LONG-TERM GOALS

The long range goal of this project is to combine computational models with observational data to form the best picture of the ocean as an evolving system, and use that picture to understand the physical influences which govern the ocean's behavior. Oceanic observations are sparse and models are limited in accuracy, but taken together, one can form a quantitative description of the state of the ocean that is superior to any based on either models or data alone. Along with the goals of analysis and prediction, we seek reliable estimates of the errors in our results. We expect our results to have implications beyond data assimilation. In particular, we hope this research will lead to enhanced understanding of the implications of nonlinearity and randomness for predictability of the ocean and atmosphere.

It is our long range goal to develop efficient methods for estimating useful statistical measures of errors in stochastic forecast models. Since the probability density functions (PDF's) of nonlinear stochastic models are not, in general, Gaussian, we must find methods for forecast evaluation based on information about the particular PDF generated by the model.

OBJECTIVES

The principle objective of this project is the development, implementation and validation of practical data assimilation methods for synoptic ocean models. By "data assimilation" we mean the construction of a composite estimate of the state of the ocean based on a combination of observed data with computational model output. Since data assimilation methods which give the most and best information are highly resource intensive, and often not practical for use with detailed models, we are particularly interested in the price paid in terms of accuracy and confidence for using economical but suboptimal data assimilation methods.

Direct calculation of full PDF's is not feasible for practical models of the ocean or atmosphere, but useful approximations to the PDF can be calculated from Monte-Carlo experiments, by virtue of the fact that the number of truly independent degrees of freedom in practical models is very much smaller than the dimension of the state vector. This intuition is the motivation for the ensemble methods that have become popular in recent years.

Our experience with Monte-Carlo methods in simplified systems has led us to investigate the details of methods for ensemble generation that have been presented in the community. The motivation for these

specialized methods for generating ensembles is precisely the specification of the PDF of a complex model whose behavior is believed to be captured by a relatively small number of independent degrees of freedom. By detailed study of the behavior of ensembles in increasingly complex models, we hope to gain the insights necessary to generate the most efficient ensembles, which should in turn lead to the error estimates necessary for data assimilation systems and prior estimates of forecast accuracy.

Optimized methods require accurate knowledge of the statistics of the errors in the model and the data. It is therefore an objective to understand in detail the sensitivity of the data assimilation scheme to the details of the defining error estimates.

APPROACH

The basic assumptions underlying data assimilation methods in use or proposed are known to be false to some degree. We plan to study the consequences of these assumptions by constructing a hierarchy of schemes with decreasing reliance on ad hoc assumptions. It is our guiding philosophy that the best way to learn how to design and implement the most economical methods that meet our needs is to begin by implementing methods which are as close to optimal as possible. From that point, we can quantify the loss of accuracy and the saving of resources associated with each simplification of the model or the data assimilation scheme.

Work is proceeding toward a theoretical basis for the next generation of data assimilation methods in which randomness and nonlinearity must be taken into account. To this end, we are applying tools from stochastic differential equations and from dynamical systems theory. Since our model systems are characterized by high dimensional state spaces, Monte Carlo methods must be used to study the behavior of the stochastic systems.

The theory of nonlinear filtering provides a framework in which problems of data assimilation with nonlinear models and non-Gaussian noise sources can be treated (see, e.g., Miller et al., 1999). In the case of linear models and Gaussian noise sources, this theory reduces to the familiar Kalman filter. In the formal theory of nonlinear filtering, the final result is not a single model state vector or trajectory in state space, but a PDF defined as a scalar function of the state variables and time. From this PDF, the mean, median, mode, or other statistic can be computed for use as the working estimate of the state of the system, along with the desired confidence intervals. The assignment of confidence limits corresponds in the case of a group of particles in physical space to drawing contours in the spatial domain which can be expected to define a region which contains, say, 90% of the particles.

