceleration factor of 2.

The following conventional 3T MRI sequences were also performed: 1) axial three-dimensional (3D) inversion recovery fast spoiled gradient recalled echo T1-weighted images (TE=1.5 ms; TR=6.3 ms; inversion time [TI]=400 ms; flip angle, 15 degrees) with 230-mm FOV, 156 contiguous partitions (1.0-mm) at 256×256 matrix; 2) axial T2-weighted fluid-attenuated inversion recovery images (TE=126 ms; TR=10 sec; TI=2200 ms) with 220 mm FOV, 47–48 contiguous slices (3.0-mm) at 256×256 matrix; and 3) axial magnetization-prepared gradient echo T2*-weighted images (TE=15 ms; TR=500 ms; flip angle 20 degrees) with 220×170 mm FOV and 47–48 contiguous slices (3.0-mm) at 256×192 matrix.

Neuroradiologist evaluation of CT and MRI studies for acute traumatic abnormalities

Each patient's head CT upon ED presentation and early brain MRI (11.2±3.3 days postinjury) was characterized using the TBI common data elements (TBI-CDE). The TBI-CDEs are consensus-based recommendations for data collection, data definitions, and best practices in TBI research established jointly by the National Institute of Neurological Disorders and Stroke (NINDS), Defense Centers of Excellence, National Institute on Disability and Rehabilitation Research, and Veterans Administration.^{42–44} Each CT and MRI was anonymized and reviewed by a board-certified neuroradiologist blinded to demographic, socioeconomic, and clinical data, except gender and age, and without concurrent access to the patient's other head imaging studies or 3- and 6-month outcome measures.

mTBI patients were divided into two subgroups: 1) CT/MRI positive, defined as patients with any acute traumatic intracranial lesion (epidural hematoma [EDH], subdural hematoma [SDH], subarachnoid hemorrhage [SAH], contusion, or evidence of traumatic axonal injury) and/or depressed skull fracture on either CT or MRI, and 2) CT/MRI negative, defined as patients without any such abnormality. Most previous studies of "complicated" mTBI, including Williams and colleagues,³⁸ demonstrated poorer neuropsychiatric test performance based solely on CT findings (presence of any acute intracranial hemorrhage or depressed skull fracture). Our dichotomization of mTBI patients according to presence of abnormalities on *either* CT or MRI is based on more recent work that demonstrated poorer 3-month outcome associated with early MRI intracranial abnormalities, whether or not visible on CT.³⁹

Diffusion tensor image processing

Nonbrain tissue was eliminated from the diffusion-weighted and 3D T1-weighted images using the Functional MRI of the Brain (FMRIB, Oxford University, Oxford, UK) Brain Extraction Tool.⁴⁵ Diffusion-weighted images were corrected for eddy currents and registered to the $b=0$ sec/mm² volume using the FMRIB Linear Image Registration Tool. A diffusion tensor model was constructed using the FMRIB DTIFit algorithm⁴⁶ to yield fractional anisotropy (FA), mean diffusivity (MD), axial diffusivity (AD), and radial diffusivity (RD) at each voxel. Tract-based spatial statistics (TBSS)⁴⁷ were used to align each subject's FA data to a white matter skeleton, after low FA values below a threshold of 0.25 were excluded to limit voxels to the white matter.

Voxel-wise nonparametric statistical comparison between 76 mTBI patients and 50 controls was performed using the FMRIB Software Library (FSL) randomise algorithm based on permutation testing, with corrections for multiple voxel-wise comparisons using threshold-free cluster enhancement (TFCE).⁴⁸ Anatomic locations of voxel clusters with statistically significant differences in FA, MD, RD, or AD between mTBI and control groups at $p < 0.05$ were

determined. This analysis was also used to compare the subgroup of 32 CT/MRI-positive patients to the 50 controls and also the subgroup of 44 CT/MRI-negative mTBI patients to the 50 controls.

In addition to the whole-brain voxel-wise approach, we performed a complementary ROI analysis to address the possibility that a whole-brain, data-driven approach might not be sufficiently sensitive to reveal white matter injury because of possibly significant spatial heterogeneity of white matter injury across mTBI subjects. Twenty-seven white matter ROIs were delineated by the intersection of the Johns Hopkins University (Baltimore, MD) ICBM-DTI-81 White Matter Labeled Atlas⁴⁹ and the reference white matter skeleton. These consisted of the anterior corona radiata, superior corona radiata, posterior corona radiata, anterior limb of internal capsule, posterior limb of internal capsule, external capsule, superior longitudinal fasciculus, sagittal striatum, ventral cingulum (parahippocampal gyrus), dorsal cingulum (cingulate gyrus), inferior fronto-occipital fasciculus, and superior fronto-occipital fasciculus, each on the left and right; and also the body, genu, and splenium of the corpus callosum. The FA, MD, AD, and RD within each of these 27 ROIs in each patient and control subject were determined. For each ROI, the mean and standard deviation (SD) of the FA within the group of 50 control subjects was calculated. Similarly, for each ROI, the mean and SD for each of the other DTI measures (MD, AD, and RD) in the group of 50 control subjects were calculated. For each of the 76 mTBI patients and 50 control subjects, an abnormal ROI was then defined as one in which a DTI measure (FA, MD, AD, or RD) was more than 2.2 SDs below or above the control-group mean, based on the distribution of the DTI measure within the 50 control patients alone.

Outcome measures

Outcome measures included the Extended Glasgow Outcome Scale (GOS-E) at 3 and 6 months postinjury, the Rivermead Postconcussion Symptoms Questionnaire (RPQ), California Verbal Learning Test–Second Edition (CVLT-II), Wechsler Adult Intelligence Scale–Fourth Edition, Processing Speed Index (WAIS-IV PSI), and Trail Making Tests A and B (TMT A and TMT B) at 6 months. The GOS-E was obtained at 3 and 6 months postinjury through structured interview with each participant by research assistants trained to uniformly assess the GOS-E. Modeled after the 5-point Glasgow Outcome Scale (GOS), the 8-point GOS-E provides better discrimination among more subtle aspects of disability within mild-to-moderate, rather than mild-to-severe, TBI and is a well-validated, widely employed measure of global function after mTBI.⁵⁰ The TMT A and B are tests of visual attention, visual-motor coordination, task switching, and executive function.^{51,52} WAIS-IV PSI is a test of perceptual processing speed with additional contribution from working memory.^{53,54} The CVLT-II is a test of verbal learning and memory and was used in place of the TBI CDE Rey Auditory Verbal Learning Test because of recent revision of the CVLT with demonstration of improved psychometric properties.^{55,56} The RPQ consists of 16 symptoms frequently reported after mTBI.^{57,58} The first three symptoms, denoted RPQ-3, are more physical symptoms (headaches, dizziness, and nausea/vomiting) typically experienced immediately after the TBI event, whereas the other 13 symptoms (denoted RPQ-13) are more psychosocial in nature (hyperacusis, sleep disturbances, fatigue, irritability, depressed mood, frustration, forgetfulness, poor concentration, requiring longer times to think, blurred vision, light sensitivity, double vision, and restlessness) and have been shown to occur later in the clinical course after mTBI.^{59,60}

We assessed for statistically significant group differences in each outcome measure between CT/MRI-positive and -negative mTBI patients. The CVLT-II, WAIS-IV PSI, and TMT A and B scores were converted to normative scores for age, and ANOVA was used to test for group differences in these variables between CT/MRI-positive and -negative mTBI patients at $p < 0.05$. Mann-

Whitney U test was used to assess for group differences in the 3-month GOS-E, 6-month GOS-E, RPQ-3, and RPQ-13 at $p < 0.05$. All statistical analyses were performed using SPSS Statistics (version 21).

Spearman's correlation and ordinal logistic regression analyses

We calculated Spearman's correlation coefficients between each outcome measure and each of 11 demographic (age, gender), socioeconomic (employment status, number of years of formal education), and clinical (history of major neuropsychiatric diagnosis, history of drug or alcohol abuse, GCS upon ED arrival, any PTA, PTA duration, any LOC, any history of mTBI with LOC duration not exceeding 5 min) predictors, 5 noncontrast head CT features (calvarial or skull base fracture, EDH, SDH, SAH, contusion), and 3 brain MRI features (contusion, hemorrhagic axonal injury, or evidence of white matter injury on DTI ROI analysis). We used Spearman's correlation, rather than its parametric counterpart, Pearson's product-moment correlation, because of the nominal or ordinal nature and/or non-normal distribution of most of these variables. We then performed multivariable logistic or linear regression of each outcome measure upon all predictors with which the outcome measure had demonstrated a statistically significant pairwise Spearman's correlation. For both Spearman's correlation and the regression analyses, the CVLT-II, WAIS-IV PSI, and TMT A and B test scaled or z-scores, as well as binary outcome variables corresponding to performance worse or better than 2 SDs worse than the normative score as determined by previous studies,^{52,54,55} were included as outcome variables. For the ordinal logistic regression analyses, tests for parallel lines were performed and confirmed the proportional odds assumption for each analysis. These statistical analyses were performed using SPSS Statistics (version 21).

Results

Study population characteristics

Table 1 summarizes demographic, socioeconomic, and clinical characteristics of participants. There were no statistically significant differences among CT/MRI-positive, CT/MRI-negative, and control subjects in age, number of years of formal education, gender, or handedness. Employment status was unknown for control subjects, but there was no difference at $p < 0.05$ between CT/MRI-positive and -negative patients. Among the clinical variables, rates of major neuropsychiatric diagnosis, history of drug or alcohol abuse, and history of previous mTBI with LOC up to 5 min were significantly higher in CT/MRI-negative and -positive mTBI pa-

tients than in control subjects, but were not statistically different between CT/MRI-negative and -positive patients. (Patients with a history of any previous TBI with LOC > 5 min had been excluded from the study.) PTA duration was longer in CT/MRI-positive patients (median PTA duration, 1–29 min) than in CT/MRI-negative patients (median PTA duration, < 1 min). There was no significant difference in GCS or LOC between CT/MRI-negative and -positive mTBI groups at $p < 0.05$ (Table 1).

Conventional CT and MRI results

Table 2 shows that MRI identifies many more acute traumatic intracranial lesions than CT. TBI-CDE-defined pathoanatomic features observed on head CT upon ED presentation and early brain MRI in our study population consisted of the following: nondepressed skull fracture; EDH; SDH; SAH; brain contusion; and hemorrhagic axonal injury. Hemorrhagic axonal injury was observed on many brain MRI exams, but on only one head CT, in this study. Other TBI-CDE features, such as midline shift ≥ 5 mm and partial or complete basal cistern effacement that are more characteristic of moderate-to-severe TBI, were also not observed on any head CT or brain MRI in this study. In addition, no depressed skull fracture was observed in this study. As shown in Table 2, all 4 of 4 (100%) patients with CT evidence of contusion also had MRI evidence of contusion $\pm$ hemorrhagic axonal injury. In contrast, 7 of 11 (64%) patients with MRI evidence of contusion and 25 of 27 (93%) with MRI evidence of hemorrhagic axonal injury had no CT evidence of any parenchymal injury. Three patients with nondepressed skull fractures had no CT or conventional MRI traumatic intracranial abnormality and were classified as CT/MRI-negative mTBI (analogous to the classification of patients with isolated nondepressed skull fracture and no acute intracranial hemorrhage as "uncomplicated" mTBI in previous literature³⁸).

Whole-brain voxel-wise nonparametric statistical comparison of diffusion tensor imaging measures in mTBI (n = 76) versus control subjects (n = 50)

Figure 1A shows many statistically significant areas of reduced FA in the 76 mTBI patients, compared to the 50 control subjects, using TBSS and voxel-wise nonparametric statistical comparison implemented in the FSL randomise algorithm and corrected for multiple comparisons with TFCE. mTBI patients demonstrated significantly lower FA in the right internal and external capsules,

TABLE 2. CT AND CONVENTIONAL MRI FINDINGS IN 76 mTBI PATIENTS

	CT				
	Normal	Nondepressed skull fracture only	Acute extraaxial hemorrhage (EDH, SDH, SAH) with no parenchymal injury	Contusion $\pm$ extraaxial hemorrhage	Hemorrhagic axonal injury only
MRI					
No parenchymal injury	41	3	2	0	0
Hemorrhagic axonal injury only	17	0	1	0	1
Contusion only	0	0	0	3	0
Both hemorrhagic axonal injury and contusion	1	1	5	1	0

Gray shaded boxes comprise uncomplicated mTBI (no CT evidence of acute intracranial hemorrhage or depressed skull fracture).³⁸

CT, computed tomography; MRI, magnetic resonance imaging; mTBI, mild traumatic brain injury; EDH, epidural hematoma; SDH, subdural hematoma; SAH, subarachnoid hemorrhage.

