WELDING OF ARMOR

Weld-Bead Tests on Samples from Union Steel Castings Company
Turret No. 3391, Poured from a Cast Armor Heat Containing Selenium

OBJECT

To deposit weld beads on samples from subject cast armor and to examine resultant welds for defects associated with presence of selenium.

SUMMARY OF RESULTS

1. Weld-bead deposits made on subject cast armor using ferritic electrodes coated with usual commercial cellulosic type coatings show considerable porosity.
2. Weld-bead deposits made on same armor using either ferritic or austenitic electrodes with all-mineral (lime base) coatings or with uncoated mild steel electrodes are free of excessive porosity.
3. The usual type of under-bead cracking (hard cracks) in the heat-affected zone, which would be expected when depositing weld bead with ferritic electrodes, having cellulosic type coatings, on steel with the hardenability of this armor and without preheat, was not evident.
4. It is considered that the porosity of weld metal associated with the use of cellulosic coated electrodes is caused by a chemical reaction in the molten weld metal between the hydrogen from the coating and the selenium from the base metal.
5. This chemical reaction between hydrogen and selenium is believed to be sufficient to reduce the hydrogen concentration in the weld metal below that required to cause hard cracks to form in the heat-affected zone.
6. No deleterious welding effects other than porosity appear likely to result from small additions of selenium to cast armor.

INTRODUCTION

Union Steel Castings Company cast armor turret No. 3391, which was poured from Heat No. 374-B containing selenium, was forwarded to this arsenal for metallurgical investigation (see Basic Correspondence, Appendix A). After complete radiographic examination, two sections 12 inches square were cut out of the turret for welding tests.

Chemical composition of Union Steel Castings Heat No. 374-B is reported in the basic correspondence (Appendix A) as follows:

<u>C</u>	<u>P</u>	<u>Mn</u>	<u>S</u>	<u>Si</u>	<u>Cr</u>	<u>Mo</u>
.31	.036	1.77	.023	.38	.42	.35

The amount of selenium added or the specific purpose of this addition is not known. However, it may be assumed that the selenium addition was for the same general purpose as discussed in U. S. Patent No. 2,258,604, A. P. Gagnebin, assignor to the International Nickel Company, wherein claims are made that the addition of an amount to about .6% of an intensifying agent comprising alkaline earth metal and an amount to about .6% of at least one sulphur-desensitizing agent from the group consisting of selenium and tellurium to molten steel results in production of castings characterized by freedom from porosity, by freedom from chain-like sulfides, by fine grain size, and by a higher combination of strength and ductility including impact strength, than a similar steel not treated with these addition agents.

Recent tests at this laboratory* indicate that additions of selenium in amounts from .01 to .12% to a .32 C, 1.5 Mn, .35 Si, .25 Mo steel do not change the hardenability or physical properties appreciably, but lower the impact values a small amount. Selenium was added as a metal to this heat, which was made in a small acid-lined induction furnace, after deoxidation with aluminum (2 lbs./ton), and the test results do not preclude the possibility of considerable improvement in properties of either inadequately deoxidized or "over-reduced" steels by addition of calcium selenide.

It is understood that serious difficulties were encountered in arc welding of the selenium-containing cast steel. Presumably the difficulty was porosity in the weld metal which was observed during repair welding with commercial ferritic electrodes. In the absence of further information, this investigation was limited to making single bead tests with various ferritic and austenitic electrodes on samples from this armor, and examining the beads for soundness of weld deposit and hardness and susceptibility to cracking of the weld heat-affected zone of base metal.

UNANNOUNCED A-1

TEST MATERIALS AND PROCEDURE

Twelve blocks, 3 x 6 x 1 inches, were obtained from Union Steel Castings turret No. 3391 after complete radiographic examination of the turret. Blocks were Blanchard ground to give smooth top and bottom surfaces.

Single weld beads, 3 inches long, were deposited along centerline of top surface of blocks using an automatic stick-feed welding head. Electrode and welding conditions used for each bead are given in Table I. The first four bead specimens were cleaned with wire brush to remove slag and scale and photographed to show porosity visible on surface. Specimens 5 through 9 were sectioned for Vickers-Brinell hardness survey, as shown by Figure 1, then macroetched for crack inspection. The tenth bead specimen was made with an uncoated electrode and examined visually for surface porosity, and for porosity after grinding bead flush with plate.