The problem is that for even schematic models of the ocean or atmosphere, an unrealistically large number of particle trajectories in phase space must be calculated in order to represent the PDF faithfully. Useful ensemble analysis therefore requires judicious choice of ensemble members. We have concentrated our recent efforts on evaluation of ensemble methods, which we see as facilitating the generation of the forecast error estimates necessary for data assimilation. These forecast error estimates are of interest in and of themselves, since they have the potential of providing a priori estimates of the reliability of a given forecast.

Our work with a simple spectral approximation of a β -plane channel with topography (Gravel and Derome, 1993) is now complete. This system was chosen as an intermediate stage between the simple problems with only qualitative resemblance to actual geophysical fluid dynamical systems, and

practical working ocean models. We are now in the process of investigating the qualitative behavior of more complex and relevant systems. At this moment, our work is focused on a model of the Kuroshio. This is a comparatively simple model which reproduces the observed bimodality. It operates on a state space with dimension two orders of magnitude greater than that of our β -plane channel model, and, for this reason alone, presents significant technical challenges.

Once we are confident that we understand the qualitative behavior of the Kuroshio model, we will apply our stochastic techniques to it, in order to understand propagation of errors and the evolution of the PDF arising from random initial and boundary conditions. This should allow us to construct reliable data assimilation systems for use with simulated and real data from the Kuroshio.

Many different models, based on fundamentally different physical assumptions, exhibit the observed bimodality of the Kuroshio in some form. We are now in the process of comparing our model to different models and to observed data in order to determine a basis for distinction between the physical mechanisms in the different models.

Professor Michael Ghil of UCLA and Professor James G. Richman of the College of Oceanic and Atmospheric Sciences at Oregon State are working with us on the dynamical analysis of the Kuroshio. Professor Ghil and his group are working with analysis of simplified basin scale models of the north Pacific and with analysis of modeled and observed time series. Professor Richman is also working on analysis of time series, and on comparison of ocean general circulation model results to data and to other models. Technical support for this project is provided by Ms. Laura Ehret. Two students, Renellys Perez and Guillaume Vernieres are now beginning work in this group, and it is anticipated that they will work directly on this project or on one with similar objectives and approach.

WORK COMPLETED

A manuscript containing a detailed description of our results of ensemble generation experiments with a simple β -plane channel model has been accepted for publication in the Monthly Weather Review, subject to revision.

RESULTS

The evolution of dynamic height differences along the coast of Japan during the transition of the Kuroshio from the non-large meander state to the large meander state is reasonably well simulated by our regional model and by the DieCast general circulation model. Output from the two models and from tide gauge data are similar.

Proxies from tide gauge data for Kuroshio inlet transport in the Tokara strait south of Kyushu and for presence or absence of the large meander (Kawabe, 1995) can be plotted as a two-dimensional phase space. The daily tide gauge signals are dominated by annual cycle, but low-pass filtered data shows distinct bimodality.

Figure 1. Typical paths of the Kuroshio with tide gauge locations shown. “K” denotes Kushimoto, “M” denotes Maisaka.

Figure 2. Evolution of sea level difference between Kushimoto and Maisaka as indicator for transition from non-large meander to large meander state. Top: observed sea level difference; center: Transport streamfunction difference in quasigeostrophic model corresponding to sea level difference; bottom: DieCast simulation of sea level difference.

IMPACT/APPLICATIONS

Major weather centers, including the U.S. National Center for Environmental Prediction (NCEP) and the European Center for Medium-Range Weather Forecasting (ECMWF) now use ensemble methods for operational forecast validation; see Molteni et al. (1996), Toth and Kalnay (1993). Our work on Monte-Carlo methods should provide enhanced capability for validation of forecasts of the ocean and atmosphere, in addition to application to data assimilation. Our work on breeding modes and planned work on other schemes for ensemble generation should provide significant guidance in optimizing methods for generation of ensembles.

We expect that our work with comparisons among models and data for the Kuroshio will lead to greater insight into the intrinsic variability of basin-scale ocean circulation.