FIG. 1. Voxel-wise nonparametric statistical comparison between mild traumatic brain injury (mTBI) patients and controls, with corrections for multiple voxel-wise comparisons using threshold-free cluster enhancement. This analysis was used to compare (A) 76 mTBI patients to 50 controls, (B) the subgroup of 32 computed tomography/magnetic resonance imaging (CT/MRI)-positive mTBI patients to the 50 controls, and (C) the subgroup of 44 CT/MRI-negative patients to the 50 controls. Voxel clusters with statistically significant differences in fractional anisotropy (FA) between mTBI and control groups at $p < 0.05$ are shown in red/orange/yellow, with yellow denoting greater statistical significance. (A) shows that the 76 mTBI patients demonstrated significantly lower FA in the genu of the corpus callosum, uncinate fasciculi, and anterior corona radiata bilaterally as well as right internal and external capsules, compared to the 50 control subjects. (B) In a comparison of a much smaller subgroup of 32 CT/MRI-positive mTBI patients to the 50 controls, areas of reduced FA were even more extensive and attained much higher levels of statistical significance (yellow regions, corresponding to $p < 0.01$) than in the comparison of 76 mTBI patients to the control group (mostly red/orange areas, corresponding to $p < 0.05$, in [A]). (C) shows that this method demonstrated no evidence for white matter injury in 44 CT/MRI-negative mTBI patients, compared to the 50 controls. Color image is available online at www.liebertpub.com/neu

genu of the corpus callosum, and uncinate fasciculi and anterior corona radiata bilaterally.

No voxel with significantly increased FA, and no significant group differences in MD, RD or AD, were found in mTBI patients, compared to the control group at $p < 0.05$ using TBSS, randomise, and correction for multiple comparisons with TFCE.

Whole-brain voxel-wise nonparametric statistical comparison of diffusion tensor imaging measures in CT/MRI-positive mTBI (n = 32) versus control subjects (n = 50)

Figure 1B shows many highly statistically significant areas of reduced FA in the CT/MRI-positive subgroup of mTBI patients, compared to the control group. Despite the expected loss of statistical power for this comparison of a much smaller subgroup of 32 CT/MRI-positive mTBI patients to the control group, areas of

reduced FA were even more extensive and attained higher levels of statistical significance (yellow regions, corresponding to $p < 0.01$; Fig. 1B) than in the comparison of 76 mTBI patients to the control group (mostly red/orange areas, corresponding to $p < 0.05$; Fig. 1A). mTBI patients demonstrated significantly lower FA in the genu and body of the corpus callosum, the external capsules, uncinate fasciculi, and anterior corona radiata bilaterally, the right internal capsule, and the right inferior longitudinal and inferior fronto-occipital fasciculi. Extensive areas of increased RD were also observed in the 32 CT/MRI-positive mTBI patients, relative to the control group, whereas none had been observed in the comparison of 76 mTBI patients to the control group. No voxel with increased FA or reduced RD was observed in CT/MRI-positive mTBI patients, relative to controls, at $p < 0.05$. There were also no voxels in which MD or AD differed significantly between CT/MRI-positive mTBI and control groups at $p < 0.05$.

Whole-brain voxel-wise nonparametric statistical comparison of diffusion tensor imaging measures in CT/MRI-negative mTBI (n = 44) versus control subjects (n = 50)

No significant group differences in FA (Fig. 1C), MD, RD, or AD were found between CT/MRI-negative mTBI and control groups at $p < 0.05$.

Whole-brain voxel-wise nonparametric statistical comparison of diffusion tensor imaging measures in most highly educated versus least educated control subjects (n = 50)

To exclude the possibility that the nonsignificant differences in educational level among CT/MRI-positive mTBI, CT/MRI-negative mTBI, and control groups (Table 1) could result in group differences in DTI parameters that could be erroneously attributed to mTBI, we assessed for group differences in DTI parameters between control subjects with the longest and shortest duration of education. The 50 control subjects were divided into two groups, one consisting of 25 patients with the most years of formal education and the other consisting of 25 patients with the fewest years of formal education. There were no statistically significant group differences in DTI parameters between these groups at $p < 0.05$. This analysis was performed to exclude the possibility that the statistically significant group differences in FA shown in Figure 1A and 1B were attributable mostly to educational level or to other socioeconomic factors that might be correlated with educational level.

Region-of-interest analysis of individual mTBI subjects

Table 3 shows that abnormally low FA (FA more than 2.2 SDs below the control-group mean) was observed in ≥ 1 ROIs for 14 of 32 CT/MRI-positive mTBI (43.8%), 11 of 44 CT/MRI-negative mTBI (25.0%), and 5 of 50 (10.0%) control subjects. Pearson's χ^2 test showed a highly significant difference between the pro-

portions of CT/MRI-positive mTBI patients (43.8%) and control subjects (10.0%) with ≥ 1 abnormal ROIs ($p = 0.0006$). There was a trend toward a significant difference between the proportions of CT/MRI-negative mTBI patients (25.0%) and controls (10.0%) with ≥ 1 abnormal ROIs ($p = 0.06$). Finally, there was no significant difference between the proportions of CT/MRI-positive mTBI patients (43.8%) and CT/MRI-negative mTBI patients (25.0%) with ≥ 1 abnormal ROIs ($p = 0.14$).

Table 3 also shows that there was no significant difference ($p = 0.93$) among the proportions of CT/MRI-positive, CT/MRI-negative, and control subjects with ≥ 1 ROI with abnormally high FA (FA more than 2.2 SDs above the control-group mean).

Outcome measures

Table 4 summarizes 3- and 6-month outcome measures of participants. There were no statistically significant differences in any 3- or 6-month outcome measure between CT/MRI-negative and -positive mTBI groups at $p < 0.05$. For the TMT A and B, the actual times for test completion, the corresponding TMT A and B z-scores adjusted for age,⁵² as well as the proportion of abnormal performances worse than 2 SDs from the age-adjusted mean, were compared between CT/MRI-positive and -negative mTBI groups, and none showed a statistically significant difference at $p < 0.05$.

Spearman's correlation

Table 5 shows the pair-wise Spearman's correlation coefficients between 3- and 6-month outcome measures and demographic, socioeconomic, clinical, CT, and MRI predictors. Gender, employment status, GCS at ED arrival, PTA, PTA duration, LOC, and history of previous TBI with LOC up to 5 min were not significantly correlated with any outcome variable, and these predictors were thus omitted from Table 5, for brevity. Similarly, worse outcomes, as measured by the 6-month TMT A (both age-adjusted z-score and the dichotomized score), TMT B (z-score), CVLT-II (both age-adjusted scaled score and dichotomized score), and WAIS-IV PSI

TABLE 3. DTI REGION-OF-INTEREST (ROI) ANALYSIS: GROUP DIFFERENCES IN PRESENCE OF ONE OR MORE ABNORMAL ROIS AMONG CT/MRI-NEGATIVE mTBI, CT/MRI-POSITIVE mTBI, AND CONTROL SUBJECTS

	<i>CT/MRI-negative mTBI (no acute traumatic intracranial abnormality or depressed skull fracture on CT or conventional MRI) (44 subjects)</i>	<i>CT/MRI-positive mTBI (positive acute traumatic intracranial abnormality and/or depressed skull fracture on CT and/or conventional MRI) (32 subjects)</i>	<i>Controls (50 subjects)</i>

^aNo statistically significant correlation was found between any imaging, demographic, socioeconomic, or clinical predictor and worse performance on 6-month TMT A (either z-score or dichotomized score), TMT B (z-score), CVLT-II (scaled score or dichotomized score), or WAIS-IV PSI (scaled score or dichotomized score), except for correlation of CVLT-II scaled score with years of education ($\rho=0.27$; $p=0.04$) and correlation of age with TMT A z-score ($\rho=-0.33$; $p=0.0097$). Thus, for brevity, these outcome measures are omitted from Table 5.

^bNo statistically significant correlation was found between gender, unemployment, GCS at emergency department arrival, PTA, PTA duration, LOC, or history of previous TBI (with LOC not exceeding 5 min) and any outcome variable. Thus, for brevity, these predictors are omitted from Table 5. There was a trend toward significant correlation between 6-month GOS-E and unemployed status ($\rho=-0.24$; $p=0.056$).

CT, computed tomography; MRI, magnetic resonance imaging; GOS-E, Glasgow Outcome Scale-Extended; CI, confidence interval; DTI, diffusion tensor imaging; ROI, region of interest; FA, fractional anisotropy; SD, standard deviation; RPQ, Rivermead Postconcussion Questionnaire; TMT B, Trail Making Test B.

* $p \leq 0.05$ (light-gray box) $^\dagger p \leq 0.01$ (medium-gray box) $^\ddagger p \leq 0.001$ (dark-gray box) $^\S p \leq 0.0001$ (dark-gray box).

(both age-adjusted scaled score and dichotomized score), were not significantly correlated with any imaging, clinical, demographic, or socioeconomic predictor (with the exception of modest correlations between CVLT-II scaled score and years of education and between age and TMT A z-score), and these outcome measures were thus also omitted from Table 5, for brevity.

Table 5 shows that among demographic, clinical, and socioeconomic predictors, previous history of neuropsychiatric disorder was the most consistent predictor of outcome, demonstrating statistically significant correlations with 3-month GOS-E ($\rho = -0.27$; $p = 0.03$), 6-month GOS-E ($\rho = -0.30$; $p = 0.02$), 6-month RPQ-3 ($\rho = 0.36$; $p = 0.003$), and 6-month RPQ-13 ($\rho = 0.31$; $p = 0.013$).

Among the imaging predictors, DTI evidence of one or more ROIs with abnormally reduced FA (> 2.2 SDs below control-group mean) was the most consistent predictor of outcome, demonstrating statistically significant correlations with 3-month GOS-E ($\rho = -0.34$; $p = 0.004$), 6-month GOS-E ($\rho = -0.25$; $p = 0.04$), abnormal 6-month TMT B ($\rho = 0.32$; $p = 0.011$), and 6-month RPQ-13 ($\rho = 0.29$; $p = 0.02$). Among other imaging predictors, MRI evidence of contusion was significantly correlated with 3-month GOS-E ($\rho = -0.36$; $p = 0.003$), as was CT evidence of SAH, though more weakly ($\rho = -0.28$; $p = 0.02$).

Regression of 3- and 6-month outcome measures on demographic, clinical, and imaging predictors

Based on the results of Spearman's correlation analysis (Table 5), we constructed regression models of each of five outcome measures: 3-month GOS-E; 6-month GOS-E; 6-month TMT B (dichotomized score); 6-month RPQ-3; and 6-month RPQ-13. The predictive (independent) variables in the model for each outcome measure were limited to only those predictors that had demonstrated a statistically significant Spearman's correlation with that outcome measure in Table 5. This resulted in a multivariable regression model for four outcome measures (3- and 6-month GOS-E, 6-month RPQ-3, and 6-month RPQ-13) and a univariable regression model for one outcome measure (6-month TMT B dichotomized score). No regression model was constructed for any outcome measure that lacked a statistically significant Spearman's correlation with at least one predictor.

For the 3-month GOS-E, age, number of years of education, neuropsychiatric history, MRI evidence for contusion, and DTI evidence of one or more abnormal ROIs with FA more than 2.2 SDs below the control-group mean demonstrated statistically significant univariable odds ratios (ORs; Table 6A), compatible with the Spearman's correlation results from Table 5. The multivariable model for 3-month GOS-E, including all of these predictors, was also significant (pseudo- R^2 of 34.5–36.9%; $p = 0.00002$; Table 6A). Although CT evidence of SAH demonstrated a nearly statistically significant univariable OR ($p = 0.053$), it was excluded from the multivariable model because of collinearity with MRI evidence of contusion. In particular, unstable ORs and a variance inflation factor > 2 were observed for CT evidence of SAH and MRI evidence of contusion when both were simultaneously included in the multivariable model.