DATA AND DISCUSSION

1. Radiographic Examination of Turret

Radiographic examination showed the porosity existing in this turret to be slightly less than that in the average cast turret. Shrinkage conditions were about average as compared to other cast turrets, while hot tears were more numerous than usual.

2. Visual Inspection of Weld Bead Deposits

Figure 2 is a photograph of the top surface of weld beads deposited on subject cast armor. FW-8 and MLY (see Table I) are ferritic deposits (AWS E-2020 and E-7010 respectively) made with electrodes which have coatings containing cellulose. AW-2C and 18/8 are ferritic and austenitic deposits, respectively, made with electrodes which have lime base all-mineral type coatings. Considerable surface porosity is evident in the first two beads while the latter two appear entirely sound. A bead made with a bare low carbon electrode was examined visually for surface porosity and porosity after grinding flush with plate, and found to be free from gas holes such as are exhibited by samples FW-8 and MLY of Figure 2.

3. Hardness Surveys

Weld-hardenability curves for single weld bead deposits made with 18/8 austenitic and AW-2C and FW-8 ferritic electrodes are plotted in Figure 3. Maximum hardness and depth of heat-affected zones are entirely consistent with expectations for single bead welds on steel of the nominal chemical composition of this armor when welded under similar conditions.

4. Macroexamination

Figure 4 is a photograph of sections of single weld bead deposits used for hardness surveys after etching for 1/2 hour in hot 1-1 hydrochloric acid. Porosity is again evident in weld metal of deposit made with Fleetweld 8 electrode, while weld metal deposits made with electrodes having lime base all-mineral type coatings are sound. No weld or base metal cracking is evident. As under-bead cracking usually occurs when making single bead deposits without preheat on steel of equivalent carbon and alloy content if ferritic electrodes having cellulose type coatings are used, additional sections were taken from the block welded with Fleetweld 8 electrode and examined for under-bead cracks. No cracks were observed.

5. General Considerations

Weld metal porosity is encountered when selenium-containing cast armor is welded with an electrode having a coating which liberates hydrogen-bearing gases during the welding cycle. A considerable volume of hydrogen is absorbed by the molten weld metal from such an atmosphere during the welding cycle and the dissolved hydrogen very possibly reacts with selenium, present in the portion of the base metal which is melted during the welding operation, generating H_2Se gas bubbles which are trapped during solidification of weld metal causing porosity. Electrodes with lime base all-mineral coatings, or uncoated electrodes, do not cause porosity apparently because much less hydrogen is available in welding atmosphere for reaction with the selenium from the melted base metal.

Under-bead cracking tendency has been related to hydrogen absorbed by the weld metal during the welding cycle.* The absence of under-bead cracks, which ordinarily would be expected to be present when single bead deposits are made using Fleetweld No. 8 electrode, without preheat, is logically associated with decrease in hydrogen concentration in the molten weld metal due to chemical reaction with selenium and diffusion of hydrogen atoms into the resultant H_2Se gas bubbles.

Further experiments have demonstrated that the same effects may be observed when welds are deposited on steels of relatively high sulphur content. Porosity in this case may be a result of formation of H_2S .

Other than porosity, which may be eliminated by use of electrodes with all-mineral type coatings, no deleterious welding effects due to small additions of selenium to cast armor, either through increased cracking tendencies or impairment of mechanical properties of weld metal or heat-affected zone, appear likely.

Subject: Union Steel Casting No. 374-B, Containing Selenium

To: Commanding Officer
Watertown Arsenal
Watertown, Mass.

1. This office has been notified by the Union Steel Casting Company, Pittsburgh, Pa., that they have shipped turret No. 3391 which was poured from heat No. 374-B containing selenium to your station for metallurgical investigation.

2. This turret is being forwarded to your station in order that a very careful check may be made on the welding qualities of such steel. If any further assistance in regard to this problem can be offered by the Union Steel Casting Company, they have signified that they will furnish any information available.

3. The above turret was shipped on P & R waybill No. 34356 in car BTE-91422.