For the 6-month GOS-E, years of education, neuropsychiatric history, and DTI evidence of one or more abnormal ROIs with FA more than 2.2 SDs below the control-group mean demonstrated statistically significant univariable ORs (Table 6A), compatible with Spearman's correlation results from Table 5. The multivariable model for 6-month GOS-E, including all of these predictors, was also significant (pseudo- R^2 of 15.3–16.3%; $p = 0.013$; Table 6A).

For 6-month RPQ-13, age, years of education, neuropsychiatric history, and DTI evidence of one or more abnormal ROIs with FA more than 2.2 SDs below the control group mean demonstrated statistically significant univariable ORs, consistent with Spearman's correlation results from Table 5. The multivariable linear regression model for 6-month RPQ-13, including all of these predictors was also significant (adjusted R^2 of 23.7%; $p = 0.0004$; Table 6B).

Because the 6-month TMT B was significantly correlated with only one predictor (Table 5), a univariable binary logistic regression model was constructed for this outcome measure. DTI evidence of one or more ROIs with abnormally reduced FA demonstrated a statistically significant univariable OR of 4.5 ($p = 0.014$; Table 6C).

For 6-month RPQ-3, only neuropsychiatric history and history of drug or alcohol abuse demonstrated statistically significant univariable ORs. The multivariable ordinal logistic regression model for 6-month RPQ-3, including both of these predictors, was also statistically significant (pseudo- R^2 of 9.5–13.9%; $p = 0.015$).

Analysis of subset of patients without pre-existing neuropsychiatric or substance abuse history

Most previous studies of DTI in mTBI have excluded patients with history of neuropsychiatric disease or substance abuse on the grounds that DTI results could be influenced by one or both of these factors. We performed whole-brain voxel-wise nonparametric statistical comparison of FA in CT/MRI-negative patients with a positive history of neuropsychiatric disease or substance abuse ($n = 24$), compared to those without ($n = 20$). Many areas of reduced FA at $p < 0.25$ (though not at $p < 0.05$) were found. Therefore, to address the possibility that a previous history of substance abuse and/or neuropsychiatric disease could have influenced our results, we separately analyzed the subset of mTBI patients without such history. Supplementary Tables S2 and S3 (see online supplementary material at <http://www.liebertpub.com>) summarize demographic, socioeconomic, and clinical characteristics, and 3- and 6-month outcome measures, for this subset of 37 mTBI patients without history of substance abuse or neuropsychiatric disease.

Figure 2A is analogous to Figure 1A, but compares only mTBI patients without history of neuropsychiatric disorder or substance abuse ($n = 37$) to control subjects ($n = 50$). Unlike Figure 1A, no significant group differences in FA (Fig. 2A), MD, RD, or AD were found.

Analogous to Figure 1B, Figure 2B compares CT/MRI-positive mTBI patients without neuropsychiatric or substance abuse history ($n = 17$) to controls ($n = 50$). There are extensive areas of reduced FA in the CT/MRI-positive mTBI patients, despite the expected loss of statistical power for comparison of this small subgroup of only 17 CT/MRI-positive mTBI patients to controls. No region of increased FA, or of increased or reduced MD, AD, or RD, was observed in CT/MRI-positive mTBI patients, relative to controls, at $p < 0.05$.

Finally, analogous to results in Figure 1C, no significant group differences in FA (Fig. 2C), MD, RD, or AD were found in CT/MRI-negative patients without neuropsychiatric or substance abuse history ($n = 20$), compared to controls ($n = 50$), at $p < 0.05$.

Table 7 shows that all 17 of 17 (100.0%) CT/MRI-positive mTBI patients without neuropsychiatric or substance abuse history had abnormal conventional MRI, but only 5 of 17 (24%) had abnormal head CT. One patient with a nondepressed anterior skull base fracture had no CT or MRI evidence of traumatic brain lesion or intracranial hemorrhage and was classified as CT/MRI-negative mTBI (analogous to the classification of isolated nondepressed skull fracture as uncomplicated mTBI in previous literature³⁸). On conventional MRI

FIG. 2. Voxel-wise nonparametric statistical comparison between mild traumatic brain injury (mTBI) patients without previous history of substance abuse or other neuropsychiatric disorder and controls, with corrections for multiple voxel-wise comparisons using threshold-free cluster enhancement. This analysis was used to compare (A) 37 mTBI patients without pre-existing substance abuse or neuropsychiatric history to 50 controls, (B) the subgroup of 17 computed tomography/magnetic resonance imaging (CT/MRI)-positive mTBI patients to the 50 controls, and (C) the subgroup of 20 CT/MRI-negative patients to the 50 controls. Voxel clusters with statistically significant differences in fractional anisotropy (FA) between mTBI and control groups at $p < 0.05$ are shown in red/orange/yellow, with yellow denoting greater statistical significance. (B) shows that CT/MRI-positive mTBI patients without substance abuse or neuropsychiatric history demonstrated significantly lower FA in the anterior and posterior limbs of the internal capsules, external capsules, uncinate fasciculi, genu of the corpus callosum, and anterior corona radiata bilaterally. In contrast, (C) shows that this method demonstrated no evidence for white matter injury in CT/MRI-negative mTBI. Color image is available online at www.liebertpub.com/neu

sequences, most CT/MRI-positive mTBI patients (11 of 17; 64.7%) demonstrated isolated foci of hemorrhagic axonal injury without brain contusion; 4 of 17 (23.5%) demonstrated both hemorrhagic axonal injury and brain contusion; 1 of 17 (5.9%) demonstrated brain contusions and EDH; and 1 of 17 (5.9%) had isolated SDH.

Tables 7 and 8 also show results of ROI analysis of the 17 CT/MRI-positive and 20 CT/MRI-negative mTBI patients without a history of neuropsychiatric or substance abuse. Table 7 shows lesions with abnormally low FA (FA more than 2.2 SDs below the control-group mean) in individual patients. Table 8 shows that such lesions were observed in ≥ 1 ROIs for 9 of 17 CT/MRI-positive mTBI (52.9%), 2 of 20 CT/MRI-negative mTBI (10.0%), and 5 of 50 (10.0%) control subjects. Fisher's exact test showed a highly significant difference between the proportions of CT/MRI-positive mTBI patients (52.9%) and control subjects (10.0%) with ≥ 1 abnormal ROIs ($p = 0.0006$). There was also a highly significant difference between the proportions of CT/MRI-positive mTBI patients (52.9%) and CT/MRI-negative mTBI patients (10.0%)

with ≥ 1 abnormal ROIs ($p = 0.0097$). However, there was no difference in the proportions of CT/MRI-negative mTBI patients (10.0%) and controls (10.0%) with ≥ 1 abnormal ROIs ($p = 1.0$). Finally, there was no significant difference among CT/MRI-positive mTBI, CT/MRI-negative mTBI, and control subject groups in terms of the proportion of subjects with ≥ 1 ROI with abnormally high FA ($p = 0.75$).

Table 9 is analogous to Table 5 and shows the pairwise Spearman's correlations between 3- and 6-month outcome measures and demographic, socioeconomic, clinical, CT, and MRI predictors in patients without a history of neuropsychiatric or substance abuse. Except for an expected correlation⁵² of years of education with TMT B z-score ($\rho = -0.50$; $p = 0.007$), and correlation of TMT A z-score with age ($\rho = -0.39$; $p = 0.04$) and with PTA duration ($\rho = 0.48$; $p = 0.014$), no demographic, socioeconomic, or clinical variable (age, gender, employment status, GCS, PTA, PTA duration, LOC, or history of earlier TBI) was otherwise significantly correlated at $p < 0.05$ with worse performance on any outcome measure; all demographic,

One or more ROIs with FA more than 2.2 SD above control-group mean	3 (15.0%) ^c	1 (5.9%) ^c	5 (10.0%) ^c

^{a,b,c}Each superscript denotes a subset of participants whose column proportions do not differ significantly from one another, by Fisher's exact test with $p < 0.05$. Row 1: There was a significant difference between the proportions of CT/MRI-positive (52.9%) and CT/MRI-negative mTBI patients (10.0%) with one or more ROIs with FA more than 2.2 SDs below the control group mean ($p = 0.0097$). There was also a highly significant difference between CT/MRI-positive mTBI patients (52.9%) and controls (10.0%; $p = 0.0006$). However, there was no difference between CT/MRI-negative mTBI patients (10.0%) and controls (10.0%; $p = 1.0$). Row 2: There was no significant difference among the proportions of CT/MRI-negative mTBI (15.0%), CT/MRI-positive mTBI (5.9%), and control subjects (10.0%) with one or more ROIs with FA more than 2.2 SDs above the control group mean ($p = 0.75$).

CT, computed tomography; MRI, magnetic resonance imaging; DTI, diffusion tensor imaging; ROI, region of interest; mTBI, mild traumatic brain injury; FA, fractional anisotropy; SD, standard deviation.

socioeconomic, and clinical variables were thus excluded from Table 9 for brevity. Similarly, 6-month TMT A (both age-adjusted z-score and the dichotomized score), TMT B (z-score), CVLT-II (both age-adjusted scaled score and dichotomized score), and WAIS-IV PSI (both age-adjusted scaled score and dichotomized score) were also omitted from Table 9 because they demonstrated no other significant correlation with any other imaging, clinical, demographic, or socioeconomic predictor at $p < 0.05$.

Table 9 shows that among the imaging predictors, no CT feature (CT evidence of nondepressed skull fracture, EDH, SDH, SAH, or contusion) was significantly correlated with any outcome measure at $p < 0.05$. In contrast, several MRI features, including MRI evidence of contusion, MRI evidence of hemorrhagic axonal injury, and presence of abnormally reduced FA in at least one ROI, demonstrated statistically significant correlations with several outcome measures (3- and 6-month GOS-E, abnormal 6-month TMT B, and the 6-month RPQ-13).

Discussion

In the current study, white matter FA was significantly reduced in CT/MRI-positive, but not in CT/MRI-negative, mTBI patients, compared to healthy control subjects, on a group level. In addition, regions of reduced FA in individual mTBI patients were modest, but statistically significant, predictors of unfavorable 3- and 6-month outcome. These results held true for both the inclusive sample of 76 mTBI patients as well as the subset of 37 mTBI patients with no history of previous substance abuse or other neuropsychiatric disorder.

Previous studies have reported evidence of white matter injury on DTI in the acute-to-subacute time period after mTBI.^{15–18,20,23–25,27–31,34–36} In essentially all of these studies, patients with history of substance abuse or other neuropsychiatric disorders were excluded. In addition, in nearly all of these studies, the mTBI study population included a mixed group of both CT/MRI-positive and -negative mTBI, based on presence of intracranial abnormalities on CT alone, CT and 1.5T MRI, or CT and 3T MRI. Miles and colleagues³¹ found, using an ROI approach, reduced average FA and increased average MD within six ROIs in a group-wise comparison of 17 mTBI patients, studied within 10 days of injury at 1.5T MRI and with no evidence of microhemor-

rhages, to 29 age- and gender-matched controls. In contrast, Ling and colleagues²⁴ found increased FA and decreased RD, within the callosal genu, in a mixture of 28 CT/MRI-negative and -positive mTBI patients who underwent MRI 15.6 ± 4.3 days after injury. Messe and colleagues,³⁰ using a whole-brain voxelwise approach to study a mixture of CT/MRI-negative and -positive mTBI patients, found higher MD values in poor-outcome patients, compared to good-outcome patients and controls, in the corpus callosum, right anterior thalamic radiations, superior longitudinal fasciculus, and inferior longitudinal and fronto-occipital fasciculi at 7–28 days after injury. Lange and colleagues,²³ using an ROI approach, found no significant difference in FA or MD in the genu, body, or splenium of the corpus callosum in 60 CT/MRI-positive and -negative mTBI patients (on the more severe end of the mTBI spectrum), relative to 34 trauma controls. A smaller number of studies^{20,25,27,35} has reported statistically significant group-wise or individual FA differences in the acute-to-subacute time period in strictly CT/MRI-negative mTBI patients versus controls. For example, Lipton and colleagues, using a whole-brain voxelwise approach, found reduced FA in multiple white matter regions at 2–14 days postinjury in 20 CT/MRI-negative mTBI patients, compared to 20 age- and gender-matched controls.²⁷ McAllister and colleagues⁵⁶ found a statistically significant correlation between mean and maximum strain rate (based on measurements from instrumented helmets and finite element biomechanical simulation) and increased FA in the corpus callosum within the first 10 days after concussion in athletes with normal conventional brain MRI.

From the above, it is evident that DTI analysis techniques have varied between more data-driven, whole-brain voxel-wise analyses and hypothesis-driven ROI approaches. In addition, although nearly all studies have employed group-comparison designs, some investigators have chosen to compare mTBI patients to healthy controls (in some cases, matched by age, gender, and/or education), whereas others have compared mTBI subgroups with good versus poor outcome. These earlier studies, most of which are limited by small sample sizes, have also not analyzed DTI results in the context of important clinical, demographic, and socioeconomic factors relevant to TBI outcomes. Finally, there is a persistent and striking inconsistency across different DTI studies, in terms of the reported direction of changes in DTI measures after mTBI.

Whole-brain voxel-wise approaches may have limited sensitivity as a result of the heterogeneity of spatial distribution of white matter

TABLE 9. SPEARMAN'S CORRELATION COEFFICIENTS (ρ) BETWEEN OUTCOME MEASURES AND EARLY NEUROIMAGING PATHOANATOMIC FINDINGS IN 37 MTBI PATIENTS WITHOUT PREVIOUS HISTORY OF SUBSTANCE ABUSE OR OTHER NEUROPSYCHIATRIC DISORDER^a

^aThe only statistically significant pair-wise correlations between any demographic, clinical or socioeconomic predictor and worse performance on any outcome variable were between years of education and TMT B z-score ($\rho = -0.50$; $p=0.007$), age and TMT A z-score ($\rho = -0.39$; $p=0.04$), and PTA duration and TMT A z-score ($\rho=0.48$; $p=0.014$). Thus, for brevity, all demographic, clinical, and socioeconomic predictors (Supplementary Table 2) (see online supplementary material at <http://www.liebertpub.com>) are omitted from Table 9. Similarly, 6-month TMT A (both z-score and dichotomized score), TMT B (z-score), CVLT-II (scaled score and dichotomized score), and WAIS-IV PSI (scaled score and dichotomized score) were omitted from Table 9, because they demonstrated no other significant correlation with any imaging, clinical, demographic, or socioeconomic predictor at $p < 0.05$. * $p < 0.05$ (light-gray boxes); $p < 0.01$ (dark-gray boxes).

injury in mTBI; on the other hand, the ROI approach may be limited by failure to interrogate less-common areas of white matter injury. We employed both of these as complementary approaches in the current study and demonstrated that microstructural white matter injury severity does vary, on a group level, according to the presence of more-familiar macroscopic pathoanatomic lesions on CT and conventional MRI. It may not be surprising that the data show that CT/MRI-positive mTBI patients have more extensive white matter injury than CT/MRI-negative mTBI patients. However, such work is relevant because any utility of DTI in outcome prediction would be contingent on demonstration of a differential increase in diagnostic or prognostic accuracy beyond conventional CT and MRI as well as clinical, demographic, and socioeconomic predictors.

In this study of 76 mTBI patients and 50 control subjects, and using current DTI acquisition and postprocessing techniques, CT/MRI-positive mTBI patients demonstrated evidence of white matter injury when employing either whole-brain voxel-wise or ROI approaches. Indeed, we found no evidence for white matter injury, using either the whole-brain voxel-wise or ROI methods, in mTBI patients without lesions on CT or 3T MRI that included high-resolution 3D T1- and T2-weighted sequences as well as T2*-weighted gradient echo sequences. These findings held true in both the inclusive group of 76 mTBI patients, as well as the subset of 37 patients with no previous history of substance abuse or other neuropsychiatric disorders. There are several possible reasons for the discrepancy between our results with a few earlier studies demonstrating statistically significant FA differences on acute-to-subacute 3T DTI between strictly CT/MRI-negative mTBI patients and controls.^{20,25,27,35} Technical differences in DTI acquisition or DTI postprocessing techniques could always be an explanation for such differences. The effect size and incidence of white matter injury in CT/MRI-negative mTBI may be too small, or the severity and/or spatial distribution too variable among patients, to show statistically significant group differences based on the number of patients and analysis approach employed in the current study. The injury-to-MRI interval may be a critical factor; it has been postulated that a variety of different biological processes within injured white matter may vary not only according to injury severity, but also at different time intervals after injury, and that FA, in particular, may be abnormally increased within the first week of injury.^{16,18,29,35,36} Patients in the current study underwent MRI during the first 3 weeks after injury (11.2 ± 3.3 days), when different biological processes and thus DTI parameters may still have been evolving. Finally, it is possible that our results differ because many cases of CT/MRI-positive mTBI in this study were placed in that group on the basis of very subtle MRI lesions at 3T, such as one or two subtle isolated foci of hemorrhagic axonal injury, and may have been classified as uncomplicated mTBI in other studies. This third explanation has the appeal of being compatible with earlier literature that reports DTI evidence of white matter injury in subjects classified as uncomplicated mTBI based on CT alone.^{15,16,18,36} Another main aim of this work was to investigate the utility of DTI parameters as predictors of individual outcome. We thus determined and compared ORs for a variety of demographic, socioeconomic, clinical, and imaging predictors, including DTI parameters. Our data suggest that MRI predictors, particularly MRI evidence of contusion and DTI evidence of one or more ROIs with reduced FA, and clinical and socioeconomic predictors, including education and previous history of neuropsychiatric disorder, surpass most CT features for prediction of most 3- and 6-month outcome measures.

Analysis of the subset of mTBI patients without a previous history of substance abuse and/or neuropsychiatric disease (Fig. 2;

Tables 7–9 and Supplementary Tables 2 and 3) (see online supplementary material at <http://www.liebertpub.com>) is informative, because it addresses the problem of a possible strong confounding influence of these pre-existing conditions owing to their potential relationships with *both* DTI parameters and outcome. In this subset analysis, it was actually necessary to separate CT/MRI-positive from CT/MRI-negative mTBI patients to see any evidence of white matter injury using either the whole-brain voxel-wise or ROI approaches. Specifically, the whole-brain voxel-wise analysis (Fig. 2) and ROI analysis (Tables 7 and 8) both demonstrate differences between CT/MRI-positive and -negative mTBI patients that are even more striking and statistically significant than in the original analysis of the inclusive group of 76 mTBI patients. Table 8 shows a strikingly higher prevalence of abnormal ROIs with reduced FA in CT/MRI-positive patients without previous history of substance abuse or other neuropsychiatric disorders, relative to both the CT/MRI-negative mTBI patients ($p=0.004$) and the control group ($p=0.0002$); in contrast, the same prevalence of abnormal ROIs with reduced FA was observed in CT/MRI-negative patients (10.0%) and in the control group (10.0%).

It is noteworthy that both conventional MRI and DTI predictors demonstrated stronger correlation coefficients with 3- and 6-month outcome measures in the *subset* of 37 patients lacking any history of neuropsychiatric disease or substance abuse (Table 9) than in the larger inclusive sample of 76 patients (Table 5), despite the much smaller sample size of the former. We postulate that this is because correlations of pre-existing factors, such as neuropsychiatric disease, with the outcome measures (e.g., in Table 5) may have weakened the apparent influence or relevance of the imaging predictors.

It is also notable that there were generally much stronger correlations of MRI predictors with 3-month GOS-E than with 6-month GOS-E. This is plausible, because the MRI exams in this study were performed within 3 weeks after mTBI. Abnormal MRI features in the initial days after injury, which demonstrated a strong correlation with 3-month GOS-E, may be less relevant at 6 months, after a variable degree of recovery has taken place in different patients. The stronger correlation with the GOS-E at 3 months, compared to 6 months, is unlikely to be attributable solely to general overall improvement in the GOS-E over time: Though many individual patients' scores changed between the two time points, there was negligible change in the overall distribution of GOS-E scores at 3 versus 6 months (Table 4 and Supplementary Table 3) (see online supplementary material at <http://www.liebertpub.com>).

In this study, we sought to minimize the influence of confounding factors on group differences in DTI parameters between patient and control groups. Thus, we did not follow the approach of presorting patients according to an outcome measure, and thereafter assessing for group differences in DTI results according to good or poor outcome, because there are many potential confounding factors that could affect both DTI measures and outcome. Further, we analyzed, in addition to the original inclusive sample, the subset of patients lacking any significant reported substance abuse or other neuropsychiatric history, because these pre-existing conditions are heterogeneous by nature and thus difficult to control for in group comparisons and could act as confounding variables that could create or exacerbate group differences in DTI measures. Finally, because there was a nonsignificant, but noticeable, difference in number of years of education among CT/MRI-positive mTBI, CT/MRI-negative mTBI, and control groups, we explicitly demonstrated that there were no group differences in DTI measures, using either the DTI or ROI approach, between the most- and least-educated control subjects.

This study has several limitations. Alteration of DTI parameters in TBI has been linked to a variety of possible pathophysiological mechanisms, such as axonal disruption, axonal degeneration, and cytotoxic edema; recent work also suggests that DTI parameters, such as FA and MD, may be correlated with strain and strain rate in mTBI.⁵⁶ Nevertheless, despite our attempt, in performing the subset analysis, to minimize or eliminate the influence of confounding factors that could account for both DTI lesions and poorer outcome, we acknowledge that lesions in the DTI ROI analysis are nonspecific and may reflect the patient's pre-existing brain structure, rather than a traumatic lesion.³³ Second, a substantial unexplained variance in outcomes remains, even for our most inclusive models that were based on DTI, conventional neuroimaging, and other predictors (Table 6). Third, because the number of predictors we investigated was large, relative to the number of patients, this study should be regarded as exploratory and in need of confirmation in a larger study population. Finally, even for pathoanatomic findings, such as contusion and SAH, that can be definitively attributed to acute TBI based on their unique imaging appearance, the existence of any direct pathophysiological mechanism that accounts for their correlation with outcome remains uncertain.

In summary, this study provides evidence for the importance of individual pathoanatomic features on MRI, including DTI parameters, for prognosis after mTBI. Specifically, several MRI predictors, including DTI parameters, surpassed CT features for prediction of 3- and 6-month outcome measures. For the subset of patients lacking any significant neuropsychiatric or substance abuse history, MRI predictors, including DTI parameters, surpassed all clinical, demographic, socioeconomic, and CT features for prediction of 3- and 6-month outcome. Our results should be viewed as relevant primarily to mTBI patients who meet ACEP/CDC ED criteria for head CT and who thus generally have more severe injuries than mTBI patients who are not triaged to head CT. Our results support the potential utility of MRI and DTI in the acute/subacute stage of acute mTBI for better classification of injury severity. Effective, practical imaging markers that identify mTBI patients who will have unfavorable outcome are essential for clinical trials to evaluate treatments and for better triage to effective follow-up care.

Abstract

Although the majority of patients with mild traumatic brain injury (mTBI) recover completely, some still suffer from disabling ailments at 3 or 6 months. We validated existing prognostic models for mTBI and explored predictors of poor outcome after mTBI. We selected patients with mTBI from TRACK-TBI Pilot, an unselected observational cohort of TBI patients from three centers in the United States. We validated two prognostic models for the Glasgow Outcome Scale Extended (GOS-E) at 6 months after injury. One model was based on the CRASH study data and another from Nijmegen, The Netherlands. Possible predictors of 3- and 6-month GOS-E were analyzed with univariate and multi-variable proportional odds regression models. Of the 386 of 485 patients included in the study (median age, 44 years; interquartile range, 27–58), 75% ($n=290$) presented with a Glasgow Coma Score (GCS) of 15. In this mTBI population, both previously developed models had a poor performance (area under the receiver operating characteristic curve, 0.49–0.56). In multivariable analyses, the strongest predictors of lower 3- and 6-month GOS-E were older age, pre-existing psychiatric conditions, and lower education. Injury caused by assault, extracranial injuries, and lower GCS were also predictive of lower GOS-E. Existing models for mTBI performed unsatisfactorily. Our study shows that, for mTBI, different predictors are relevant as for moderate and severe TBI. These include age, pre-existing psychiatric conditions, and lower education. Development of a valid prediction model for mTBI patients requires further research efforts.

Key words: GOS-E; prognostic models; TBI; validation

Introduction

TRAUMATIC BRAIN INJURY (TBI) IS AMONG THE LEADING causes of death and disability. In the United States, at least 1.7 million patients a year seek some form of medical treatment.¹ TBI exacts significant health, social, and economic hardships on patients, their

families, and health systems.^{2,3} Approximately 70–90% of all TBIs are categorized as mild (mTBI), that is, presenting with a Glasgow Coma Scale (GCS) score of 13–15 after nonpenetrating head trauma. Although most mTBI patients will recover without residual impairments, persistent sequelae remain in a subgroup of 5–15%.⁴ These complaints may include physical symptoms, behavioral disturbances,

and cognitive dysfunction, any of which may interfere with return to work or resumption of social activities. Prognostic analyses are essential to identify patients at increased risk of developing residual sequelae and for leveraging resources to follow a more risk-prone subgroup. Closer observation and early intervention as part of clinical practice may alleviate the psychological burden of injury on these patients, as well as the related economic burden on society.

The heterogeneity in case definition of mTBI, the variety of outcome measures, and the variability in time elapsed for scoring both predictors and outcome render interpretation and comparison of results from mTBI prognostic studies difficult. Further, most studies only report on the association between predictors and outcome in univariate analyses.^{5,6}

To our knowledge, only two studies have combined predictors and developed a prediction model specifically for mTBI.^{7,8} One other model (Corticosteroid Randomization After Significant Head Injury; CRASH) was developed on patients with GCS 3–14 and thus captured a segment of the mTBI population, but not patients with GCS 15.^{9,10} Further, none of the models have been externally validated in mTBI. Before a prognostic model can reliably be applied to clinical practice, external validation is required to determine generalizability. In this study, we aimed to evaluate the performance of existing mTBI prognostic models using a recent, prospective, unselected population of mTBI patients enrolled across three level 1 trauma centers in the United States and explore relevant predictors of poor outcome after mTBI.

Methods

Patient population

The study population consisted of patients included in the Transforming Research and Clinical Knowledge in TBI (TRACK-TBI) Pilot study.¹¹ In this study TBI patients age > 16 years were enrolled upon arrival in the emergency departments (EDs) at San Francisco General Hospital (University of California San Francisco; UCSF), University of Pittsburgh Medical Center, and University Medical Center Brackenridge. All participants or their legally authorized representatives gave written informed consent. At follow-up outcome assessments, participants previously consented by legally authorized representative, if neurologically improved and capable, were consented for continuation in the study.

Inclusion criteria were presentation to study hospital within 24 h of injury and history of trauma to the head sufficient to triage to noncontrast head computed tomography (CT) using the American College of Emergency Physicians/Centers for Disease Control evidence-based joint practice guidelines.¹² We selected patients with mTBI and available 3- or 6-month outcome. All study protocols were approved by the institutional review boards at each participating level 1 trauma center.

Measures

Details on loss of consciousness, amnesia, and source of trauma were recorded upon admission and informed consent was obtained. GCS score was assessed by a neurosurgeon at admission.¹³ Trained study personnel in the ED obtained demographic data, patient history, and clinical information from the patient. All patients underwent CT imaging at the time of initial presentation to the ED. Each patient's head CT was characterized using the National Institutes of Health/National Institute of Neurological Disorders and Stroke TBI Common Data Elements (TBI-CDEs).^{14–16} Clinical brain CTs were transmitted to a radiology picture-archiving and communications system with software that allow controlled remote access for multiple users at study sites. To comply with the Health Insurance Portability and Accountability Act of 1996, the UCSF Quantitative

Image Processing Center built a multiplatform tool that completely anonymized CT studies during the transmission process. Each CT was then reviewed by a single board-certified neuroradiologist blinded to demographic, socioeconomic, and clinical data, except gender and age, and scored on 26 of the 93 CDEs developed by the TBI-CDE neuroimaging working group.^{17,18}

Outcome

The outcomes for this study were the Glasgow Outcome Scale Extended (GOS-E) at 3 and 6 months after injury.¹⁹ The GOS-E provides eight categories of outcome: dead; vegetative state; lower severe disability; upper severe disability; lower moderate disability; upper moderate disability; lower good recovery; and upper good recovery. Ratings are based on patient consciousness, independence, ability to work, social and leisure activities, social relationships, and other sequelae of TBI. Upper good recovery (GOS-E score of 8) indicates return to preinjury baseline with no residual effects of the TBI.

Prediction models

Our literature search identified three prediction models that were developed (partly) on mTBI patients.^{7–9} We could not validate the Stuhlemeijer and colleagues model because not all of the former's predictors were available in our data set.⁷ We thus undertook to validate the Nijmegen and CRASH models.⁹ The characteristics of the model are described in Table 1.

The Nijmegen model was built specifically for mTBI, with 6-month GOS-E < 7 as the endpoint. Multivariable analysis of 1069 patients with GOS-E yielded age, Abbreviated Injury Score for head (AIS_h), Injury Severity Score (ISS) without head, and alcohol intoxication as significant predictors in the clinical model and number of hemorrhagic contusions and facial fractures as predictors of unfavorable outcome in the CT model and age, ISS without head, number of hemorrhagic contusions, and alcohol intoxication in the combined model.⁸

The Medical Research Council CRASH trial built and externally validated two prognostic models in mild, moderate, and severe TBI.⁹ A basic model included age, GCS, pupillary reactivity, and presence of extracranial injury. In a CT model, additionally included were petechial hemorrhage, obliteration of third ventricle and cisterns, subarachnoid hemorrhage (SAH), mid-line shift, and nonevacuated hematoma emerged as predictors for mortality at 14 days and unfavorable outcome on the GOS (< 4) at 6 months postinjury.⁹ In this study, we only validated the models for 6-month unfavorable outcome. We note that the CRASH model excluded patients with GCS 15, a score that represents a majority of this subpopulation.

Statistical analysis

If patients had a missing outcome at 6 months, but an observed outcome at 3 months, the 3-month value was extrapolated to 6 months. Similarly, 6-month outcomes were interpolated when 3-month outcome was missing. Patients with missing outcome at both time points were excluded. Missing values in predictors were statistically imputed using single imputation with the *AregImpute* function in R statistical software (version 2.14; R Foundation for Statistical Computing, Vienna, Austria).

Patients' baseline characteristics were described by median and interquartile range (IQR) for continuous variables and frequencies and percentages for categorical variables. These descriptive statistics were reported on the nonimputed data.

The prediction models were applied to the patients in the validation set, that is, a predicted probability of unfavorable outcome was calculated for each patient using the CRASH and Nijmegen models. Accordingly, the external validity of the models was assessed by studying calibration and discrimination. Calibration refers to the agreement between observed and predicted outcomes. The

TABLE 1. CHARACTERISTICS OF THE VALIDATED MODELS

<i>Model</i>	<i>Development population (n)</i>	<i>Predictors</i>	<i>Outcome</i>
Nijmegen Clinical model	GCS 13–15 (<i>n</i> = 1069)	-Age -AIS head -ISS without head -Alcohol intoxication	6-month GOS-E < 7
CT model		-Number of hemorrhagic contusions -Facial fractures	
Combined model		-Age -ISS without head -Number of hemorrhagic contusions -Alcohol intoxication	
CRASH Basic model	GCS 3–14 (<i>n</i> = 10,008)	-Age -GCS -Pupillary reactivity -Extracranial injury	6-month GOS < 4
CT model		Basic model plus -Petechial hemorrhage -Obliteration of third ventricle and cisterns -Subarachnoid hemorrhage -Mid-line shift -Nonevacuated hematoma

extent of over- or underestimation, relative to the observed and predicted rate, was explored graphically using validation plots.²⁰ We assessed calibration-in-the-large by fitting a logistic regression model with the logit of model predictions as an offset variable. The intercept indicates whether predictions are systematically too low or high and should ideally be zero. The calibration slope reflects the average effects of the predictors in the model and was estimated in a logistic regression model with the logit of the model predictions as the only predictor. For a perfect model, the slope is equal to 1. The area under the receiver operating characteristic curve (AUROC) was used to quantify the ability of the model to discriminate between patients who died versus survived. Because the development of the CRASH model did not include patients with GCS 15, we validated it both on patients with GCS 13–14 and on our total study population.

To further explore relevant predictors of 3- and 6-month GOS-E, we selected 21 possible predictors from the literature and based on clinical knowledge. These were analyzed in univariate and multi-variable proportional odds regression models with 3- and 6-month GOS-E as ordinal outcomes. This means that the full range of the GOS-E is considered instead of dichotomizing at a fixed point (e.g., favorable vs. unfavorable outcome). Simulation studies have shown that ordinal analysis is more efficient than dichotomization, also when the proportional odds assumption is violated. Each predictor was tested in the univariate models, and those with a *p* value of 0.30 in both the 3- and 6-month model were selected for inclusion in the multi-variable models. The liberal *p* value was motivated by the fact that we performed an exploratory analysis in a relatively small sample size and did not want to exclude possible predictors.

All analyses were performed with R statistical software (version 2.14; R Foundation for Statistical Computing).

Results

Patient population

TRACK-TBI Pilot enrolled 485 patients with mTBI, including 480 with nonpenetrating injury who were eligible for our study.

Patients with penetrating brain injury (*n* = 5) or missing outcome at both 3 and 6 months after injury (*n* = 94) were excluded. A total of 386 patients were included in our analysis. The median age of our population was 44 years (IQR, 27–58). The majority (*n* = 271; 70%) was male. Most patients (*n* = 290; 75%) presented with a GCS of 15 and two reactive pupils. Most patients were injured in a motor vehicle traffic accident (*n* = 179; 47%). Almost one third (*n* = 118; 31%) of the patients had self-reported psychiatric (mental health) history, which was obtained at the time of injury through patient interview using a checklist of common psychiatric conditions as defined by the TBI CDE V1.0 (e.g., anxiety, depression, sleep disorders, post-traumatic stress, bipolar disorder, schizophrenia, and others). Patients need not have been formally diagnosed with a mental health disturbance; however, to qualify as “positive” for psychiatric history, the patient must deem the condition to be significantly disturbing for their baseline quality of life. More than half (*n* = 198; 53%) of the patients reported history of previous TBI as defined by external force injury to the head. Over half of the patients (*n* = 232; 60%) had no visible CT pathology (Marshall’s CT classification I).²¹ The most common pathologies observed on CT were contusions (61; 16%), SAH (103; 27%), and facial fractures (53; 14%). Most baseline variables had very few missing values (< 2%), but the AISh, ISS, and extracranial injury had almost 40% missing values. Alcohol intoxication, as measured by blood alcohol levels, was missing in almost 60% of cases (Table 2).

At 3 months after injury, 116 (24%) were lost to follow-up. Of those with observed outcomes, 33% (*n* = 121) completely recovered (GOS-E, 8) and 32% (*n* = 118) had some remaining symptoms (GOS-E, 7). Of the remaining one third of the sample 2% (*n* = 6) died, 4% (*n* = 15) were severely disabled (GOS-E, 3–4), and 28% (*n* = 104) were moderately disabled (GOS-E, 5–6; Table 3).

After 6 months, an additional 181 (38%) patients were lost to follow-up. Of those with observed outcome, 34% (*n* = 102) made a complete recovery (GOS-E, 8) at 6 months and 30% (*n* = 89) had

^aOf 485 patients, 5 were excluded because they had penetrating injury and 94 had missing outcome, leaving 386 for inclusion.

IQR, interquartile range; GCS, Glasgow Coma Scale; TBI, traumatic brain injury; ISS, Injury Severity Score; AIS, Abbreviated Injury Score; CT, computed tomography; EDH, extradural haematoma; tSAH, traumatic subarachnoid hemorrhage.

some remaining symptoms (GOS-E, 7). Three percent ($n=9$) had died, 3% ($n=9$) were severely disabled (GOS-E, 3–4), and 30% ($n=90$) were moderately disabled (GOS-E, 5–6).

Between 3 and 6 months after injury, 3 patients died and another 65 deteriorated, based on worsening GOS-E. Conversely, 66 patients showed improved GOS-E scores between 3 and 6 months. The 94 patients with missing outcome at both time points were excluded from this analysis.

Model validation

The Nijmegen models performed poorly in the external validation, with AUROCs of 0.52 (95% confidence interval [CI], 0.49–0.56; clinical model), 0.55 (95% CI, 0.49–0.55; CT model), and 0.56 (95% CI, 0.49–0.56; combined model) (Fig. 1). The CRASH models performed poorly in the total mTBI population, including GCS 15 (AUROC basic model, 0.49; 95% CI, 0.43–0.70; AUROC CT model, 0.49; 95% CI, 0.42–0.66) (Fig. 2). However, performance was very well with AUROCs of 0.90 (95% CI, 0.82–0.97; basic model) and 0.91 (95% CI, 0.85–0.98; CT model) (Fig. 3) in the population they were developed on. The proportion of unfavorable outcome in TRACK-TBI Pilot was overestimated by most models. For example, the predicted proportion of patients with unfavorable outcome by the CRASH CT model was 12%; however, the actual observation of unfavorable outcome at 6 months was 8%.

Predictors

In univariate analyses (Table 4), we identified a large number of characteristics as potential predictors of outcome both 3- and 6-month GOS-E: age; cause of injury; GCS; pupil reactivity; psychiatric medical history; hypoxia; hypotension; education; ISS; extracranial injury; SAH; mid-line shift; and third ventricle obliteration and contusions (all $p < 0.30$ for both 3- and 6-month GOS-E; Table 4). Some predictors had a different effect on 3-versus 6-month outcome. A GCS of 13 or 14 was a strong predictor for a lower 6-month GOS-E (odds ratio [OR]=0.3; $p=0.015$), but less predictive for lower 3-month GOS-E (OR=0.5–0.6; $p=0.299$). In contrast, the CT characteristics were more predictive of 3-month outcome, compared with 6-month outcome (e.g., SAH: 3-month OR=2.2, $p < 0.001$; 6-month OR=1.3, $p=0.224$).

In multivariable analyses (Table 5), the strongest predictors of both lower 3- and 6-month GOS-E were older age (OR, 1.2; $p < 0.001$), history of psychiatric conditions (OR=2.2–2.4; $p < 0.001$), and lower education (OR, 0.4–0.8; $p < 0.05$; Table 4). Injury caused by assault and extracranial injury were important predictors of poorer outcome at both time points ($p=0.05$ –0.1). Finally, a lower GCS was predictive of lower 6-month GOS-E (OR, 0.3–0.4; $p=0.039$).

Discussion

In this study, we externally validated two prognostic models for prediction of outcome after mTBI. We found that both models performed unsatisfactorily in our validation data set. In exploratory analyses, we identified older age, pre-existing psychiatric conditions, lower education, injury caused by assault and extracranial injury, and lower GCS as predictors of 3- and 6-month GOS-E.

Study population

We included only patients with a so-called mTBI, as defined by a GCS 13–15. However, the population did contain some patients

with one or two unreactive pupils, an AISh of 4 or 5, or a Marshall's CT classification of 5 or 6, characteristics that indicate a more severe head injury. This illustrates the limitations of a unidimensional approach to classification of TBI. More than half of the patients reported a previous head injury. This might be an overestimation given that it was self-reported.

Outcome

Our findings that one third of the patients made a complete recovery (GOS-E, 8), one third had some minor remaining symptoms (GOS-E, 7), and the final one third had significant disabling complaints at 3 and even 6 months are consistent with previous research.⁷ Although our study population might include somewhat more severe patients than the general population as a result of the case mix at our level 1 trauma enrollment centers, these results illustrate that the consequences of mTBI should not be underestimated. The overall outcome distribution was similar at 3 and 6 months, but there were some patients who died between 3 and 6 months and some that deteriorated. Unfortunately, we were unable to trace whether those that deteriorated did so as a result of the initial head injury or from other events. The lost to follow-up percentage increased to 38% at 6 months. This lost to follow-up percentage is similar to, or better than, other TBI studies.^{22–24} However, higher follow-up rates are generally achieved in randomized, controlled trials. TBI patients are a difficult group to follow, and researchers should recognize the fact that it requires substantial resources to achieve acceptable follow-up rates in TBI studies.

Approximately half of the patients (94 of 181) who were lost to follow-up at 6 months also did not have a 3-month outcome. Of the patients with observed outcome at 3 months, the majority (56 of 87) had a GOS-E of 7 or 8. This is consistent with previous findings that willingness to participate in research is less in those who fully recover and may result in an overestimation of the rate of unfavorable outcome.²⁵ Given that it is unlikely that predictors have differential relative effects in patients with more-favorable outcome, we do not expect the results of the prognostic analyses to be affected by the missing outcomes.

Models

With AUROCs of 0.52–0.56, the Nijmegen model's ability to discriminate between patients with favorable and unfavorable outcome was hardly better than chance (AUROC=0.5). The reason for this poor performance is likely to be related to the original modeling strategy used in this study. Their development sample included 1069 patients, of which 257 had unfavorable outcome. In this sample, 33 possible predictors were tested, corresponding to one predictor for seven outcome events. A rule of thumb in prognostic modeling is that at least 10–20 outcome events are required to test one predictor. Testing too many predictors for the sample size may result in models that are overfitted, resulting in a good apparent performance in the development data, but poor performance at external validation. The amount of overfitting can be assessed and quantified with internal validation (e.g., in a bootstrap procedure), but this was not done by Jacobs and colleagues. The

FIG. 1. Calibration plot Jacobs combined model. x-axis shows predicted probabilities by the model in quintiles of patients (triangles with horizontal lines as 95% confidence intervals); y-axis shows observed probabilities. Dotted diagonal represents perfect predictions. Spikes along the x-axis are numbers of patients with favorable and unfavorable observed outcomes. ROC, receiver operating characteristic.

FIG. 2. Calibration plot CRASH computed tomography model. x-axis shows predicted probabilities by the model in quintiles of patients (triangles with horizontal lines as 95% confidence intervals); y-axis shows observed probabilities. Dotted diagonal represents perfect predictions. Spikes along the x-axis are numbers of patients with favorable and unfavorable observed outcomes. ROC, receiver operating characteristic.

FIG. 3. Calibration plot CRASH computed tomography model (original population). x-axis shows predicted probabilities by the model in quintiles of patients (triangles with horizontal lines as 95% confidence intervals); y-axis shows observed probabilities. Dotted diagonal represents perfect predictions. Spikes along the x-axis are numbers of patients with favorable and unfavorable observed outcomes. ROC, receiver operating characteristic.

difference between the discriminative ability in the development data (AUROCs, 0.57–0.71) and in the validation data likely indicate that the Jacobs model is overfitted, but may also be attributed to true differences in prognostic relations.

The CRASH models discriminated equally poor in the total mTBI population, with AUROCs of 0.49–0.50. However, the CRASH models were not developed for patients with a GCS of 15, which was the majority of our sample. When patients with GCS 15 were excluded, the CRASH models discriminated well. In contrast to the Nijmegen models, the CRASH models were developed by testing 14 predictors in 3556 outcome events and were internally and externally validated in moderate and severe TBI.²⁶ It should be noted that the outcome predicted by the CRASH models was GOS<4, whereas the Nijmegen model predicts GOS-E<7. Possibly, it is easier to discriminate between patients above or below a cutoff in the middle of the GOS-E, compared with a cutoff at the higher end. This is supported by the finding that our ordinal multivariable models had AUROCs of 0.68–0.69, representing the discriminative ability over the complete GOS-E. When the models were refitted with CRASH outcome GOS<4, the AUCs increased to 0.86. In all, the validation of these previously developed models supports the need for further research to develop valid prognostic models for mTBI patients.

Predictors of unfavorable outcome

Age, pre-existing psychiatric conditions, and lower education were the strongest predictors for both 3- and 6-month GOS-E in our data. Older age is a recognized predictor of poorer outcome in many diseases, including TBI, and our finding is consistent with the literature.²⁷ Pre-existing psychiatric conditions are less often studied, but also have been found to predict unfavorable outcome.²⁸ While speculative, it is possible that individuals with a pre-existing mental health condition may have less reserve to overcome the additional strain of an mTBI. Alternatively, symptoms that relate primarily to this comorbidity may falsely be attributed to the head injury.²⁹ More highly educated patients may have more-adaptive coping skills that allow them to return to their previous levels of functioning.⁷

Additional strong predictors of lower 6-month GOS-E were injury caused by assault, extracranial injury, and lower GCS. GCS is an indication of more-severe injury resulting in less favorable outcome. Violence as a cause of injury has been previously described as a predictor of fatigue after mTBI. The researchers suggested that post-traumatic stress might play a role in this relation.²⁸ Extracranial injury may result in disability independent of the head injury and has been described as a predictor of poor outcome before, especially in unselected TBI populations.³⁰

It has been suggested that in moderate and severe TBI, outcome is determined by what “the injury brings to the patient” whereas in mTBI it is what “the patient brings to the injury,” and our data support this statement. Generally accepted prognostic models for moderate and severe TBI include, in addition to age, indicators of injury severity, such as GCS, pupillary reactivity, and CT parameters.^{9,10,26} These predictors are less relevant in mTBI. Here, indicators of social background, history of psychiatric conditions, assault as cause of injury, and low education seem to be predictive of poorer outcome. However, the combination of pre-existing psychiatric conditions, low education, and assault as a cause of injury as predictors of 6-month outcome poses the question of whether persistent complaints are fully attributable to the TBI. Future studies that follow up with

more-sensitive and -specific outcome measures in larger cohorts are required to answer this question. In this study, we neither aimed nor had enough patients to fully disentangle the mechanisms causing poor outcome. This would be essential to target treatment to patients at high risk for poor outcome and should be a main focus of future studies and large ongoing efforts such as CENTER-TBI and TRACK-TBI.

The predictors we combined in our multi-variable analysis had a moderate discriminative ability (AUROCs, 0.68–0.69). Emerging technologies that could improve prognostication in mTBI include proteomic biomarkers,^{31–33} genetic factors,^{34–36} and improved imaging biomarkers, including magnetic resonance imaging.³⁷ Additionally, prediction models for mTBI may require more-sensitive and -specific outcome measures beyond the GOS-E.

We recognize several limitations to our study. We included patients with GCS 13–15, which are classified in the category of mTBI. However, there were patients with one or two unreactive pupils, an AISh of 4 or 5, or a Marshall’s CT classification of 5 or 6 (indicative of “complicated” mTBI with pathological head CT findings), all indicating quite severe injury. More than half of the patients reported previous head injury, which may be an overestimation given that it was self-reported without necessarily requiring hospital admission. Pre-existing psychiatric conditions proved to be one of the strongest predictors to poorer outcome. A goal of the TRACK-TBI Pilot Study was to evaluate the feasibility of implementing the TBI CDEs V1.0, which did not include a validated structured interview for preinjury psychiatric history. Even though we implemented the highest level of granularity for baseline data collection, we were unable to capture the specific types, durations, and formal diagnoses of pre-existing psychiatric conditions. In moving forward, establishing a standard set of tools and questionnaires to obtain this level of granularity will be helpful in evaluating the true associations among pre-existing mental health conditions and post-TBI outcome.

Conclusion

Reliable outcome prediction in mTBI is important for clinical practice. Identifying patients at increased risk of unfavorable outcome permits targeting closer observation and early intervention, which may reduce the psychological burden of injury on patients, as well as the related economic burden on society. Our study demonstrates that existing models for mTBI perform unsatisfactorily. We tested 21 variables in ordinal analysis of 386 patients, which is 1 in 18 and thus reasonable from a statistical perspective. Although we have found some strong predictors of poor outcome, such as age and history of psychiatric condition, given the sample size, we consider the results of our prognostic analysis as hypothesis generating. These predictors will need further validation in ongoing prospective, longitudinal studies, such as those that are part of the International TBI Research Initiative.^{38,39}

Abstract

Glial fibrillary acidic protein and its breakdown products (GFAP-BDP) are brain-specific proteins released into serum as part of the pathophysiological response after traumatic brain injury (TBI). We performed a multi-center trial to validate and characterize the use of GFAP-BDP levels in the diagnosis of intracranial injury in a broad population of patients with a positive clinical screen for head injury. This multi-center, prospective, cohort study included patients 16–93 years of age presenting to three level 1 trauma centers with suspected TBI (loss of consciousness, post-trauma amnesia, and so on). Serum GFAP-BDP levels were drawn within 24 h and analyzed, in a blinded fashion, using sandwich enzyme-linked immunosorbent assay. The ability of GFAP-BDP to predict intracranial injury on admission computed tomography (CT) as well as delayed magnetic resonance imaging was analyzed by multiple regression and assessed by the area under the receiver operating characteristic curve (AUC). Utility of GFAP-BDP to predict injury and reduce unnecessary CT scans was assessed utilizing decision curve analysis. A total of 215 patients were included, of which 83% suffered mild TBI, 4% moderate, and 12% severe; mean age was 42.1 ± 18 years. Evidence of intracranial injury was present in 51% of the sample (median Rotterdam Score, 2; interquartile range, 2). GFAP-BDP demonstrated very good predictive ability (AUC=0.87) and demonstrated significant discrimination of injury severity (odds ratio, 1.45; 95% confidence interval, 1.29–1.64). Use of GFAP-BDP yielded a net benefit above clinical screening alone and a net reduction in unnecessary scans by 12–30%. Used in conjunction with other clinical information, rapid measurement of GFAP-BDP is useful in establishing or excluding the diagnosis of radiographically apparent intracranial injury throughout the spectrum of TBI. As an adjunct to current screening practices, GFAP-BDP may help avoid unnecessary CT scans without sacrificing sensitivity (Registry: ClinicalTrials.gov Identifier: NCT01565551).

Key words: biomarkers; imaging; traumatic brain injury

Introduction

CLINICAL CARE AND RESEARCH in traumatic brain injury (TBI) rely on classification systems, such as the Glasgow Coma Scale (GCS), that are not adequately calibrated for injury assessment across mild and

moderate TBI.¹ Radiographic evaluation is central to the initial stratification of injury severity and to monitor for acute changes; however, its use is limited by cost and perceived risk of ionizing radiation.

Simpler, sensitive, and specific tests for identifying and stratifying TBI would provide more rapid and tailored diagnosis of TBI

while minimizing the time, risk, and cost associated with current standards. To this end, there has been increasing investigation into serum proteins as biomarkers of TBI; however, none have yet been validated for routine use. Potential biomarkers under investigation include glial protein S-100 beta (S100B), neuron-specific enolase (NSE), myelin basic protein, ubiquitin c-terminal hydrolase, and glial fibrillary acid protein (GFAP).^{2,3} GFAP, initially investigated in the 1970s, has emerged as a promising biomarker candidate to improve diagnosis, triage, and targeted treatment of TBI patients.⁴ GFAP is an intermediate filament protein component of the astrocyte cytoskeleton expressed almost exclusively in the central nervous system (CNS). While insoluble in intact astrocytes, over-activation of calpain after initial injury and gliolysis produce soluble GFAP polymers (or breakdown products) that are released into interstitial fluid.⁵ These GFAP breakdown products (GFAP-BDP) can be measured in serum in association with a number of CNS disorders, including TBI.^{1,2} Previous studies have correlated elevated GFAP-BDP with the presence of clinical and radiographic injury as well as worse outcome and need for neurosurgical intervention.^{2,3} To date, previous work has focused primarily on the severe TBI population or compared TBI patients against either uninjured patients or those not meeting clinical criteria for head injury. Our previous study was one of the first to prospectively assess GFAP-BDP with regard to presence and severity of radiographic injury on computed tomography (CT) across the entire spectrum of disease after TBI.^{4,6}

The aim of this study was to evaluate and validate the utility of GFAP-BDP for the diagnosis of intracranial injury in patients with a positive clinical screen for head injury across the spectrum of TBI typically presenting to a level 1 trauma center. We expand on our previous analysis of the utility of GFAP-BDP to identify TBI, including injury evaluation by MRI, cut-off values for GFAP-BDP specifically in the mild and moderate TBI groups, and analysis of the potential reduction of CT scans by utilizing the biomarker for injury detection.⁶

Methods

Study population

Recruitment of subjects was part of the TRACK-TBI (Transforming Research and Clinical Knowledge in Traumatic Brain Injury) Pilot Study, a National Institute of Neurological Disorders and Stroke-funded, multi-center, prospective collaboration among three U.S. level 1 trauma centers enrolling acute TBI patients (University of Pittsburgh Medical Center [UPMC]; University Medical Center Brackenridge [UMCB]; and University of California, San Francisco [UCSF]) and one rehabilitation center (Mount Sinai Rehabilitation Center) enrolling late-presenting TBI patients to develop, test, and refine TBI common data elements (TBI-CDEs) for research across four major domains: demographics, neuroimaging, biomarkers, and outcome measures.⁷ The TBI population under investigation spanned the entire injury spectrum, from severe to mild. Both patients with negative imaging and those discharged from the emergency department (ED) are also included in the total population. Institutional review boards of participating centers approved all study protocols. All participants or their legal authorized representatives gave written informed consent. At follow-up, participants previously consented by legal authorized representative, if neurologically improved to be cognizant, were consented for continuation in the study.

To be eligible for this analysis, patients must have presented to an ED within 24 h of their injury and had a positive clinical screen for acute TBI necessitating a noncontrast head CT according to American College of Emergency Physicians/Centers for Disease

Control and Prevention (ACEP/CDC) evidence-based joint practice guidelines.⁸ These guidelines represent an amalgam of the Canadian CT Head Rule and the New Orleans Criteria (Haydel, Indications for computed tomography in patients with minor head injury; Stiell, The Canadian CT Head Rule for patients with minor head injury). GCS score was assessed by a neurosurgeon at admission and was reconfirmed by study personnel at the time of biomarker collection. TBI severity was broadly defined by GCS, with mild between 13 and 15, moderate between 9 and 12, and severe between 3 and 8. Patients were excluded if they were younger than 16 or greater than 95 years of age, suffered penetrating head injury, or had a premorbid neurologic condition.

Sample collection and measurement of glial fibrillary acidic protein and its breakdown products

Data from the three level 1 trauma centers were used for this analysis. Serum samples were collected within 24 h of injury and were dated and time stamped to compare with time of injury. The TBI-CDE Biospecimens and Biomarkers Working Group Guidelines for sample preparation were followed.⁹ Samples were centrifuged and serum aliquots stored at -80°C for future batch processing. UPMC and UMCB batch-shipped samples, overnight on dry ice, to UCSF. All deidentified samples were then stored with a unique study number specific to site and subject. A central database was maintained by the coordinating center (UCSF) with each site entering site-specific data for final statistical reporting. Blinded sample analysis occurred in a single laboratory (Banyan Biomarkers, Alachua, FL) using a sandwich enzyme-linked immunosorbent assay (ELISA) to GFAP-BDP. The GFAP ELISA utilized a proprietary mouse monoclonal antibody for solid-phase immobilization, and a proprietary polyclonal rabbit antibody for detection.^{10,11} Testing procedure and detection of GFAP was carried out as previously described.⁶ Both whole GFAP molecules as well as GFAP-BDPs are detected by the assay, potentially resulting in a more complete measure of overall GFAP released into circulation. All samples were analyzed in duplicate concomitantly with calibrators prepared in compatible matrix, as described previously.⁶ From high concentration to low, the previously reported intraassay coefficient of variance for the ELISA is 4.3–7.8% and the inter-assay coefficient of variance is 7.8–14.3%. The estimated limit of detection for GFAP is ~ 0.01 ng/mL.¹¹

Evaluation of endpoints

All patients underwent CT imaging of the brain at the time of initial presentation to the ED. Patients were offered a follow-up, out-patient MRI upon enrollment in the TRACK-TBI study. The MRI was on a voluntary, opt-in basis to be performed 1–2 weeks postinjury. Radiographic images were deidentified, uploaded to a central imaging database, and reviewed by a blinded central reader. Imaging features were extracted and entered into the TRACK-TBI database. Each patient's head CT and magnetic resonance image (MRI) were characterized using the recommendations of the TBI-CDE Neuroimaging Working Group regarding specific radiologic features, data definitions needed to characterize injuries, and best practices needed to optimize and harmonize imaging data acquisition for TBI research during data collection.^{12,13} Specifically, the presence of cisternal effacement, mid-line shift, epidural hematoma, subarachnoid hemorrhage, and intraventricular hemorrhage were recorded to determine the Rotterdam score for all scans (assessment of TBI severity based on noncontrast head CT). The presence of any intracranial abnormalities on MRI was considered a positive scan. Imaging studies were performed at the discretion of each study site using their standard equipment and protocols.

The primary endpoint for analysis was intracranial injury, as identified on CT scan at time of presentation. Secondary endpoints included severity of intracranial injury, as measured by the

Rotterdam score, and presence of intracranial injury, as identified by delayed MRI.

Statistical analysis

Continuous demographic characteristics were assessed for normality using the Kolmogorov-Smirnov's test; normally distributed data were analyzed by *t*-test, whereas the remainders were compared using the Wilcoxon's rank-sum test. Categorical data were analyzed by Pearson's chi-squared or Fisher's exact test. Differences between groups in multi-level ordinal measurements (i.e., Rotterdam score, GCS, and Glasgow Outcome Scale) were tested using Kruskal-Wallis' test. Univariable regression analysis was performed to assess the association between GFAP-BDP level and radiographic presence of intracranial injury. Multi-variate regression models were later built to evaluate the predictive capabilities GFAP-BDP after adjustment for known factors associated with severity of intracranial injury (age, pupillary reactivity, GCS, and Injury Severity Score [ISS]). The ability of GFAP-BDP to predict severity of intracranial injury was assessed using ordered logistic regression modeling.

The ability of GFAP-BDP to predict the presence of intracranial injury was analyzed apropos of accuracy, discrimination, calibration, and clinical utility. Discrimination was assessed using the area under the receiver operating characteristic (ROC) curve (AUC). Using current statistical consensus, AUCs of 0.8–0.9 are considered very good, 0.7–0.8 as adequate, and below 0.7 as poor. Calibration was tested with the Hosmer-Lemeshow's goodness-of-fit test. Cut-off values for GFAP-BDP were assessed both for the highest accuracy and for the highest specificity, specifically in the mild to moderate injury groups. Values were determined utilizing ROC curves and AUC and Brier scores were calculated. Clinical utility was evaluated by decision curve analysis.¹⁴ Statistical significance was set at $p < 0.05$. All data were analyzed using STATA statistical software (12; StataCorp LP, College Station, TX).

Results

Baseline demographics

A total of 215 patients were available for analysis. Demographic characteristics are shown in Table 1. Mean age was 42 ± 18 years, with a minimum of 16 and maximum of 93 years. Approximately 73% of patients were male. Median GCS for the entire sample was 15 (interquartile range [IQR], 1), with mild TBI (GCS, 13–15)

constituting 83% (GCS, 13–15), moderate 4% (GCS, 9–12), and severe 13% (GCS, 3–8). Seventy percent of patients had a documented loss of consciousness (LOC), whereas 38% had documented post-traumatic amnesia (PTA). Median Injury Severity Score (ISS) was 10 (IQR, 17), with 36% suffering significant polytrauma (ISS, ≥ 16). Mean GFAP-BDP was 1.59 ± 2.98 ng/mL, and minimum and maximum levels detected were 0.02 and 20.1 ng/mL, respectively. Pair-wise correlation between CT and MRI was 0.33 ($p = 0.0096$). There was no significant correlation between MRI and Rotterdam score.

Glial fibrillary acidic protein and its breakdown products and computed tomography outcomes

Fifty-one percent ($n = 110$) of patients presenting with positive clinical screen for TBI had intracranial pathology demonstrated on admission CT. Median Rotterdam score of this cohort was 3 (IQR, 1). Serum level of GFAP-BDP was significantly higher in those with CT-positive intracranial injury, compared to those without (2.86 ± 3.74 vs. 0.26 ± 0.41 ng/mL, respectively; $p < 0.001$). Figure 1 presents a box plot of GFAP-BDP values for the two patient cohorts. Univariable analysis demonstrated elevated GFAP-BDP level and conferred significant risk of intracranial injury on initial CT (odds ratio [OR], 8.9; 95% confidence interval [CI], 2.3–2.5; $p < 0.001$), as also demonstrated in our previous study.⁶ Further, elevated GFAP-BDP remained a significant predictor after adjustment for known predictors of intracranial injury severity and functional outcome (i.e., age, pupillary activity, GCS, and ISS; OR, 5.5; 95% CI, 2.00–14.9; $p < 0.001$).

Figure 2 shows GFAP-BDP levels in relation to radiographic injury severity classification according to Rotterdam score. Level of GFAP-BDP differed significantly as a function of Rotterdam score ($p < 0.001$). Ordinal regression analysis revealed that elevated GFAP-BDP level significantly predicted worse Rotterdam score, both independently (OR, 1.20; 95% CI 1.1–1.3) as well as after adjustment for age, GCS, and ISS (OR, 1.17 95% CI, 1.1–1.3; $p < 0.001$).

GFAP-BDP level was the most accurate predictor of the presence or absence of intracranial injury detected by radiographic imaging (accuracy, 81%), as compared with accepted clinical predictors of intracranial injury (age, 65%; GCS, 62%; LOC and/or

TABLE 1. BASELINE DEMOGRAPHIC CHARACTERISTICS AT TIME OF ADMISSION BY PRESENCE OF INTRACRANIAL INJURY ON CT

Baseline characteristics	All (n=215)	CT negative (n=105)	CT positive (n=110)	p value

Rotterdam score, median (IQR)	—	—	3 (1)	
GFAP-BDP, mean $\pm$ SD (ng/mL)	1.59 $\pm$ 2.98	0.26 $\pm$ 0.41	2.86 $\pm$ 3.74	<0.01

CT, computed tomography; GCS, Glasgow Coma Score; ISS, Injury Severity Score; SD, standard deviation; IQR, interquartile range; GFAP-BDP, glial fibrillary acidic protein and its breakdown products.

FIG. 1. Box plots showing median levels of GFAP-BDP measured on admission in two groups of patients. Boxes show interquartile ranges, and I bars represent highest and lowest values. CT, computed tomography; GFAP-BDP, glial fibrillary acidic protein and its breakdown products.

PTA, 54%; pupillary status, 52%). In our sample, accuracy of GFAP-BDP for injury prediction was superior to the ACEP/CDC recommended criteria for neuroimaging in TBI (81% vs. 65%, respectively).⁸ Discriminatory analysis of GFAP-BDP resulted in an AUC of 0.88 (95% CI, 0.83–0.93), indicating very good discriminatory ability. Level of GFAP-BDP retained its discriminatory value after adjustment for age, pupillary exam, GCS, and ISS (AUC, 0.96; 95% CI, 0.7–0.91; Fig. 3). Calibration analysis did not show systematic error across risk deciles ($p=0.15$). Calculation of a cut-off value to maximize accuracy in the mild and moderate injury range specifically yielded a GFAP-BDP level of 0.6 ng/mL, with a sensitivity of 67%, a specificity of 89%, and a Brier score of 0.21. A cut-off value to maximize specificity was calculated at a GFAP-BDP concentration of 1.66 ng/mL, resulting in a sensitivity of 45%, specificity of 99%, and a Brier score of 0.29.

FIG. 2. Box plots showing median levels of GFAP-BDP measured on admission among patients in each of the Rotterdam classifications of injury on CT. Boxes show interquartile ranges, and I bars represent highest and lowest values. Overall, GFAP-BDP was significantly different across each level of Rotterdam score ($p \leq 0.001$). CT, computed tomography; GFAP-BDP, glial fibrillary acidic protein and its breakdown products.

FIG. 3. Receiver-operating-characteristic curves for various cut-off levels of GFAP-BDP in differentiating presence or absence of intracranial injury on CT. Curves for GFAP-BDP alone and after adjustment for known predictors of injury and severity (age, GCS, pupillary reactivity, and ISS). AUC, area under the receiver operating characteristic curve; CI, confidence interval; CT, computed tomography; GCS, Glasgow Coma Scale; GFAP-BDP, glial fibrillary acidic protein and its breakdown products; ISS, Injury Severity Scale.

Clinical utility of GFAP-BDP was evaluated through decision curve analysis as an extension of currently established practice guidelines.¹⁵ Decision curves are displayed in Figure 4. Use of GFAP-BDP displayed superior net benefit, as compared to scanning all patients with a positive clinical screen for head injury beginning at a threshold probability (i.e., perceived risk of injury) of approximately 20% or higher. This correlated to a net reduction of 12 CT scans per 100 patients without missing a single injury (12% reduction in unnecessary imaging). Reduction of unnecessary scans increased to 18% when applied to patients with a perceived risk of injury of 25% and by more than 30% if the risk of injury was equivalent to the prevalence of injury in this sample (CT-positive after clinical screen, ~51%).

Glial fibrillary acidic protein and its breakdown products and magnetic resonance imaging outcomes

Sixty patients underwent MRI in the subacute injury phase; of these, 35% ($n=21$) had positive scans (see Table 2). Of note, MRI revealed injuries in 13 patients who had had negative CT imaging on initial evaluation. Further, 4 patients with positive CT scans had negative follow-up findings on MRI. There was no significant difference between MRI-positive and -negative patients in age, gender, pupillary status, GCS, ISS, or functional outcome (Glasgow Outcome Scale Extended at 6 and 12 months). Admission GFAP-BDP values were significantly higher in MRI-positive patients (1.31 ± 1.8 vs. 0.28 ± 0.57 ng/mL, respectively; $p=0.001$). In univariable analysis, GFAP-BDPs significantly predicted the presence of intracranial pathology, as observed on MRI (OR, 2.7; 95% CI, 1.2–5.7). GFAP-BDP remained an independent predictor of injury on MRI after multivariate analysis, adjusting for age, pupillary status, GCS, and ISS (OR, 3.8; 95% CI, 1.3–11.3). Post-hoc, subgroup analysis performed on CT-negative, MRI-positive patients, in comparison with the remainder of the CT-negative cohort (35 patients), did not demonstrate significant differences in age, GCS, ISS, or GFAP-BDP levels.

Analysis of GFAP-BDP for the prediction of injury on MRI demonstrated an accuracy of 72%, adequate discrimination of 0.70

FIG. 4. (A) Decision curve analysis of the net benefit of GFAP-BDP to predict injury compared to current clinical screening method or scanning all patients regardless of screening across various probabilities of injury. (B) Decision curve analysis of the reduction of unnecessary CT scans per 100 patients using GFAP-BDP as an adjunct to predict injury compared to current clinical screening methods across various probabilities of injury. CT, computed tomography; GFAP-BDP, glial fibrillary acidic protein and its breakdown products.

(AUC; 95% CI, 0.55–0.85), and adequate calibration ($p=0.41$). Decision curve analysis demonstrated that GFAP-BDP contributes a net benefit above an injury-risk threshold of 25%, with a 13% reduction in unnecessary scans. Utilization of the cut-off value of 0.6 ng/mL in the mild-to-moderate range of injury was calculated to have a net benefit at an injury threshold of 24% and an overall net reduction in CT scans of 30 per 100 patients in this group.

Discussion

This multi-center, prospective study demonstrates that serum measurement of GFAP-BDP as a biomarker possesses the necessary characteristics (accuracy, discrimination, calibration, and clinical utility) for improved prediction of radiographically evident injury across the spectrum of TBI. Additionally, GFAP-BDP levels were able to discriminate severity of intracranial injury independent of other classic injury predictors. GFAP-BDP also accurately predicted persistence of intracranial injury on imaging performed in the subacute period, again independent of other markers of injury risk. These data expand upon our previous study demonstrating a correlation between injuries observed on CT scan and elevated levels of GFAP-BDP.⁶ Taken together, these results indicate that GFAP-BDP is a viable early indicator of intracranial injury and represents a useful adjunct to current diagnostic methods for TBI.

Numerous serum biomarker candidates for the diagnosis of TBI have come under intense scrutiny; however, none to this point have demonstrated sufficient utility to justify routine clinical use. Studies have reported a consistent correlation between elevated serum levels of S-100B and GCS, radiographic findings, and outcome.¹⁶ Despite its sensitivity, S-100B has been shown to be elevated in trauma patients without head injury, as well as after hemorrhagic shock and in normal pediatric patients.¹⁶ This lack of specificity limits its possible diagnostic practicality. Similarly, NSE, although rapidly elevated post-TBI, is also found in states of hemolysis.¹⁷ GFAP-BDP is a product of astrocyte cytoskeleton degradation by calpain protease activation and therefore considered specific to the CNS. This has already been corroborated by a number of studies evaluating levels after TBI, compared to noninjured controls, as well as those suffering only traumatic extracranial injuries.^{11,18} This study further supports the specificity of GFAP-BDP to detect radiographically evident injury given that predictive ability was evaluated among patients with similar clinical scenarios and presenting neurological exams. Against this clinically relevant sample, GFAP-BDP remained a sensitive and specific predictor of injury even after adjustment for the presence of polytrauma (i.e., ISS).

Previous evaluations of GFAP-BDP, largely focusing on severe TBI, have demonstrated a correlation between elevated marker levels and injury severity, number of lesions, and mortality.¹⁹ More recently, Papa and colleagues specifically studied GFAP-BDP within the mild-to-moderate TBI population and found that GFAP-BDP adequately predicted presence of injury, severity of injury, and need for neurosurgical intervention.¹¹ The current study evaluates GFAP-BDP across the entire spectrum of TBI, in the context of all patients who screen positive for intracranial injury using established guidelines. Alone, GFAP-BDP demonstrated the highest accuracy among predictors and very good discrimination (AUC, 0.88). Importantly, despite varied injury states and severity, calibration did not demonstrate systematic errors, further supporting the use of GFAP-BDP across severity cohorts. Importantly, GFAP-BDP also independently predicted the degree of radiographic injury throughout the spectrum of presenting neurological exams. This correlation supports the idea that GFAP release, breakdown, and translocation to serum mirrors radiographic evidence of parenchymal injury and disruption of the blood–brain barrier.

Pressure to deliver cost-effective care and concern over the potential effects of unnecessary ionizing radiation have prompted more judicious use of CT imaging for the evaluation of head injury. Despite the implementation of the Canadian CT Head Rule and/or New Orleans Criteria to stratify patients, approximately 60–90% of

patients imaged for head injury will have a negative CT.²⁰ Biomarkers, ideally, could act as adjuncts to these validated approaches, to better and more cost-efficiently classify at-risk patients. To assess clinical utility in this context, we analyzed GFAP-BDP utilizing decision curve analyses to determine the probability of injury above which GFAP-BDP benefits diagnosis without increasing unnecessary scans. This study found that use of GFAP-BDP has a superior net benefit from a threshold probability of injury of 20% and greater. This suggests that measuring serum GFAP-BDP, in conjunction with current practice guidelines, would lead to a 12% reduction in unnecessary imaging at this relatively low-risk threshold for injury (common probability thresholds for cancer and cardiac screening are 10–20%). Specifically in the mild to moderate groups, where there is the most potential benefit from a reduction in CT scans, we calculated that, at a concentration of 0.6 ng/mL, there is a net benefit at an injury probability threshold of 24% with a potential reduction in scans of 30 per 100 patients. When used as an adjunct to ACEP Guidelines, GFAP-BDP would reduce unnecessary CT scans by greater than 20% at a risk threshold of 25%, and by more than 30% in a population with a prevalence of injury similar to our sample (~51%).⁸ Currently only 6–10% of patients with GCS 13–15 have lesions detected on CT scan, and only 0.4–1% of these require neurosurgical intervention, indicating that many patients may not need imaging if other reliable and accurate options for injury detection are available.²¹ With approximately 1.5 million patients diagnosed as sustaining a mild TBI, estimating 80% receive a CT scan, and an average cost of \$216 per CT scan, a reduction in scans of 30% could yield a potential savings of \$77.8 million dollars per year in this population.^{22,23}

There are several limitations to our study. GFAP-BDP was only measured at initial presentation and thus levels were unable to be trended to evaluate whether decreasing GFAP-BDP correlates with injury resolution or to track the trend in concentration over time. This precluded analysis of changes in concentration of GFAP-BDP over time as compared to evolution of injury on imaging. Our analysis included only those patients who received a head CT as part of enrollment in the TRACK-TBI study, and we therefore had a relatively high number of mild TBI patients with positive findings on CT scan. This may have excluded the less severely injured patients from GFAP-BDP measurement. Additionally, our analysis was limited to the clinical indicators of injury as defined by the TRACK-TBI study, and we were unable to compare GFAP-BDP against the numerous indicators of intracranial injury that may otherwise be used. We also were unable to include cost data on serum analysis for GFAP-BDP concentrations given that the data are publicly not available and remain confidential owing to the fact that the test is not yet U.S. Food and Drug Administration approved for clinical use. Therefore, we were unable to provide further analysis as to potential cost savings compared to CT scans. This is the first study, to our knowledge, to evaluate the performance of GFAP-BDP against the Rotterdam score and against positive findings on MRI. However, MRI data were collected on an opt-in basis at up to 2 weeks postinjury, potentially biasing this cohort to include patients with more-severe or persistent symptoms. This may help to account for the lower discriminatory ability of GFAP-BDP among MRI patients; nonetheless, GFAP-BDP remained a significant predictor after adjustment.

This analysis demonstrates that GFAP-BDP can reliably detect the presence of injury on radiographic imaging as well as predict injury severity across the spectrum of TBI. Early measurement of GFAP-BDP can contribute to more-accurate diagnosis and triage of

TBI patients, decreasing the number of unnecessary CT scans and allowing more tailored management of the brain injury.
